In a meta-analysis conducted of 15 studies including 1,573 women diagnosed with EP and managed nonsurgically, there was no significant difference in the success rate of treatment; however, single-dose MTX was associated with fewer side effects than two-dose/multiple-dose regimen.[24,25]

Surgical Treatment

If the serum β-hCG level is high (>5,000 IU/L), the EP is larger than 4 cm or there has been significant internal bleeding, and if the patient is hemodynamically unstable, surgery becomes the first choice of management.

Surgery is also indicated in cases of failed expectant or medical management.

Surgery can be performed laparoscopically or by conventional laparotomy. Laparotomy is generally reserved for hemodynamically unstable patients with a ruptured ectopic and massive hemoperitoneum or in patients with poor visualization of the pelvis at the time of laparoscopy.[26] The type of procedure will be salpingectomy or salpingostomy based upon the damage to the affected tube and the condition of the contralateral tube.

Salpingectomy (removal of the affected tube) is the procedure of choice if the contralateral tube is normal, especially if the affected tube looks unhealthy or is adherent.

Salpingostomy is the removal of an EP by making a small cut on the tube while leaving the tube in situ. It is the surgery of choice in women with:

- History of a previous EP
- Damaged/unhealthy contralateral tube
- Previous history of an abdominal surgery
- A previous PID
- Preservation of fertility.

There is a minimum chance of persistent ectopic pregnancy (PEP) in these patients. Hence, they should be informed and counseled regarding the same and they should be closely followed up with serum β-hCG levels. In case the PEP is not resolved, these patients may need systemic MTX or salpingectomy.

As per the NICE guidelines, serum β-hCG levels should be repeated after a week following salpingotomy and then weekly until normal levels are reached.

In a randomized controlled trial on 446 women—after 2 years of trying for natural conception, 60.7% after salpingotomy and 56.2% after salpingectomy, persistent trophoblast occurred more frequently in the salpingotomy group [14 (7%) vs. 1 (<1%); RR 15.0, 95% confidence interval (CI) 2.0–113.4].

Repeat EP occurred in 18 (8%) women in the salpingotomy group and 12 (5%) in the salpingectomy group (RR 1.6, 95% CI 0.8–3.3).

It was concluded that in women with a tubal EP and a healthy contralateral tube, salpingotomy does not significantly improve fertility prospects compared with salpingectomy.[27]

Higher rates of subsequent intrauterine pregnancy have been found if salpingotomy is done versus salpingectomy in women with a history of fertility-reducing factors.

Becker et al. found a subsequent intrauterine pregnancy rate of 75% with salpingotomy and 40% with salpingectomy in such women. However, subsequent intrauterine pregnancy rates were >90% in both groups in women without fertility-reducing factors.[28]

A 2007 Cochrane review found no difference in the success rates, tubal patency, and subsequent fertility rates between laparoscopic salpingostomy and medical treatment with intramuscular MTX.[29]

Laparoscopic Surgical Approach is Preferred than Conventional Open Approach

The advantages of laparoscopy over laparotomy are:

- A shorter operative time
- Lower intraoperative blood loss
- A shorter hospital stay
- Lower cost
- Lesser quantity of analgesia is required.
- Lower rate of adhesion formation.

No differences have been noted in subsequent successful pregnancy outcomes.

MANAGEMENT OF NONTUBAL ECTOPIC PREGNANCY

Interstitial Pregnancy

Management depends upon the clinical presentation, the presence of fetal cardiac activity, and serum β-hCG levels.

Medical management with MTX or surgical management by laparoscopic cornual resection or salpingotomy are effective options.

Cornual Pregnancy

Treatment involves open/laparoscopic excision of the fibrous band that attaches the rudimentary horn to the unicornuate uterus with removal of the rudimentary horn.

Laparoscopic technique is safe, but the possibility of associated urinary tract anomalies should be kept in mind.

Cervical Pregnancy

If cervical pregnancy is diagnosed early, medical treatment with MTX is recommended, either administered directly into the gestational sac under ultrasound guidance or systemically by intramuscular injection. Local administration is more effective.

The disadvantage of medical treatment is that the trophoblast remains in situ, causing hemorrhage. Thus, simultaneous suction evacuation or uterine artery embolization is preferred.

In late cases, hysterectomy may be needed.

Cesarean Scar Pregnancy

Wedge resection and repair of the implantation site by laparotomy or laparoscopy is often needed along with medical management with MTX.[12]

Ovarian Pregnancy

Definitive surgical treatment in the form of minimal access surgery is preferred if laparoscopy is required to make the diagnosis of ovarian EP.

The gestational products can be removed either by enucleation or by wedge resection. This should be carried out bluntly to avoid damage to the surrounding ovarian tissue. Electrocautery can be used to achieve hemostasis.

Intramuscular MTX is recommended when the surgery is high risk or postoperatively in patients with residual trophoblastic disease or with persistently raised β-hCG levels.

Oophorectomy is done in case of a coexisting pathology or when there is excessive bleeding from the ovary.

Heterotopic Pregnancy

Utmost care of the intrauterine pregnancy should be taken in the management of a heterotopic pregnancy.

Methotrexate to be given only in case of a nonviable intrauterine pregnancy or if the woman wishes to discontinue the pregnancy, in which case the Regulations of the Abortion Act will apply.

Local injection of potassium chloride or hyperosmolar glucose with aspiration of the sac contents is an option for clinically stable women.

Laparoscopic surgical removal of the EP is the method of choice for hemodynamically unstable women and may also be an option for hemodynamically stable women.

Expectant management is an option in heterotopic pregnancies, where the ultrasound findings are of a nonviable pregnancy.

POST-TREATMENT

After medical treatment with MTX, it is important to wait for at least 3 months after the treatment has finished before getting pregnant again.

Methods of Contraception

- Combined oral contraceptive pill
- Contraceptive vaginal ring/patch
- Progestogen-only pill (POP)
- Barrier methods—condoms
- Natural methods of family planning.

LONG-TERM FERTILITY PROSPECTS FOLLOWING AN ECTOPIC PREGNANCY (ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS, 2016)

There is no difference in the fecundity rates, tubal patency, and risk of future tubal EP with the different types of management methods in the absence of any cause for subfertility or history of tubal pathology.

Women with a history of subfertility should be managed expectantly and medically to improve the reproductive outcomes as compared to radical surgical management.

Methotrexate with either single- or double-dose protocol has no effect on the ovarian reserve.

For nontubal ectopic pregnancies, uterine artery embolization with systemic MTX can be tried. Live births have been reported after that.

COUNSELING AND PSYCHOLOGICAL SUPPORT

Women should be educated about the advantages and disadvantages of each and every approach. Along with the recommendations of the treating clinician, she should make an appropriate decision.

The psychological impact of early pregnancy loss may seriously affect a large number of women and their families. She should be encouraged to talk with support groups such as the Ectopic Pregnancy Trust or utilize the local bereavement counseling services.

Further plans of management should be explained to the patient properly.

KEY POINTS

- Women should be made aware that the recurrence rate in a woman with a history of one EP is 10%. Hence, an early sonography at 6 weeks of gestation is recommended to confirm an intrauterine pregnancy.
- Along with a history of tubal infertility and PID, the embryo transfer technique is significant for late cases of EP.

- A high level of suspicion along with an early measurement of serum β-hCG and transvaginal sonography as early as the 5th gestational week can identify an early EP. These women should be closely monitored with repeated ultrasound and serum β-hCG levels until a definitive diagnosis is reached.
- Treatment must be customized according to the clinical condition of the patient and her future fertility requirements.
- In heterotopic pregnancy, a viable intrauterine pregnancy can be preserved with removal of extrauterine pregnancy with laparoscopic surgical management.

CHAPTER 68

Multiple-order Births

Veronica Irene Yuel

INTRODUCTION

After Louise Brown was born in 1975, assisted reproductive technique (ART) has reached great heights. Also, there has been a proportionate rise in the number of infertile couples, hence, leading to a rise in the number of couples opting for fertility treatment much earlier. A rise in fertility treatment has in turn shown its impact on the number of multiple-order pregnancies referred to as twins, triplets, and a higher number of fetuses (quadruplets, quintuplets, etc.).

Multifetal pregnancies have a higher risk of maternal and neonatal morbidities and mortality.[1] This is because these pregnancies have higher chances of preterm deliveries leading to low-birth-weight babies and, thus, the associated morbidities due to prematurity.

INCIDENCE

Owing to the increase in the number of multiple births, its incidence has also risen.[2] On an average, multiple pregnancies constitute about 3 in 100 births and the incidence is constantly rising. The incidence of multiple-order births is significantly different in different regions and countries. Smits et al. in their study have reported a twining rate of <9/1,000 births in India.[3] The National Center for Health Statistics has reported a twin birth rate of up to 70%. It is now 32.6/1,000 live births. Differences in twining rates in various geographical distributions can be attributed to differences occurring in the frequencies of dizygotic twinning. However, the frequency of monozygotic twins remains constant worldwide at about 4/1,000 births.

Higher order births are much less in incidence. Naturally occurring triplets happen in about 1 in 10,000 pregnancies[4] and quadruplets in about 1 in 700,000 pregnancies.[5]

Quintuplets (five babies), sextuplets (six babies), septuplets (seven fetuses), and octuplets (eight fetuses) have also been reported though their incidence is extremely rare.

ETIOLOGY

The exact etiology of multiple gestations remains unknown. Several factors have been associated in causing this rise in higher order births. These causes are enumerated in the following text.

Maternal Age

A higher incidence of multiple-order births has been seen in women of advanced age. In developed nations, the average reproductive age at which women plan their childbirth has gone up on the scale to around and above 30 years.[6] This could be attributed to more women attending fertility clinics and seeking treatments as many of them are delaying childbearing in the present era. Also, higher age, as an independent variable, is associated with multiple pregnancies.[7]

Parity

It has been shown that multiparous ladies have higher chances of developing multiple-order pregnancies when compared to nulliparous ones[8] as an independent factor.

Geographical Distribution

The rates of multiple gestation pregnancies vary in different geographical distributions. The authors have mentioned earlier in the chapter that the incidence of multiple-order births differs among countries; Australia and USA seem to be following a similar pattern compared to the UK. The lowest twinning rates have been found in Japan, Singapore, and Hong Kong though these, in turn, have also increased from 0.05% in 1972 to 0.09% in 2001.[8] The highest rates of dizygotic twinning have been reported in Nigeria and Zimbabwe and the least in Asian countries,[9] whereas the rate of monozygous twins remains constant.

Socioeconomic Strata

Multiple-order birth has been found to be more prevalent among the high socioeconomic strata. This can be directly

related to those women who delay childbearing due to their careers and thus seek fertility treatments for conception at a higher age, though fertility treatment is an independent factor affecting the incidence of multifetal gestation.

Genetic Predisposition

Studies have shown that multiple pregnancies run in families which are passed down from both maternal and paternal sides.[9]

Use of Fertility Drugs

Over the years, there has been a tremendous rise in couples seeking fertility treatments. This may be due to an increase in awareness about fertility, an increase in the educational status of the couple, and better and affordable services offered by the fertility clinics. A rise in the liberal use of ovulogens and gonadotropins is the most important factor associated with multifetal pregnancy.[10] In fact, the use of these drugs is more commonly associated with multiple births than in vitro fertilization (IVF) techniques.

Assisted Reproductive Techniques

Assisted reproductive technique procedures such as intrauterine insemination (IUI) and IVF are commonly associated with multiple births. There has been a direct relationship between multifetal pregnancies and the number of embryos transferred[10] during the IVF procedures.

Maternal Weight (Body Mass Index) and Height

A positive association of body mass index (BMI) with multiple pregnancies has been reported in the observation by Basso et al., who referred to the Danish National Birth Registry, which reported a statistically significant correlation of women who had a BMI ≥30 kg/m^2 with a higher rate of naturally conceived twins. Further, they also observed that women whose BMI was <20 kg/m^2 had a lower rate of naturally conceived twins even after correcting for maternal age and parity. They further observed that women who were tall were more likely to give birth to twins.[11]

Miscellaneous

Maternal smoking, a seasonal variation where the length of the day and food supply is affected, and usage of drugs such as oral contraceptives and folic acid are some factors mentioned in the literature; however, more definite evidence is needed to support these causes. An increase in the frequency of coitus has also been reported to be an independent factor behind the increase in twinning rate, although this needs to be supported with more research.

PATHOPHYSIOLOGY

Zygosity is determined at the time when splitting occurs after fertilization. Monozygous twins occur when a fertilized ovum splits within 48 hours leading to the formation of amnion and chorion separately. Thus, there are two separate placentae, which may be fused off separately. Nearly 30% of all monozygous twins are dichorionic diamniotic **(Figs. 1A and B)**.

When the splitting occurs after 72 hours till 8 days, monochorionic diamniotic twins are formed, which comprise around 70% of the twins **(Figs. 2A and B)**.

Monochorionic monoamniotic **(Figs. 3A and B)** twins develop when splitting happens between 9 and 12 days. These twins are rare, comprising only 1% of the monozygous twins. These twins have a higher incidence of complication rates, especially cord accidents, twin-to-twin transfusion, etc.

Splitting of fertilized ovum beyond 12 days leads to only partial splitting resulting in the development of conjoined twins.

Higher order pregnancies, such as triplets and quadruplets, i.e., dizygotic and trizygotic births, occur when two or three or multiple separate ova fuse with sperms separately and therefore will have separate amnion, chorion, and placentae. The placentae in dizygotic twins are fused,

if the area of implantation is close by, but, at birth, they are easily separable.

Pregnancy with triplets occurs when fertilization, then splitting, and later development of ovum and sperm occur at separate levels. Triplet pregnancies may be, therefore, monozygotic, dizygotic, or trizygotic. Trizygotic triplets are formed when three different sperms fertilize with three different ova. Dizygotic triplets develop when one set of monozygotic co-triplets and another co-triplet develop from a different zygote. Rarely, two consecutive zygotic splittings with a vanished fetus can also give rise to monozygotic triplets. Zygosity in quadruplets and higher order multiples varies.

The examination of the placentae after birth is an important feature in all higher order births, as it helps in identifying the chorionicity and zygosity: however, it may not always be helpful.[12]

PATHOGENESIS

Ultrasonographic evaluation of the placenta to determine chorionicity during the early gestational period and later following the birth of babies helps us in determining the type of multifetal gestation.

Monozygotic twins develop when the splitting of a fertilized ovum occurs within 48 hours of conception producing chorions and amnions separately. These twins have separate placentae and can be separated, forming the dichorionic-diamniotic placenta, or fused forming the monochorionic-diamniotic placenta. When this splitting of the zygote occurs between 3 and 8 days after fertilization, it leads to the formation of monochorionic/diamniotic placentation. Further, if the splitting happens between 9 and 12 days of fertilization, monochorionic/monoamniotic placentation occurs. Splitting beyond 12 days after fertilization leads only to partial split, which further leads to the formation of conjoined twins.

Higher order pregnancies, such as triplets and quadruplets, i.e., dizygotic and trizygotic births, occur when two or three or multiple separate ova fuse with sperms separately and therefore will have separate amnion, chorion, and placentae.

The pathogenesis of multiple births has been shown in **Table 1 and Figure 4**.

CLINICAL FEATURES

In the current times, most women are already aware of their diagnosis and they visit the doctor with the diagnosis (based on history) and a variety of symptoms.

History

The history of the patient may reveal about the lady carrying multifetal pregnancy. Women who are not aware may give a

history of using ovulation-inducing drugs. Along with this, all the other symptoms of pregnancy may be exaggerated in presentation. Patients will give a history of hyperemesis, excessive weight gain, excessive fetal movements, etc. A family history of twins or triplets may be there.

Symptoms

Excessive weight gain, dehydration—if the patient has hyperemesis, and all other symptoms of pregnancy may be exaggerated. On examination, the uterine height will be more than the period of gestation, striae gravidarum and chloasma may be severely increased, multiple fetal parts will be felt on palpation, and multiple fetal heart sounds will be heard on auscultation. Along with this, there may be other systemic features. Many a times, multifetal pregnancies are associated with high blood pressure recordings, i.e., pregnancy-induced hypertension (PIH), and thus, may be comorbidly associated with all the other features of PIH.

TABLE 1: Pathogenesis of twins.

Dividing membrane	*Type of placenta*	*Type of twin*
None	Monochorionic monoamniotic	Monozygotic
Amnion	Monochorionic diamniotic	Monozygotic
Amnion + Chorion	Dichorionic diamniotic	Monozygotic or dizygotic
No common membrane	Dichorionic diamniotic	Dizygotic

Conjoined Twins

Twins that are joined at various levels of the body parts, i.e., fused at various levels, are called conjoined twins. Conjoined twins have a very rare incidence, ranging from 1 in 50,000 to 1 in 100,000.[10] "Pagus" means "fusion" and therefore conjoined twins are named depending on the level of fusion. The varieties of conjoined twins are depicted in **Figure 5**.

Discordant Twins

When there is a difference in the weights of the twins, they are called discordant twins. It is defined as a discrepancy of ≥10% difference in the weights of the twins. This occurs in around 16% of all the twins, where the discordancy is around 20%.[13] This commonly occurs due to hyperperfusion of one sac, while the other is hypoperfused. A variety of associated maternal comorbidities, fetal abnormalities, and placental causes seems to be causing the discordancy, but the exact cause remains unknown.

DIAGNOSIS

Diagnosing a pregnant woman with multiple-order gestation should be on the basis of history, clinical examination, and imaging modalities. History and clinical examination have already been discussed earlier in this chapter. Imaging and other diagnostic studies include the following.

Placental Examination

Since time immemorial, examination of the placenta after delivery has been a useful tool in determining the zygosity of multiple pregnancies.[14] Earlier, it was believed that a single placenta meant monozygous twins, while two separate placentae were dizygotic. However, this was found to be quite incorrect because if the eggs implant close together, the placentae can become fused and take on the appearance of one placenta, and in such a case twins will then be wrongly diagnosed as monozygotic. Therefore, more important than the placenta itself is an examination of the membranes. Amnion is the inner membrane and chorion is the outer membrane. If the amnion is common between the two fetuses, it always means monozygotic twins, but this is very rare. Two amnions and one chorion also mean monozygotic twins (monochorionic diamniotic). If there are two amnions and two chorions, the twin type can be either mono- or dizygotic (dichorionic diamniotic).

Dizygotic twins will have separate placentae; however, sometimes they may be fused, leading to a confusion, but this placenta is very easily separable into two separate placentae.

Clinical Features

Dizygotic twins are known to be genetically similar with nearly 50% similarity in the genetic constitution, an observation similar to that in the nontwin sibling. They are also known as "fraternal twins." Among these twins, half of the twins are of the same sex and half of different sex, but each fetus has its own placenta, which is continuous with the chorion.

Monozygotic twins, also known as "identical" twins, develop when an ovum is fertilized by a sperm and during the first 2 weeks after conception; this embryo then splits into two, forming two identical babies of almost the same sex and genetic constitution. One third of the monozygotic twins have separate placentae, while the other two thirds have a single placenta though they have their own amnion, umbilical cord, and placental mass.

Imaging Modality

Ultrasonography is the test to confirm multiple-order pregnancies. It is also to be carried out for antenatal surveillance of these pregnancies. Chorionicity of twin fetuses is detected on ultrasonography by 10–14 weeks of gestation at the earliest by visually inspecting the intervening membrane of the fetuses. Demonstration of "T-sign" at the intertwin membrane–placental junction suggests monochorionic-diamniotic twins (this is the junction between the intertwin membrane and the external rim forming a right angle), whereas dichorionic twins present with a "lambda (λ) sign" (that is the chorion forms a wedge-shaped protrusion into the intertwin space, creating a rather curved junction). This "lambda sign" is also known as the "twin peak sign" **(Fig. 6)**. In the ultrasound assessment at 16–20 weeks of pregnancy, the presence of "lambda sign" suggests dichorionicity; however, if this sign is not found at this gestation, it does not exclude the diagnosis.[15]

Ultrasonography is also a diagnostic tool to assess multiple pregnancies in those who develop complications such as twin-to-twin transfusion syndrome, growth discordancy, conjoined twins, malpresentations, intrauterine demise of one twin, and abnormal Dopplers.[16]

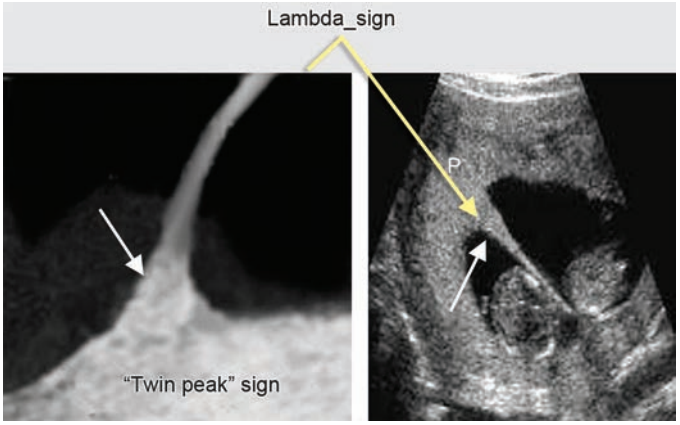

Fig. 6: Ultrasonographic feature of dichorionic-diamniotic placentae. *Source:* Twins for Undergraduate. (2014). Lambda Sign (Slide 21). Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is another modality in diagnosing multiple pregnancies, especially conjoined twins. Diagnostic features in conjoined twins include a bifid fetal pole, absence of separating membranes between fetuses, unseparated fetuses and their parts, number of blood vessels in the umbilical cord exceeds three, fetal heads and bodies positioned in the same plane, unusual extension of the fetal spines, unusual proximity of fetal extremities, and fetal positions.[17]

COMPLICATIONS

Multiple-order gestations are known to have both fetal and maternal risks.[18] Mortality in both cases is currently less due to better medical facilities.

Maternal Complications

Higher order pregnancies lead to a higher incidence of maternal complications such as preeclampsia, anemia, labor difficulties, postpartum hemorrhage, failed lactation, and, last but not the least, psychological disturbances in a woman.[19] In 2005, Flanders, from Belgium, reported the perinatal outcome in 26,656 ART pregnancies in the study conducted at Study Center for Perinatal Epidemiology (SPE);[20] preterm delivery was the most common: 95.9% of triplet pregnancies (mean gestation of 32.7 weeks) and 53.8% among twins (mean gestation of 35.6 weeks). Early preterm delivery (<32 weeks) and very-low-birth-weight infants (<1,500 g) were almost three times more among triplets compared with twins after assisted reproduction. Thus, it was clearly observed that as the number of fetuses increased, the duration of gestation reduced to a mean of 3 weeks per additional fetus. A comparable figure was also reported by Martin et al.[4] Twin-to-twin transfusion[21] and conjoined twins[22] are separate complications associated with multiple pregnancies. Many studies evaluated psychosocial risks such as quality of life, depression, and social stigma prevailing in families who underwent ART treatment, resulting in multiple birth children. They found a greater incidence of parenting stress and decreased parenting satisfaction when compared with families who conceived twins spontaneously.[21] Thus, these studies suggested that the infertility treatment experienced by these couples makes them more vulnerable to psychosocial stress.

Neonatal Complications

Prematurity is the most common morbidity associated with multiple pregnancies leading to low-birth-weight babies. Intrauterine growth restriction (IUGR) also leads to low-birth-weight babies. Various studies have reported that the average birth weight of these babies range between 1.1 and 2.5 kg.[5,23] All these factors independently lead to higher chances of neonatal morbidity and intensive care unit admission, birth asphyxia, neonatal metabolic complications such as hypoglycemia and hypocalcemia, respiratory distress, and eventually mortality.[5,23] It should be mentioned here that the higher the number of fetuses, the more the severity of morbidity and, thus, mortality.

In monozygotic pregnancies with single chorion and amnion (monochorionic-monoamniotic), both fetuses have one large amniotic sac. These twins not only possess all the risks of monochorionic-diamniotic twins, but they also have the risk of fetal and umbilical cord entanglement which have a reported fetal mortality rate of up to 60%.[24]

TREATMENT

Prophylactic Management

Strategies aimed at reducing multifetal gestation and thus reduce the morbidity and mortality in multiple-order births. These include the following:

Elective Single Embryo Transfer

Currently, elective single embryo transfer (eSET) has been advocated to be adopted as a standardized practice in those ART cycles where the chance of resulting in a live birth is high.[25] However, considering the live birth rates may be reduced with single embryo transfer; therefore, a careful selection of patients is advocated who would benefit from eSET and result in a live birth. Also, strategies to improve culture conditions, embryo grading, and selecting the most viable and competent embryo need to be developed.[26]

Excess Oocyte Aspiration and Vitrification

In patients undergoing ART and ovarian stimulation, a direct correlation between the number of follicles and multiple

pregnancy rates has been observed. Studies have shown that cycles in which three or four follicles result in no substantial gain in the overall pregnancy rate, but there occurs an increase in multiple fetuses, thus increasing the multiple pregnancy rate.[27] A low-dose or minimal-stimulation protocol can therefore be advocated for such women to prevent multifollicular development and thus reduce the multiple pregnancies after ovarian stimulation.[28] The use of excess oocyte retrieval and vitrification technique may further improve the cost-effectiveness in stimulated IUI cycles by reducing multiple pregnancy rates and increasing the overall chances of pregnancy by cryopreserving the excess embryos. This technique, however, should not become a substitute for carefully monitored ovulation induction (OI). This modality of treatment has been widely studied, reporting excellent outcomes for oocyte cryopreservation.[29]

Fetal Reduction

Fetal reduction in multifetal pregnancies has been advocated to reduce them to twin pregnancies in order to improve perinatal outcomes.[30] This also decreases the early miscarriage rates, antenatal complications, preterm births, cesarean deliveries, low birth weight, and neonatal mortality. Outcomes from multifetal reduction to twins have been found to be comparable to those obtained from twin pregnancies conceived either spontaneously or through assisted reproductive technologies.[31]

Others

Cycle cancellation, coasting in ovarian stimulation, aspiration of follicles before human chorionic gonadotropin (hCG) administration, and switching to IVF in an IUI cycle are some of the other strategies advocated that help in the reduction of multiple pregnancies.[32-34]

Definite Management

Treatment of multiple-order births is directed toward its type. Monochorionic-monoamniotic twins carry maximum risk during the antenatal period; hence, they need extra attention and care.

Antenatal

Pregnancies complicated with multiple fetuses are high-risk pregnancies; therefore, these women should have regular and frequent antenatal checkups. Initially, monthly checkups are up to 24 weeks and then every fortnight. These pregnancies are at an increased risk of preterm deliveries, PIH, anemia, and antepartum hemorrhage (abruptio placentae) warranting close monitoring. Antepartum surveillance with nuchal translucency (NT) scan, level II anomaly scan, and time-to-time obstetric Doppler studies is indicated at 10–12, 18–20, and >28 weeks onward, respectively.[2]

The recommendations[16] for ultrasound monitoring for twins made according to the guidelines developed by the Canadian Task Force on Preventive Health Care are as follows:

- All patients who are suspected to have a twin pregnancy on first-trimester physical examination or who are at risk (e.g., pregnancies resulting from ART) should have a first-trimester ultrasound performed (II-2A).
- Every attempt should be made to determine and report amnionicity and chorionicity when a twin pregnancy is identified (II-2A).
- Although the accuracy in confirmation of gestational age at the first and second trimesters is comparable, dating should be done with first-trimester ultrasound (II-2A).
- Beyond the first trimester, a combination of parameters rather than a single parameter should be used to confirm gestational age (II-2C).
- When twin pregnancy is the result of IVF, accurate determination of gestational age should be made from the date of embryo transfer (II-1A).
- There is insufficient evidence to make a recommendation of which fetus (when discordant for size) to use to date a twin pregnancy. However, to avoid missing a situation of early IUGR in one twin, most experts agree that the clinician may consider dating pregnancy using the larger fetus (III-C).
- In twin pregnancies, aneuploidy screening using NT measurements should be offered (II-2B).
- Detailed ultrasound examination to screen for fetal anomalies should be offered, preferably between 18 and 22 weeks' gestation, in all twin pregnancies (II-2B).
- When ultrasound is used to screen for preterm birth in a twin gestation, endovaginal ultrasound measurement of the cervical length should be performed (II-2A).
- Increased fetal surveillance should be considered when there is either growth restriction diagnosed in one twin or growth discordancy (II-2A).
- Umbilical artery Doppler should not be routinely offered in uncomplicated twin pregnancies (I-E).
- For defining oligohydramnios and polyhydramnios, the radiologist should use the deepest vertical pocket in either sac—oligohydramnios when <2 cm and polyhydramnios when >8 cm (II-2B).

Folic acid, hematinics, calcium, and other dietary supplements should be prescribed. Immunization schedule is to be followed as in any other pregnancy.

If the twins are conjoined, it should be clearly decided whether they would be viable after birth following a corrective surgery. Such twins should be allowed to continue and electively terminated at 36 weeks by cesarean section. This should be in a tertiary care unit with a neonatal intensive care unit (NICU) backup. However, if the twins are not viable, termination should be offered like any other pregnancy within legal limits.

Discordant twins and twin-to-twin transfusions are to be managed as "high risk" on similar lines with closed surveillance.

Intrapartum

Management depends on the number of fetuses. Pregnancies with more than two fetuses should be delivered by cesarean section. Twins where both the fetuses are either cephalic or first twin cephalic and second breech can have vaginal births with close intrapartum monitoring. Malpresentations are to be planned for the cesarean section.

Postpartum

Multifetal pregnancies have an increased risk of postpartum hemorrhage; hence, they should be encouraged to deliver in a well-equipped facility, preferably under a tertiary care unit. Failed lactation and postpartum blues are also associated with a higher frequency than singleton pregnancies.

Neonatal Care

Most outcomes from multifetal pregnancies if born after 34 weeks require only routine pediatric care; though some may require specialized care, NICU admissions, and regular close follow-up. The American College of Obstetricians and Gynecologists has postulated guidelines for the evaluation and management of such newborns, which include the following:[2]

- *Neonatal:* A complete blood count (CBC) for evaluating anemia and polycythemia
- *Neonatal arterial blood gas and cord blood gas:* To evaluate for respiratory distress, hypoxia, acidosis, and perinatal depression
- *Metabolic panel:* Fluid status and electrolyte levels should be evaluated and metabolic status should be determined, including through screening for hypoglycemia and hypocalcemia
- *Bilirubin level:* This is obtained to screen for increased risk of hyperbilirubinemia associated with prematurity and polycythemia.

CONCLUSION

A significant rise in multiple-order births has been there because of a rise in women taking fertility drugs and assisted reproduction. Twin pregnancies are more common than triplets and quadruplets; though higher-order births are rare, nevertheless they have also been reported. Zygosity of twins is dependent on the timing of splitting after fertilization and is diagnosed with a placental examination at birth, ultrasonography, and features of the twins after birth. Preterm delivery is the most common complication associated with multifetal gestation. Other comorbidities may be PIH, anemia, twin-to-twin transfusion, growth discordancy, etc. Prematurity leading to the birth of low-birth-weight babies is the most common neonatal morbidity and is thus associated with neonatal complications. All possible efforts should be made to reduce the occurrence of multifetal pregnancies; some strategies in this direction include eSET, excess oocyte aspiration and vitrification, coasting, cycle cancellation, converting IUI cycle to IVF, and multifetal reduction. All these pregnancies should be monitored with regular antenatal surveillance. Delivery should be in a well-equipped hospital because there are higher chances of operative intervention and babies requiring NICU care.

Multiple-order births are frequent as more couples are seeking fertility treatments. These are high-risk pregnancies and are often complicated with PIH, anemia, abruption, and the most common being preterm deliveries. Prematurity leads to the birth of low-birth-weight babies and higher associated morbidity and mortality. Ultrasonography is the simplest, easiest, and noninvasive test used for diagnosis and also antenatal surveillance though MRI may be better in select cases. Regular antenatal monitoring, nutritional supplements, immunization, and delivery in tertiary care unit are recommended.

KEY POINTS

- Multiple-order births have increased as more couples are opting for infertility treatments.
- Zygosity depends on the timing of splitting after fertilization.
- The most common order of multiple gestations is twin pregnancy—monochorionic-diamniotic being the most common, though triplets and higher-order births also occur.
- Preterm delivery is common, which leads to prematurity, and low-birth-weight babies and hence leading to increased neonatal morbidity and mortality.
- Recommended guidelines that lower the chances of multiple pregnancies during assisted reproductive technique (ART) procedures should be followed.
- Recommended guidelines should be followed for fetal surveillance and maternal treatment.
- Delivery should be planned in a tertiary care unit with neonatal intensive care.

Third Party Reproduction

CHAPTER 69

Oocyte and Sperm Donation

Jaideep Malhotra, Ashwini Mohandas, Narendra Malhotra, Neharika Malhotra

INTRODUCTION

If we conceive society as a cultural concept in which the people's behaviors are representative of the types of relationships they have with each other, then it necessitates evaluating the cultural aspect of each event for investigating its social dimension. Therefore, in order to have an accurate understanding of fertility and infertility as a social phenomenon and for evaluating its social dimensions, a careful review of the event's cultural background is required

Human response to new developments regarding birth, death, marriage, and divorce is largely shaped by religious beliefs.

The possibility of conceiving through assisted reproductive technologies (ARTs), more specifically from a third-party, has provoked different reactions in different cultures, which have received and interpreted them to befit their own reproductive norms and practices. As Unnithan-Kumar points out "[Reproductive] technologies in themselves do not bring about social transformation but it is in how they are made socially meaningful that their power lies."

Third party reproduction is a form of assisted reproduction in which woman agrees to bear child on behalf of and relinquish the child to and individual or couple who intend to rear the child. Introducing a stranger's gamete to conceive has the potential of disrupting the biological continuity and, inevitably, leads to a redefinition of what is "biological" and what is "social" as far as family and kinship are concerned. When assisted reproduction was introduced into medical practice in the last quarter of the 20th century, it was fiercely attacked by some religious groups and highly welcomed by others. Today, assisted reproduction is accepted in nearly all its forms.

Unlike the recent advances in assisted reproduction, the concept of third-party reproduction is not new and has been in vogue since the mythological era **(Figs. 1 and 2)**.

With the advent of ART and gamete freezing, anonymous gamete donation has become feasible/possible. It involves use of sperms (sperm donation) or eggs (oocyte donation) or uterus (surrogacy) from persons other than the commissioning couple involved. This was limited initially to sperm donation till egg donation came into the picture

Fig.1: Abraham with Sarah and Hagar.

Fig. 2: Sarah exiles Hagar and her child.

with the development of techniques for oocyte harvesting. Trounson et al. reported the first pregnancy using donor eggs in 1983. The first conception was reported after transplanting an unhatched embryo flushed out from the donor by uterine lavage using a special device into the recipient uterus. Over the past 20 years, the number of births from gamete donation has increased exponentially from 30,000–60,000 in the United States.[1]

This chapter reviews the need, clinical effectiveness, and implications of oocyte donation and sperm donation.

OOCYTE DONATION

In vitro fertilization with the use of donor oocytes (IVF-OD) has become an integral part of infertility treatment today. The procedure is used to achieve pregnancy in women with premature and age-related ovarian failure, poor ovarian reserve (due to disease or advanced age), Turner's syndrome, recurrent implantation failure due to poor oocyte quality, and recurrent abortions.[1,2] Couples also opt to use donated oocytes to avoid transmission of severe genetic diseases.[3]

Results achieved in recipients surpass those attained with use of autologous oocyte IVF[4-6] in good prognosis patients, resulting in an exponential rise in the procedure. In the USA, the annual number of donor oocyte cycles increased from 10,801–18,306 between 2000–2010,[7] whilst the European IVF Monitoring (EIM) consortium for the European Society of Human Reproduction and Embryology (ESHRE)[4] reported 7,171 IVF-OD cycles in 2006 and 33,605 cycles in 2012. Indeed, couples will travel outside their country if local laws forbid oocyte donation. The procedure is so popular that oocyte banks[8] have been established to allow for sharing of oocytes from a donor, reduced waiting times involved in sourcing and screening donors, and circumventing donor–recipient synchronization. Cross-border reproductive care too is gaining attention, as ART practices and obstetric care may differ between countries.[9]

The donor–recipient model has provided an insight into various aspects of ART, such as the importance of oocyte age in implantation,[11] endometrial receptivity,[12,] and the contribution of male factors to IVF failure.[13] Perhaps the most thought-provoking realization is the knowledge that the reproductive system can function perfectly in the absence of a genetic connection.[2]

Indications for Oocyte Donation

Premature Ovarian Insufficiency

Premature ovarian insufficiency (POI) is defined as cessation of menstrual cycle, increased serum follicle-stimulating hormone (FSH) levels, and decreased serum estradiol levels in women before the age 40 years.[14] POI concerns about 1% of women and is characterized by severely diminished fertility.

BOX 1: Causes of premature ovarian failure.

- Gonadal dysgenesis
- Turner syndrome
- Perrault syndrome
- 46, XX gonadal dysgenesis/46, XY gonadal dysgenesis
- Genetic associations
- Familial ovarian failure
- Galactosemia
- Enzyme defects—P450c17
- FRAXA premutation
- Blepharophimosis, ptosis, and epicanthus inversus syndrome (also called BPES)
- Small X chromosome defects
- FSH receptor mutations/LH receptor mutations

Autoimmune:

- Autoimmune polyendocrinopathy syndrome 1
- Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy/autoimmune Polyendocrinopathy syndrome 2
- Association with various autoimmune diseases
- Isolated autoimmune ovarian failure
- Iatrogenic chemotherapy
- Radiotherapy
- Pelvic surgery
- Environmental toxins
- Idiopathic

(FRAXA: fragile X; FSH: follicle-stimulating hormone; LH: luteinizing hormone).

The etiopathogenesis of this disorder is related to a multifactoral background **(Box 1)**. A major part is regarded as idiopathic, although it is suspected to be genetically determined.[4,5] Autoimmunological causes are involved in the pathogenesis of 4–30% of POI cases.[14] The presence of antiovarian autoantibodies (AOAs), lymphocytic oophoritis, and associated autoimmune disorders are key evidence of autoimmunological background.

Over the past decades, many genes have emerged as POI candidates, but only a minority has been proven causative by functional validation.

These include genes involved in primordial germ cell migration and proliferation (NANOS3), in cell death (PGRMC1 and FMR1), oocyte specific transcription factors (FIGLA and NOBOX genes).[2]

The increasing number of POI cases is also related to iatrogenic background (use of radiotherapy, chemotherapy, and pelvic surgery in patients treated due to oncological diseases).

Turner Syndrome

One of the most common chromosomal abnormalities is Turner syndrome (TS), its incidence being 1 in 2,000 live born female infants. These women have an absent or partial loss of one X chromosome leading to severe and often irreversible POF, presenting prior to menarche. Though sporadic spontaneous pregnancies are reported among women with

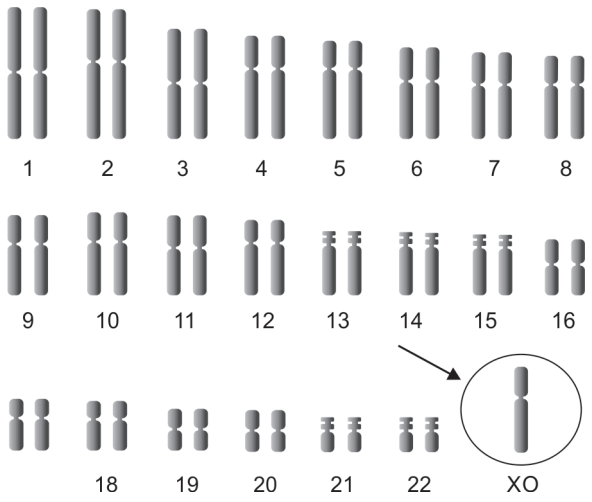

Fig. 3: Turner syndrome.

TS these can be associated with a high risk of miscarriage and an increased risk of trisomy 21 in the offspring **(Fig. 3)**.[3]

Turner syndrome patients are also candidates for in vitro fertilization with oocyte donation. However, it is well known that in these patients a high rate of cardiovascular anomalies is observed. There have been studies associated with early implantation failure after oocyte donation in these women possibly due to an inherent endometrial abnormality.[3] Therefore, according to the American Society of Reproductive Medicine (ASRM), women with TS before attempting to become pregnant should undergo medical and cardiovascular control[13]; this can decrease the high rate of cardiovascular mortality during pregnancy.

In a retrospective study, conducted in 10 of the 27 French oocyte donation centers between 2012–2016, on all the patients presenting with TS included in an oocyte donation program, the pregnancy rates were 53%. Pregnancies were complicated by gravid arterial hypertension in 28.2% of cases, preeclampsia in 10.3% of cases, and gestational diabetes in 7.7% of cases.[15]

Diminished Ovarian Reserve

Women with greatly reduced ovarian reserve as determined by ovarian reserve markers [anti-Müllerian hormone (AMH) <0.5 ng/mL, FSH >15 IU/L] or previous poor response to stimulation or advanced age can opt for oocyte donation after proper counseling.

Women with diminished ovarian reserve can be categorized and treated accordingly as per the POSEIDON criteria. The POSEIDON stratification helps to not only guide clinicians regarding clinical management of the patient, but also to be a counseling tool to help set patient expectations prior to initiation of ovarian stimulation. Various clinics can have different cutoffs of age and ovarian reserve tests above which ovarian stimulation is deferred.

In such patients IVF with oocyte donation has seen benefits.

Repeated Implantation Failure Due to Poor Quality Oocytes

In patients with repeated implantation failure (RIF), oocyte donation has been suggested as an alternative especially if oocyte quality is implicated and offers an option with acceptable pregnancy rates although sometimes couples with unexplained RIF are also treated using this method.

Genetic Disorders

In women not willing or affording for preimplantation genetic diagnosis, egg donation is an acceptable alternative for the prevention of heritable genetic disorders such as single gene defects or balanced translocations with good success rates.

LEGALITIES PERTAINING OOCYTE DONATION AS PER ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) ACT, 2021

In 2021, the Parliament passed the Assisted Reproductive Technology (Regulation) Act, 2021 (hereinafter referred to as "ART Act") which received the assent of the President on 18.12.2021 and came into force on 25.01.2022 vide the notification in the Gazette of India No. CG-DL-E-21012022-232818.

The aim of the ART Act is regulation and supervision of the ART Banks, prevention of misuse, and safe and ethical practices of ART Services for addressing the issue of reproductive help where ART is required for becoming a parent or for freezing gametes, embryos, embryonic tissues for further use due to infertility, decease or social or medical concerns and regulation and supervision of research and development.

The Commissioning Couple

An infertile married couple who approaches an ART Clinic or an ART Bank for obtaining the services authorized by such clinics or banks for the purpose of bearing a child is referred to as a commissioning couple.

Regulatory Authority

The *"National Assisted Reproductive Technology and Surrogacy Board"* constituted under Section 15(1) of the Surrogacy (Regulation) Act, 2021 is the National Board that regulates ART in India and exercises and discharges various functions.

The *"State Assisted Reproductive Technology and Surrogacy Board"* constituted under Section 24(1) of the Surrogacy Act, 2021 acts as the State Board for the purposes of the ART Act and has the responsibility to follow the policies and plans laid by the National ART Board for ART Clinics and

Banks in the State. Further, the ART Board is responsible to follow the policies and plans made by the National Board and take into account its recognition, and policies and regulating and coordinating enforcement and implementation of such policies and guidelines for assisted reproduction.

The Registry

The Central Government under Section 9 of the ART Act has established a registry called the *National Assisted Reproductive Technology and Surrogacy Registry,* which consists of scientific and other technical information pertaining to surrogacy.

- It acts as a central database in the country through which the details of all the clinics and banks of the country including the nature and types of services provided by them, the outcome of the services, and other relevant information obtained on regular basis.
- It assists the National Board in its functioning by providing the data generated from the central database of the Registry.
- The data generated from the National Registry are utilized by the National Board for making policies, and guidelines and to help in identifying new research areas and conducting research in the area of assisted reproduction and other related fields in the country.

Appropriate Authority

The Central and State Governments appoint Appropriate ART and Surrogacy Authorities for each Union Territories and state.

The appropriate authority under Section 13 of the ART Act discharges the following functions:

- To grant, suspend or cancel the registration of a clinic or bank.
- To enforce the standards to be fulfilled by the clinic or bank.
- To investigate complaints relating to the breach of the provisions of this Act and take appropriate legal actions regarding misuse of ART by any person and also to initiate independent investigations in such matters.
- To recommend to the National Board and State Boards the modifications required in the rules, in accordance with changes in technology or social conditions.
- To take action after investigation of complaints received by it against the ART clinics or banks or discharge any other function as may be prescribed by the Central Government.

IMPORTANT POINTS REGARDING OOCYTE DONATION IN THE ART ACT

- A bank shall not supply the sperm or oocyte of a single donor to more than one commissioning couple.
- The donor eggs should be obtained from women between 23–35 years of age.
- An oocyte donor shall be an ever-married woman having at least one live child of her own with a minimum age of 3 years and should donate oocytes only once in her life.
- All unused oocytes shall be preserved by the banks for use on the same recipient or given for research to an organization registered under this Act after seeking written consent from the commissioning couple.
- Assisted reproductive technology clinics should ensure the eligibility of both recipients and the donors by medically testing them for sexually transmitted diseases (STDs) and other communicable diseases, which can be harmful to anyone.
- They should elicit all relevant information for donor selection.
- Sperm or egg donation by any person known or related to the recipients should not be permitted.
- Full confidentiality should be maintained regarding the identity of the couple/woman/donor. Disclosure of information regarding the donor by any staff is a punishable offence under ART Bill regulations.
- Recipient is entitled to know about physical characteristics of donor, her ethnicity, educational background, and relevant medical history and family background.
- Counseling regarding implications and chances of success should be done and written consent forms to be signed.
- Couple and donor should be made aware of the rights of the children born using third-party reproduction.
- No clinic can advertise for oocyte, semen donors, and surrogates apart from registered ART banks.
- It is essential that detailed records should be maintained in the laboratory of all aspects of gamete donation such as the number of oocytes retrieved from donor, quality of oocytes, number of recipients, details of recipients, and pregnancy outcome.
- Records should be maintained up to 10 years and then transferred to centralized registry. Immediate transfer of all records to central data base has to be done in case of closure of ART bank or clinic before 10 years.
- It is a gross violation to treat any woman with gametes or embryos of different origins during a treatment cycle or mix semen of two individuals for any ART procedure.
- If multiple pregnancies occur, it is responsibility of the respective clinic to inform patient immediately of its medical implications and fetal reduction may be thought of after appropriate counseling.
- Preimplantation genetic diagnosis should not be used to screen embryos except in couples who are known carriers of inheritable genetic disorders.
- Embryos can be cryopreserved for a maximum period of 5 years with appropriate consent. Consent should also

include information whether the couple wants to donate these embryos for research or discard them at the end of this tenure and manner of their use in case of death of one partner.
- According to the ART Bill 2020, insurance cover should be provided to the oocyte donor by the commissioning couple from any registered insurance company .
- The child born through ART shall be deemed to be a biological child of the commissioning couple and the said child shall be entitled to all the rights and privileges available to a natural child only from the commissioning couple under any law for the time being in force.
- A donor shall relinquish all parental rights over the child or children which may be born from his or her gamete.
- Under Section 26 of the ART Act, no ART clinic can offer to provide a couple or woman the child of a predetermined sex and the same is also subject to the provisions of the Pre-complication and Pre-natal Diagnostic Techniques (Prohibition of Sex Selection) Act, 1994.
- It is also prohibited for anyone to do any act at any stage to determine the sex of the child to be born during the process of the ART, support, or yield fractions enriched in sperm of x or y variation.
- It is also prohibited for any person to knowingly provide, prescribe, or administer anything that can ensure or increase the probability that an embryo shall be of a particular sex or that can identify the sex of an in-vitro embryo, except to diagnose, prevent or treat the sex-linked disorder or disease.

EVALUATION

Recipient

- Thorough evaluation of the recipient (complete history, general and local examination) should be performed to rule out any abnormalities which can affect pregnancy outcome.
- Endocrinological investigations that affect the fertility potential and subsequent pregnancy prognosis such as thyroid function test, serum prolactin, fasting glucose, etc., should be done.
- Serological screening for human immunodeficiency virus (HIV) 1 and 2, hepatitis B by hepatitis surface antigen or hepatitis core antibody (IgG and IgM), hepatitis C by hepatitis C antibody, syphilis by venereal disease research laboratory is mandatory and investigations for other reproductive tract infections such as chlamydia, and tuberculosis should be done if deemed necessary.
- A good two-dimensional (2D) ultrasonography (USG) to rule out the presence of any uterine or ovarian pathology such as fibroids, polyps, hydrosalpinx, ovarian cyst, uterine anomalies should be performed and confirmed by three-dimensional (3D) USG. Mock endometrial preparation cycle should be a part of the protocol with enrolment in the program only once an adequate response is observed.
- Uterus can be evaluated for any abnormality by sono-hysterography, 3D scans, or any another suitable procedure. Hysteroscopy is indicated in case of suspicion of any abnormality.
- Endometrial biopsy for histopathological examination, TUBERCULOSIS-PCR (Polymerase chain reaction), and culture may be done if previous history of TB or RIF or persistently thin endometrium with visible lesions or adhesions on hysteroscopy.
- Screening for concurrent medical conditions such as hypertension, cardiac diseases, Pap smear, and mammography should be done, especially if the woman is >40 years old.
- The risks related to pregnancy increases as women approach their 50s hence additional testing such as screening for diabetes and ECG to assess heart health as well as a clearance by a high-risk obstetrician.
- Rubella and varicella titer scan be done, and non-immune recipients should be immunized (not mandatory).
- Genetic tests should be prescribed depending on the history, ethnic background, and current recommendations.[8]
- Special tests such as karyotype and autoimmune screening in women with POI and cardiac evaluation in known case of Turner syndrome.
- Psychological screening of the couple is recommended.

Recipient Partner

- Thorough evaluation of the recipient partner (complete history, general, and local examination) should be performed to rule out any abnormalities, which can affect pregnancy outcome.
- It is essential that a detailed evaluation of semen sample has been done and appropriate therapy initiated. In case of any abnormality, semen analysis should be repeated 1–3 months later[9].
- Serological screening of the partner for hepatitis B, hepatitis C, and HIV should be done.
- Endocrinological investigations as appropriate should be carried out in oligospermic and azoospermic men.
- It is advised to have at least two frozen samples of the partner as a backup for the day of donor pickup in case, he is not able to supply a fresh sample.

Donor Selection and Evaluation

- Screening of gamete donors has to be done by an independently registered ART bank. A thorough medical history, physical examination, lab evaluation, and screening for hereditary disorders should be carried out.

BOX 2: Checklist of investigations for the donor.

- Complete blood count
- ABO and Rh
- Peripheral smear
- Random blood sugar
- Blood urea or serum creatinine
- SGPT
- Routine urine examination
- HBsAg status
- Hepatitis C status
- HIV status
- VDRL for syphilis
- Hemoglobin A2 (for thalassemia) status
- Anti-Müllerian hormone (AMH)—optional

(ABO: A,B,O blood group; HBsAg: hepatitis B surface antigen; HIV: human immunodeficiency virus; Rh: Rhesus factor; SGPT: serum glutamic pyruvic transaminase; VDRL: venereal disease research laboratory).

- Donors should be screened for STDs or any other communicable diseases liable to endanger the health of the recipient.
- Donor should undergo appropriate genetic evaluation based on history, in accordance with ethnic background and current guidelines. Though ART bill does not specify any genetic tests for oocyte donors' other societies such as ASRM recommend genetic screening. Implementation of expanded carrier screening (ECS), in a recent study has resulted in 63% risk reduction in adverse outcomes observed in oocyte donation program from a potential adverse event rate of 4.2% to an actual 1.55% incidence of adverse outcomes.[11]
- According to the Human Fertilisation and Embryology Authority (HFEA) 2009 guidelines (revised in October 2017), if there is history of poor-quality gamete formation with oocytes from a particular donor or any history of serious physical, psychological or medical harm to the resulting progeny then that donor should not be accepted again.[12]
- Women with high-risk sexual behavior, close contact with hepatitis B (HepB) or hepatitis C (HepC) infected persons, history of treatment for STDs in last 12 months, recent blood transfusion, and transplant recipients should not be accepted as donors.
- Oocyte donors should have a good screening transvaginal sonography to rule out any pelvic pathology and to assess the ovarian reserve using the astral follicle count.[13]
- Checklist of blood investigations for the donor is described in **Box 2**.

COUNSELING

Recipient Couple

Assisted reproductive technology bill stresses the need to counsel the commissioning couple regarding the implications and chances of success of all ART procedures including cost, side effects, risks especially that of multiple births, limitations of donor screening, to help them make an informed decision. The decision to opt for oocyte donation itself can be taxing for the couple as there can be fear of unknown genetic material.

In a systematic review of 144 couples choosing oocyte donation, given a choice, about two-thirds opted for known donors and one-thirds only opted for anonymous donors. Counseling the couple regarding the laws related to third party reproduction and reassurance of confidentiality is very important.[16] Couple should be reassured that the process of gamete donation shall be kept confidential in accordance with the National ART Bill and identity of the donor can be disclosed only in unexceptional circumstances by a court order.

TABLE 1: Various consent forms under Indian Council of Medical Research.

FORM - K	Consent form for the donor of oocytes
FORM - L	Consent form for the donor of sperm
FORM - M	Information on semen donor
FORM - M1	Information on oocytes donor
FORM - R	Contract between the assisted reproductive technology bank and the semen donor
FORM - R1	Contract between the assisted reproductive technology bank and the oocyte donor

Donors

Professional counseling of the donor should be a part of the clinic's protocol. It should include assessment of the mental wellbeing and understanding regarding details of the procedure, need for regular visits, and possible complications due to ovarian stimulation such as nausea, headaches, abdominal bloating, and rarely ovarian hyperstimulation. Furthermore, donors should understand that they will, before going any right to future offspring, need to be fully capable and free from any kind of coercion in giving informed consent.

Consent of an oocyte donor should be obtained in local language or in presence of an interpreter if necessary and can be withdrawn at any time before embryos are created. Consent of the spouse of oocyte donor must also be obtained if there **(Table 1)**.

Offspring of Gamete Donation

Controversy exists regarding the disclosure of the facts of conception via gamete donation and identity of donor to the children born via this method. As per the ACT, a child born through ART will be deemed to be a biological child of the commissioning couple, and the said child will be

entitled to all the rights and privileges available to a natural child only from the commissioning couple, under any law for the time being in force. A donor relinquishes all parental rights to offspring born by gamete donation. Various ethical committees and human right organizations are encouraging ART programs and ART banks to conduct gamete donation in ways that promote interests of offspring in learning the facts of their conception while respecting the privacy interests of donors and recipient parents.[17]

According to Indian Council of Medical Research (ICMR), a child >18 years or legal guardian of a minor can ask for information about the donor except for identification if necessary for the child's welfare. The identity of a donor can be divulged only if there is a life-threatening medical emergency. ASRM recommends that provisions to be made in such a way that, if consented by the donor, the identity can be revealed by the ART bank at the request of the offspring.[18]

SEX-SELECTIVE ASSISTED REPRODUCTIVE TECHNOLOGY PRACTICE

Any clinic must not issue, publish, distribute, or communicate any advertisement in any manner including the internet, regarding facilities of sex-selective ART. Doing so is a punishable offense.

Anyone who is found guilty of sex-selective ART practice will be punishable with imprisonment for a term, which is not <5 years but may extend to 10 years or with a fine, which shall not be <10 lakh rupees but may extend to 25 lakh rupees.

STIMULATION PROTOCOLS IN OOCYTE DONOR IN VITRO FERTILIZATION CYCLE

There has been a steady shift toward the use of gonadotropin hormone-releasing hormone (GnRH) antagonist protocol for stimulation of oocyte donors from the earlier cycles when agonist protocols were preferred. Antagonist cycles in donors offer the advantage of ease, fewer injections, lower cost, and most importantly lower incidence of hyper stimulation without compromising the oocyte or embryo quality.

A Cochrane review also suggested similar clinical outcomes using either GnRH agonist or antagonist cycles in donor oocyte cycles, providing clinicians' reassurance for using either option without compromising results.[19]

Gonadotropin hormone-releasing hormone antagonist protocols also allow the use of GnRH agonist trigger further reducing the risk of ovarian hyperstimulation syndrome (OHSS). Several prospective and randomized studies have found that GnRH agonist trigger does not negatively impact oocyte quality, embryo quality or recipient pregnancy rates while reducing the risk of OHSS when compared to human chorionic gonadotropin (HCG) trigger.

A recent meta-analysis by Guan et al. published in 2021, also did not find any difference between agonist and antagonist protocols or with the use of progesterone primed ovarian stimulation protocols.[16]

Random-start ovarian stimulation protocols have emerged allowing treatment to begin at any day of the menstrual cycle. Concomitantly, in what is called progestin primed oocyte stimulation (PPOS), the use of progestins seem similarly as effective as GnRH antagonists in preventing LH surge as suggested in a recently published study by Farfan et al.[18]

ENDOMETRIAL PREPARATION OF RECIPIENT

The key challenges to a successful oocyte donation program are endometrial preparation of the recipient and embryo-endometrial synchronization. Endometrial preparation is a key factor for successful ART outcomes, particularly in oocyte donation (OD) cycles.

In case of anovulatory recipients, either a fresh transfer can be planned by synchronizing the recipient with the donor or freezing the embryos and plan for frozen embryo transfer (FET). The easiest way to synchronize and plan for a fresh embryo transfer is by downregulating the recipient. The benefit of a fresh cycle transfer is that patient can avoid the cost of freeze-thaw cycle. The downside of a fresh cycle is the task of synchronizing the cycle of a recipient with that of a donor, which is not needed in FET cycles.

- Methods of synchronizing recipient cycle with that of donor is to give a GnRH depot to the recipient on D21-D22 of the pre-transfer cycle. Hormone replacement therapy (HRT) can be started after 2 weeks of depot after confirming for downregulation using a serum estradiol and serum progesterone level, (E2 <60 pg/mL; P4 <0.5 ng/mL) or clinically by USG measurement of endometrial thickness <5 mm. Donor stimulation should be started 3–4 days after initiating HRT in the recipient. The aim is to prime the endometrium with estrogen for at least minimum 10 days before oocyte retrieval of the donor.[20]
- Oral contraceptive pills can also be started from the 2nd day of pre-transfer cycle in recipient and withdrawn 7 days before the expected menses of the donor. The recipient usually starts bleeding from the 7th day after stopping the pills.
- In woman with complete cessation of cycles due to premature ovarian failure, it is advised to give at least one cycle of trial HRT to assess the endometrial response and prime the uterus as well. In these women use of GnRH agonists for downregulation is not required.
- Hormone replacement cycles involve sequential administration of estrogen followed by progesterone. Estrogen preparations with either (oral estradiol 4–8 mg or transdermal 0.2–0.4 mg) are usually initiated 3–4 days before stimulation in donor. There is no difference in the use of constant or increasing dosages of estrogen for endometrial preparation as well as route of administration.[21] Progesterone is started for the recipient from the day of oocyte retrieval if the endometrium is at least 7 mm thick.

- In FET cycles, embryo transfer is planned on the 4th day of progesterone for a day 3 transfer and similarly on the 6th day for a blastocyst embryo. Recent prospective study carried out in donor oocyte recipients found that serum P levels <9.2 ng/mL on the day of ET were associated with poor outcomes in patients on vaginal P. In case of ovulatory patients, transfer can be planned in a natural cycle such that blastocysts are replaced 5 days after an LH surge is detected. Similarly in a cycle using cryopreserved oocytes, they can be thawed 1 day post LH surge with subsequent transfer of day 3/5 embryos.

Several meta-analyses have demonstrated equal efficacy of different protocols of endometrial preparation in maximizing the endometrial receptivity. However natural cycle transfers have less flexibility and increased chance of cancellation. Large RCT showed that pregnancy rates in natural transfers are higher if vaginal (400 mg) progesterone is initiated after embryo transfer compared to no progesterone.[22]

FACTORS PREDICTING SUCCESS OF A DONOR PROGRAM

Recipient Related Factors

Maternal Age

The age of the recipient seems to be the most important factor predicting a successful outcome. In a prospective study of 270 cycles, woman <40 years had significantly higher implantation rate and ongoing pregnancies as compared to those >40 years (22.1% vs. 11.5%; 36.8% vs. 23.6% p = 0.001). The importance of age was emphasized by another retrospective cohort study of 27,959 fresh donor oocyte transfer cycles from the Society for Assisted Reproduction Technology (SART) registry which concluded that donor oocyte recipients have stable rates of pregnancy outcomes before age 45 years, after which there is a small but steady and significant decline. This is indicative probably of uterine senescence leading to decreased fertility potential, despite younger oocytes.[23]

Paternal Age

There are conflicting reports in literature regarding the effect of paternal age on the pregnancy rates of donor oocyte cycles. A systemic review and meta-analysis including 12,538 oocyte-donation cases concluded that the available evidence did not suggest an association between advanced paternal age and adverse reproductive outcome in donor oocyte cycles, although the quality of evidence was suboptimal.[24]

Endometrial Thickness

The evidence regarding impact of endometrial thickness on oocyte donation cycles is conflicting. Whereas a recently published retrospective analysis of 4,070 cycles reported that endometrial thickness ≥5 mm is a reasonable parameter for determining success in oocyte donation cycles.[25] The best reproductive outcomes tend to be achieved if the endometrium is >8–9 mm. There is no consensus in literature regarding the impact of trilaminar hypoechogenic pattern of endometrium on reproductive outcomes.[26] Another 2022 study revealed that ENT change after 6 days of progesterone administration, whether increased or decreased, does not have any significant effect on LBR and clinical pregnancy rates (CPR) in fresh OD recipients.[27]

Recipient Diagnosis

The cause of infertility in the recipient did not seem to affect the reproductive outcome of the donor cycle.[25,26]

High Body Mass Index

It is not an independent predictor of live birth in recipient cycles. Large meta-analysis comparing pregnancy outcomes amongst obese and non-obese recipients of egg donation cycles did not find any difference in implantation, clinical pregnancy, and live birth or miscarriage rates.[28] This was contrary to cohort and cross-sectional studies showing a poorer reproductive outcome of obese women using their own oocytes. This might imply that high body mass index (BMI) might have a significant negative impact on the quality of the oocyte rather than endometrial receptivity which is overcome in an obese recipient by using an oocyte donor.[28] Interestingly though, study by Cardozo et al. found increased donor BMI to be associated with decreased pregnancy and live birth rates.[29] In a most recent September 2022 study conducted over 5 years aimed to determine if overweight and obese oocyte recipients had similar pregnancy outcomes compared with healthy weight controls after the transfer of a single euploid frozen–thawed embryo transfer (FET).[30] The results of the study showed that BMI alone does not adversely alter endometrial receptivity and is not the cause of poor IVF outcomes in patients with increased BMI. These deleterious IVF outcomes might be the result of diminished oocyte and/or embryo quality or other factors that have not yet been elucidated.

Blastocyst Transfer

Advances in the culture systems and improved blastocyst cryopreservation programs have played a major role in improving the success rates of oocyte donation cycles. Various prospective randomized and retrospective series have shown superior results per transfer in blastocyst cycles compared to cleavage day 3 embryo cycles. Thus, recipients of oocyte donation cycles can opt for blastocyst transfer as an effective method for increasing pregnancy rates and reducing multiple pregnancies.[31]

This has led to a recommendation in 2013 from the American Society for Reproductive Medicine stating that in the case of young oocyte donors, only a single blastocyst-stage (eSET) or no more than two cleavage-stage embryos may be transferred. However there has been poor compliance with these guidelines and a retrospective analysis of 13,939 cycles found only 18% to be complaint. A study conducted in March 2022 stated that among fresh donor oocyte transfers, only (55%) underwent eSET. Non-adherence with transfer guidelines was associated with dramatically increased multiple pregnancies, preterm births, and low birth weights.[32]

Fresh versus Frozen Embryo Transfer

Frozen embryo transfer (ET) with vitrification has been associated with improved pregnancy rates, but also increased rates of large for gestational age infants.[38] Donor oocyte recipients represent an attractive biological model to attempt to isolate the impact of embryo cryopreservation on IVF outcomes, yet there is a paucity of studies in this population. Recent retrospective cohort study of the SART data from 2014–17 analyzing 33,893 cycles also found that that in cycles using fresh donor oocytes, live birth rates were statistically significantly higher following fresh embryo transfer compared with cryopreserved-thawed embryo transfer, even when PGT-A was performed.[33] However, this study is limited by the potential for selection and confounding bias.

Recent study in 2022 suggested that there was no significant difference between the fresh ET and FET groups in terms of mean birth weight. However, artificial endometrial preparation was associated with a higher birth weight when compared with a transfer in a natural cycle. No other statistically significant differences were found in the remaining neonatal and maternal outcomes studies between the fresh ET and FET groups.

On the contrary another 2022 study in October stated that vitrified donor oocytes were associated with improved pregnancy outcomes compared with fresh donor oocytes in patients undergoing single embryo transfer.[34]

Preimplantation Genetic Testing

Although a study of US data from the Society for Assisted Reproductive Technology Clinic Outcome Reporting System from 2005–2013, found the adjusted odds of live birth to be reduced by 35% in donor recipient cycles, this could be as they included cleavage stage PGT-A, which is no longer in clinical practice.[35] A retrospective analysis of 398 donor frozen ET (FET) cycles comparing blastocyst embryos that either underwent trophectoderm biopsy PGT-A using array comparative genomic hybridization or next-generation sequencing (NGS) versus unbiopsied and untested embryos demonstrated higher live birth rate for PGT-A embryos.[39]

TABLE 2: Correlation between number of retrieved oocytes with live birth rates.

Oocyte source and day of transfer	*No. of retrieved oocytes*	*Overall live birth rate in %*
Donor, day 2–3 (n = 14,744)	1–5	15.1
	6–10	23.6
	11–15	27.5
	16–25	33.5
	>26	46.3
p value for trend	<.0001	

On the contrary, a most recent 2021 cohort study stated that preimplantation genetic testing for aneuploidies does not increase success rates in fresh oocyte donation cycles.[36,37]

Donor Factors

Age

Age of the donor seems to be the only factor influencing the outcome in egg donation cycles. Study was conducted by Wang et al. to compare the pregnancy and live delivery rates in oocyte recipients of various age groups as well as different donor age groups. Donor age was found to have the most significant effect with the highest live birthrate observed in cycles with donors aged 30–34 years (25.0%), followed by 24.1% in donors aged <30 years and lowest rates in cycles with donors aged >40 years. A recent population-based cohort study also found donor age to be critical to cumulative birth rates in recipients, irrespective of recipient age.[40]

Although previous reproductive outcome of donor has been shown to have a positive effect on reproductive outcome in egg donation cycles, there is no evidence suggesting a significant difference.

Number of Mature Oocytes (MII) Retrieved

A retrospective cohort study in Massachusetts of 237 fresh donor oocyte ET cycles, the greatest probability of live birth was observed in cycles with more oocytes retrieved (>10), more mature oocytes, and an increased number of cleavage stage embryos.[41]

An analysis of Society for Assisted Reproductive Technology data has revealed a positive correlation between number of retrieved oocytes with live birth rates and embryos available for cryopreservation even after adjusting for age and previous births **(Table 2)**.

REPRODUCTIVE AND OBSTETRIC OUTCOMES

Pregnancy and Implantation Rates

The European IVF Monitoring (EIM) consortium report of 2014 on reproductive outcome with use of donor oocytes, reported a PR of 50.4% per fresh embryo transfer, and 48.7% using frozen oocytes.[42] In comparison, use of autologous

oocytes resulted in a CPR of 29.9% per aspiration, 35.8% per transfer, and 27 .6 % with FET, and an overall multiple PR of 17.9%. The rate of twin pregnancy was also significantly higher in women with IVF-oocyte donation compared to IVF and spontaneous pregnancy (39.4% vs. 15.0% with IVF and 2.5% with spontaneous, $p<0.001$).[43]

A recent study of 40,485 IVF cycles using donor oocytes reported to the Society for Assisted Reproductive Technology registry in 2016–2018 was published. There was decline in LBR with increasing age and BMI of the recipients. They observed an increase in LBR with >16 oocytes retrieval as well as with blastocyst transfer versus a cleavage transfer.[44]

Maternal Outcomes

Most studies have demonstrated good obstetric outcomes for recipients of egg donation cycles except for an increase in hypertensive disorders and cesarean section rates.[45]

A total of 217 OD and 363 control singleton pregnancies were compared for percentage of hypertensive disorders of pregnancy for OD versus controls.[46] The results of this large, comparative, matched cohort study detected a tripling of the pregnancy induced hypertension (PIH) risk for young women with OD pregnancies that was confirmed by multivariate analyses. In addition, they demonstrated an increase in the severity of PIH among OD recipients, as evidenced by higher rates of preeclampsia and even eclampsia compared with controls.[47] The underlying cause for this increase in hypertensive disorder is believed to be placental dysfunction. It is postulated that the trophoblastic human leukocyte antigen-C in donated oocytes is less recognizable to the maternal immune system, leading to an altered functionality of the uterine natural killer cells and consequently an altered maternal blood supply to the placenta.

Studies have also found an increased occurrence of first-trimester bleeding, gestational diabetes,[39] placental abnormalities,[40] intrauterine growth restriction (IUGR), preterm delivery,[40,41] prolonged maternal hospitalization after delivery, and increased prevalence of cesarean section in oocyte donation recipients.[48]

Neonatal Outcomes

Neonatal complications include an increased risk of prematurity, extreme prematurity, small for gestational age (SGA), low birth weight (LBW), and very LBW (VLBW). The perinatal outcomes between pregnancies with donor and autologous eggs have been found to be similar in a meta-analysis of 23 studies by Adams et al.[49] Subsequently Kamath et al. analyzed large HFEA data and found the adjusted odds ratio to be significantly higher for preterm birth and LBW after oocyte donation.[50]

On Donor

Women who donate their oocytes to others are exposed to physical and psychological burdens they would not otherwise face. There is some risk of unintentional pregnancy because hormonal contraceptives must be discontinued for donation to occur. Donors also are exposed to risks of morbidity and a remote risk of mortality from controlled ovarian stimulation and oocyte retrieval. Young women may be prone to dismiss the potential psychological consequences of donation, particularly those that could arise if they later experience infertility problems themselves. In addition, they may underestimate the psychological and legal consequences of their agreement to forgo parental rights and future contact with children born to oocyte recipients.

There is still not much evidence and many unanswered questions regarding the long-term medical and psychological effects of egg donation on donors.

Short-term risks of egg donation include OHSS (0.38%), intra-abdominal bleeding, infection, ovarian torsion, and short-term subfertility (5–10%). Serious complications seem to be rare (<1%).[51,52] Few studies have examined the long-term medical effects of egg donation, such as fertility, cancer, and other potential health risks.

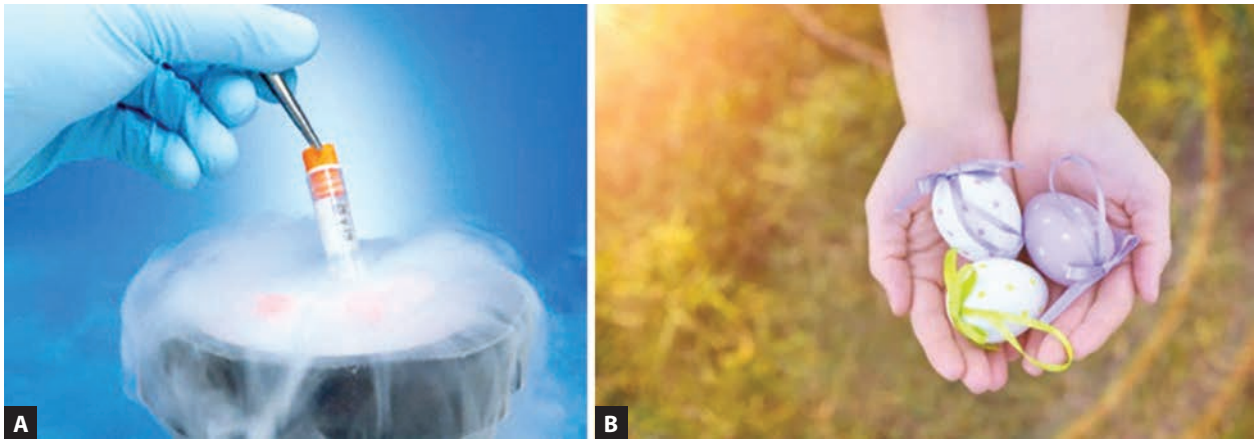
OOCYTE BANKING

The first pregnancy using cryopreserved oocyte was reported in 1986 and in India in 2009. Advances in cryopreservation techniques especially vitrification led to the ASRM revoking the experimental tag for oocyte cryopreservation in 2012.[53]

In the first reported experience with the establishment of a commercial donor egg bank in 2007, Akin et al. recruited donors according to ASRM guidelines for gamete and embryo donation. Studies have shown comparable ongoing pregnancy rates in oocyte donor IVF cycles utilizing either cryobanked oocytes or fresh oocyte donation **(Figs. 4A and B)**. Owing to the advances in vitrification, comparable survival rates, and reproductive outcomes, there has been shift in trend with more couples opting for oocyte banking.

Potential Benefits of Commercial Egg Banks

Commercial egg banks offer multiple potential benefits over conventional donor oocyte programs. Benefits of oocyte cryopreservation include simplified IVF logistics since coordinating donor and recipient cycles is no longer necessary, reduced costs, and a faster flow as donors can be selected from a bank and used relatively quickly.[54] According to the ASRM guideline, recipients can be counseled that cryopreserved donor oocytes are a reasonable option with no significant difference in per transfer pregnancy rates compared to fresh donor oocytes.[55] In addition, the ability to routinely implement a quarantine period for infectious



Figs. 4A and B: Oocyte banking.

disease testing, analogous to the practice in sperm banking, increases patient safety. Furthermore, an increasingly global network of commercial egg banks will permit a larger pool of ethnically diverse donors for selection.

Apart from the cost-effectiveness, the waiting time for a donor is also significantly lesser when an oocyte bank comes into picture. This also ensures reduction in wastage of gametes. Donor oocyte vitrification has become more commercialized in recent years with the development of multiple egg bank programs.[56] As per the ART ACT in India, it states that oocytes collected from "donors" shall be stored for 10 years.

OOCYTE SHARING

The system of oocyte sharing is that in which an indigent infertile couple that needs to raise resources for ART agrees to donate oocytes to an affluent infertile couple wherein the wife can carry a pregnancy through but cannot produce her own oocyte, for IVF with the sperm of the male partner of the affluent couple, for a monitory compensation that would take care of the expenses of an ART procedure on the indigent couple.[58] This concept has generated considerable interest, especially in countries where commercial egg donation is not allowed or there is paucity of egg donors.[57]A successful cycle needs careful assessment of the donor by antral follicle count, AMH, age, and cause of infertility.[59] If the number of eggs recovered is lower or of poor quality, both donor and recipient's cycles may be compromised with neither having sufficient good quality embryos to transfer and/or cryopreserve, necessitating a fresh IVF cycle with its inherent costs.

Oocyte vitrification and banking have changed the concept of oocyte sharing from one that involved sharing of oocytes between two sub fertile couples to one where the eggs of a commercial donor are shared. A second scenario is where the number of oocytes obtained from a single donor is shared between two recipients and the cost of the cycle is shared between the recipients. In vitro fertilization patients in these sharing arrangements generally donate up to half the oocytes retrieved in a single cycle to another patient, in return for a 50–60% reduction in the total costs of the IVF cycle. Oocyte-sharing programs reportedly exist in a number of other countries, including the United Kingdom, Israel, Denmark, Australia, Spain, and Greece.

Donors in oocyte-sharing programs also may be required to undergo the additional medical and psychological screening required of oocyte donors. They also may experience extra psychological burdens. A donor who remains childless may feel added distress based on her knowledge that another couple may become the parents of a child genetically related to her. The major advantage of oocyte sharing is drop in financial burden. However, as per the new rules in the ART ACT in India, a bank shall not supply the sperm or oocyte of a single donor to more than one commissioning couple.

OOCYTE DONOR PROGRAMS FOR STEM CELL RESEARCH

The IVF procedures may also be used to create blastocysts for non-reproductive purposes. Blastocysts may be created for fundamental research to study basic biological mechanisms of early embryo development. Human embryonic stem cells (ESCs) typically derived from human blastocysts have been used to develop specific human ESC lines, thus enabling the study of specific diseases[55]

REMUNERATION

In recognition of the significant time, inconvenience, and discomfort associated with oocyte donation, two types of remuneration are common. One is monetary compensation to women who undergo COS and oocyte retrieval for the sole purpose of providing donor oocytes. Another form of financial compensation involves an arrangement known as oocyte sharing as described formerly in this chapter.

The legal status and cost or compensation models of egg donation vary significantly from one country to another **(Table 3)**.

TABLE 3: Legal implications of donor cycle.

Legal status of oocyte donation[44]	*Country*
Totally legal	Italy, Germany, Austria
Legal only if anonymous and gratuitous. Without any compensation for the egg donor	France
Legal only if non-anonymous and gratuitous	Canada
Legal only if anonymous, but egg donors may be compensated	Spain, Czech Republic, South Africa, India
Legal only if non-anonymous, but egg donors may be compensated	UK
Legal whether or not it is anonymous, and egg donors may be compensated	USA

Compensation for egg donors is another ethical gray area with much debate regarding adequate compensation amount which should at least be generous enough for undergoing the necessary medical procedures rather than according to number of eggs. The regulations of the respective country influence the reproductive process in the sense that, in countries that prohibit compensation there is an extreme dearth of young women willing to go through this procedure. There is an increase in medical tourism to countries where the process is legal and anonymous. Half the donor cycles in Europe occur in Spain as egg donation is illegal in a number of European countries including Germany, Austria, and Italy.[60] Similarly many Canadians travel to the US for ART procedures due to lenient laws. A law enacted in California in 2019 likewise requires women who provide human oocytes for research to be compensated for their time, discomfort, and inconvenience in the same manner as other research subjects, removing a previous prohibition of compensation of research donors.

Additionally, in most countries where it is legal and compensated, the law places a cap on the compensation and that cap tends to be in the vicinity of $1,000–$2,000 in western countries while maybe a meager 25,000–30,000 rupees in India. Higher compensation may be offered in some clinics according to favorable physical attributes, educational qualifications, or previous good outcomes in recipients.

In India, as per ART ACT 2021, clause 3.9.2. banks will be encouraged to obtain (for example, through appropriate advertisement) and maintain information on possible oocyte donors. The oocyte donor may be compensated suitably (e.g., financially) by the bank when the oocyte is donated.

DISCLOSURE AND COUNSELING

Prospective donors should be fully informed about the potential medical and psychological risks of undergoing oocyte retrieval for reproduction or research. This ethical obligation to ensure the informed consent of prospective donors attaches to any party or program seeking the services of an oocyte donor, including providers assisting intended parents, fertility clinics, egg banks, and agencies involved in recruiting or matching donors and recipients. Women donating oocytes for research should be afforded the additional protection of review by an institutional review board or other required oversight body with authority for approval of the informed consent process and documents.

BOX 3: Advantages of donor regulations.

- Protection of intended couple rights
- Protection of donor rights
- Avoiding physical and psychological exploitation of donors
- Increase in medical tourism

The potential negative health and psychological effects of oocyte donation should be openly acknowledged **(Box 3)**. Prospective donors should understand the measures they must take to avoid unwanted pregnancy during a stimulation cycle. They also should understand that they could later develop desires to establish contact with their genetically related children, desires that may be difficult to satisfy because of legal or other barriers. Alternatively, donors should be apprised that remaining anonymous to the recipient(s) or resulting offspring may not be possible because of increasingly sophisticated genetic tracing and social-media technologies.

ETHICAL CONCERNS REGARDING OOCYTE DONATION

Both monetary compensation and oocyte sharing create the possibility of undue inducement and exploitation in the oocyte donation process. Women may agree to provide oocytes in response to financial need. High payments could lead some prospective donors to conceal medical information relevant to their own health or that of their biologic offspring. Patients undergoing IVF who cannot afford the procedure may, because of the intensity of their desire to have children, consent to share oocytes without careful consideration of risks and burdens. With both types of compensation, there is a possibility that women will discount the physical and emotional risks of oocyte donation out of eagerness to address their financial situations or their infertility problems. Financial compensation also could be challenged on grounds that it conflicts with the prevailing belief that gametes should not become products bought and sold in the marketplace.

OFFENSES AND THEIR IMPLICATIONS

Any registered medical practitioner is bound to perform certain duties, and under any circumstances, the person must not:

- Abandon, disown or exploit (or cause to be abandoned, disowned, or exploited) the child born through ART.
- Sell human embryos or gametes or run an agency, a racket, or an organization for selling, purchasing, or trading in human embryos or gametes.

- Import, or help in getting imported the human embryos or human gametes.
- Exploit the commissioning couple, woman, or gamete donor in any form.
- Transfer a human embryo into a male person or an animal.
- Sell any human embryo or gamete for the purpose of research.
- Use any intermediates to obtain gamete donors or purchase gamete, donors.

The ART Act has made the abovementioned acts punishable under the law. Anyone found guilty of the commission of any of these acts is punishable with a fine which is not <5 lakh rupees but may extend to 10 lakh rupees for the first contravention; and for subsequent contravention, will be punishable with imprisonment for a term which is not <3 years but may extend to 8 years and with fine which is not <10 lakh rupees but can extend to 20 lakh rupees.

Courts can only take cognizance of an offense punishable under the ART Act if a complaint is made to it by the National Board or the State Board, or by an officer authorized by it.

No court inferior to that of a Metropolitan Magistrate or a Judicial Magistrate of the first class can try any offense punishable under the ART Act. Further, all offenses under this Act are cognizable and bailable.

In addition, it is pertinent to add that where an offense under the ART Act has been committed by any clinic or bank, the executive head of such clinic or bank will be deemed to be guilty of an offense and will be liable to be proceeded against and punished accordingly, unless he/she proves that the offense was committed without their knowledge or that he/she exercised all due diligence to prevent the commission of such offense.

SPERM DONATION

Indications

Donor semen insemination is mainly used for couples where the male partner is suffering from azoospermia or severe oligoasthenoteratozoospermia **(Box 4)**.

The rules, duties, and regulations regarding sperm banking have been discussed earlier.

BOX 4: Common indications for artificial insemination with donor sperm.

- Non-obstructive azoospermia with failure to retrieve testicular sperms
- Severe oligozoospermia with financial restrictions
- Hereditary genetic defect in male partner not willing for PGD
- The couple has Rh incompatibility
- Anejaculation or retrograde ejaculation not willing for sophisticated ART such as ICSI
- Failed fertilization on ICSI

(ART: assisted reproductive technology; ICSI: intracytoplasmic sperm injection; PGD: preimplantation genetic diagnosis).

Quarantine of Semen Samples

One of the important reasons for freezing semen from donors is that any donor semen has to be quarantined for 6 months. Donors whose semen is frozen for future use are required to report to the ART bank 6 months after donation to be checked for HIV infection or disease status. This helps in avoiding donors who are infected of with venereal diseases, hepatitis B or C, or HIV. The safety of using frozen sperm has been abundantly proven, both by experimental work and the actual results in humans. The only drawback of sperm freezing is the likelihood of an approximately 20% loss in motility after thawing which is an acceptable bargain compared with the risk of acquiring infections.[60,61]

Sperm Donor Screening

The investigation described in **Box 5** should be performed on the intended donor.

Apart from this, the basic information that has to be obtained is listed in **Box 6**.

BOX 5: Investigations for sperm donor.

- Complete blood picture, blood group, and Rh status:
  - Hemoglobin
  - Total RBC count
  - Total WBC count
  - Differential WBC count
  - Platelet count
  - Peripheral smear
- Random blood sugar
- Blood urea or Serum creatinine
- SGPT
- Routine urine examination
- HBsAg status
- Hepatitis C status
- HIV1 status with date of the tests done
- Hemoglobin A2 (for thalassemia) status
- HIV PCR2 (positive or negative)

(HIV PCR2: human immunodeficiency virus polymerase chain reaction 2; SGPT: serum glutamic pyruvic transaminase).

BOX 6. Information to be obtained from the donor.

- Identification number (Donor ID)
- Age or date of birth
- Marital status
- Education: a. Donor b. Spouse
- Occupation: a. Donor b. Spouse
- Monthly income
- Religion
- Obstetric history of wife: a. Number of deliveries b. Number of abortions c. Other points of note
- History of use of contraceptives
- Medical history
- Family history from the medical point of view
- History of any abnormality in a child of the donor
- History of blood transfusion
- History of substance abuse

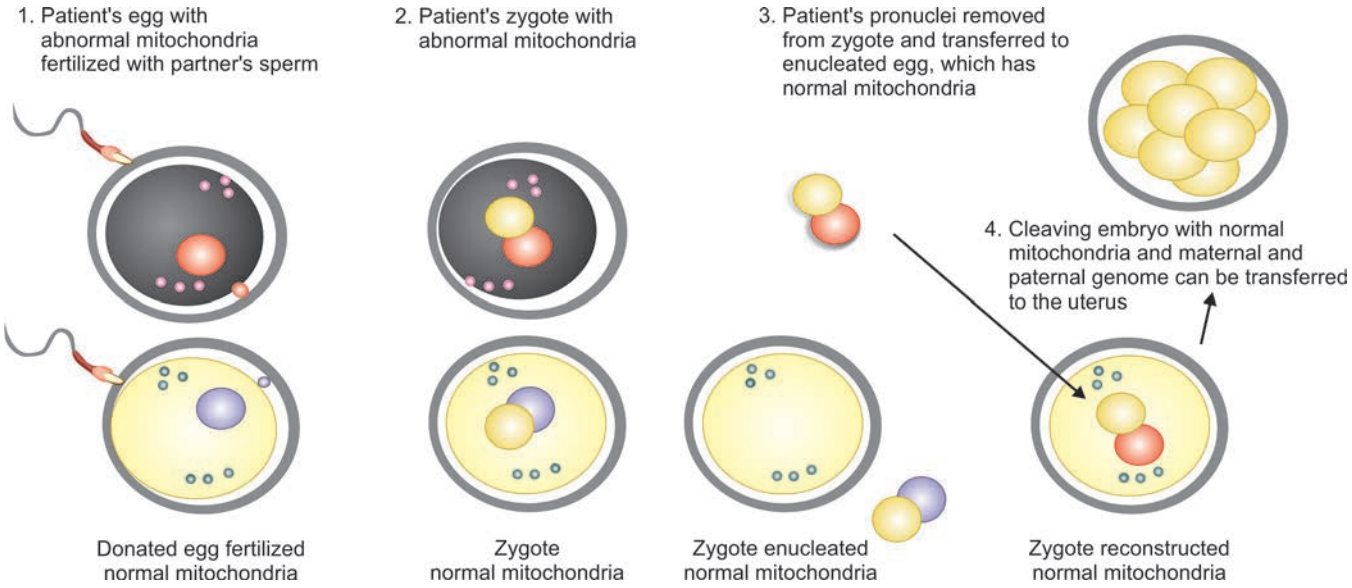


Fig. 5: Use of assisted reproductive technology to prevent inheritable mitochondrial disease.

The consent for the husband is mandatory to perform a donor insemination.

Consent for semen freezing should also include clauses such as ownership of semen sample in case of the death of the donor. If there is non-payment of fees, ART bank would have the right to destroy the semen sample or donate it for research in case due charges are not paid or if there are no bona fide claimants in case of death of the donor.

Posthumous Artificial Insemination Husband through Sperm Bank

Since according to Indian Evidence Act, 1872, a child born within 280 days after dissolution of marriage (by death or divorce) is a legitimate child; the same can be extrapolated in context of ART using cryopreserved semen to bear a child after death of the husband. Thus, a child born via posthumous autoimmune hepatitis through sperm banking is considered legitimate.

THREE-PARENT ASSISTED REPRODUCTIVE TECHNOLOGY

Mitochondrial diseases arise due to mutations in either mitochondrial DNA or in nuclear genes involved in mitochondrial function. The morbidity of such diseases is severe because they affect critical organs such as brain, heart, muscle, and central nervous system and are non-curative. Novel ART techniques to prevent inheritable mitochondrial disease include transfer of genetic material between oocytes and embryos.

Either replacement of the nucleus from the pronuclear stage zygote of an affected woman to a healthy enucleated zygote; in the second technique, the metaphase II spindle from the unfertilized oocyte of an affected woman is transferred to an enucleated donor oocyte.[61] These technologies have been found encouraging in animal models but need more robust human data before implementation. Offspring resulting from such fertilized ova containing ooplasm (including mitochondria) from a donor ovum now have three genetic parents. In such cases, ooplasm donor must be thoroughly screened and give consent **(Fig. 5)**.

KEY POINTS

- Third-party reproduction is an essential part of ART helping infertile couples to achieve the dream of parenthood.
- Meticulous evaluation of the recipients and donors coupled with adequate counseling helps in the smooth running of a donor program.

ANNEXURE

FORM-L

Consent Form for the Donor of Sperm.

I, Mr. ..... consent to donate my sperm to couples/individuals who are unable to have a child by other means. I have had a full discussion with Dr..... ..... (Name and address of the clinician) on ....., I have been counseled by..... ..... (Name and address of independent counselor) on I understand that there will be no direct or indirect contact between the recipient, and me, and my personal identity will not be disclosed to the recipient or to the child born through the use of my gamete. I understand that I shall have no rights whatsoever on the resulting offspring and vice versa. (If applicable) My wife has agreed to the donation of my sperm. (Strike off if not applicable.) Endorsement by the ART bank I/we have personally explained to..... .....the details and implications of his signing this consent/ approval form and made sure to the extent humanly possible that he understands these details and implications.

Signed: .....

Name and address of the donor .....

Name and signature of the Doctor

Name, address, and signature of the witness from the ART bank

Name and address of the ART bank

Dated:

CHAPTER 70

Surrogacy in Assisted Reproductive Technology

Nayana H Patel, Yuvraj D Jadeja, Harsha K Bhadarka, Niket H Patel, Molina N Patel, Harmi Thakkar

WHAT IS SURROGACY?

The word "surrogate" is rooted in Latin "Subrogare" (to substitute), which means "appointed to act in the place of." It means a substitute, especially a person deputizing for another in a specific role. As per draft ART Bill, 2014, "Surrogacy" means an arrangement in which a woman agrees to a pregnancy, achieved through assisted reproductive technology (ART), in which neither of the gametes belongs to her or her husband, with the intention to carry it and hand over the child to the commissioning couple for whom she is acting as a surrogate.[1] It is important to be noted that the definition from the European Society for Human Reproduction and Embryology (ESHRE)[2] does not state the sexuality of the intended parents.

HISTORY

The first surrogacy arrangement is believed to have happened about 2,000 years before the birth of Christ and was mentioned in the Old Testament of the Bible. Sarah and Abraham were unable to conceive and Sarah hired her maid Hagar to carry a child for her husband. Subsequently, Hagar gave birth to a son, Ishmael, for Sarah and Abraham. The concept of surrogacy is also rooted in Hindu mythology, as despite of taking birth from the womb of Rohini, Balraam was regarded as the son of mother Devaki and the elder brother of Lord Krishna.

TYPES OF SURROGACY

Surrogacy is of two types—*traditional* and *gestational*.

Traditional (also called genetic or partial) surrogacy is the result of artificial insemination of the surrogate mother with the intended father's sperm, making her a genetic parent along with the intended father.

Gestational [in vitro fertilization (IVF)/host/full] surrogacy is defined as an arrangement in which an embryo from the intended parents, or from a donated oocyte or sperm, is transferred to the surrogate's uterus. In gestational surrogacy, the gestational carrier has no genetic connection to the child.

Surrogacy may be *commercial (compensated)* or *altruistic*, depending upon whether the surrogate receives monetary benefits for her pregnancy. In commercial surrogacy, the surrogate is reimbursed for medical costs and paid for her gestational services. With altruistic surrogacy, the surrogate who could be a friend or acquaintance or relative may be reimbursed for medical costs directly related to the pregnancy and for loss of income due to the pregnancy.

To be a surrogate mother could be a life-changing choice that can be tremendously rewarding, but with challenges. Surrogate requires commitment for a year or more as she has to undergo medical and psychological evaluations, procedures, and challenges related to pregnancy with a baby that is not her own. Surrogacy not only gives surrogate the unique opportunity to give an incredible and selfless gift to another person or couple but also provides her with financial benefits and can create lasting, meaningful relationships between her and the family she helped in creating.

WHO NEEDS SURROGACY? THE INDICATIONS

- *Congenital or acquired absence of a functioning uterus:* Congenital absence of the uterus such as Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome is relatively rare with an incidence of 1 per 4,000–5,000 newborn girls.[3,4]
- *Hysterectomy for various reasons:* Obstetric complications during delivery or medical diseases, such as cervical cancer, could also be a cause for hysterectomy and lead to uterine infertility in spite of healthy ovaries.
- Significant *structural abnormalities* and the presence of *multiple fibroids*
- *Severe adenomyosis*
- *Persistently thin endometrium due to endometrial tuberculosis (TB)*
- *Asherman's syndrome*

- *Repeated miscarriages* and repeated *unexplained IVF failures* despite good-quality embryo
- Repeated IVF failure due to nonreceptive uterus
- Heart and renal diseases and other *medical conditions*, which might be life threatening for a woman during pregnancy, are also considered indications for surrogacy only if her life expectancy is reasonable to take care of a child after birth.
- Biological inability to conceive or bear a child, which applies to same-sex male couples or single men, also approaches surrogacy.
- **Figure 1** depicts indications that required treatment by gestational surrogacy; these data were acquired from one private IVF setup in India.

STEPS INVOLVED IN THE SURROGACY PROCESS

The steps involved in the surrogacy process are:

1. Patient selection
2. Source of the surrogate (ART bank)
3. Selection and screening of the prospective surrogate

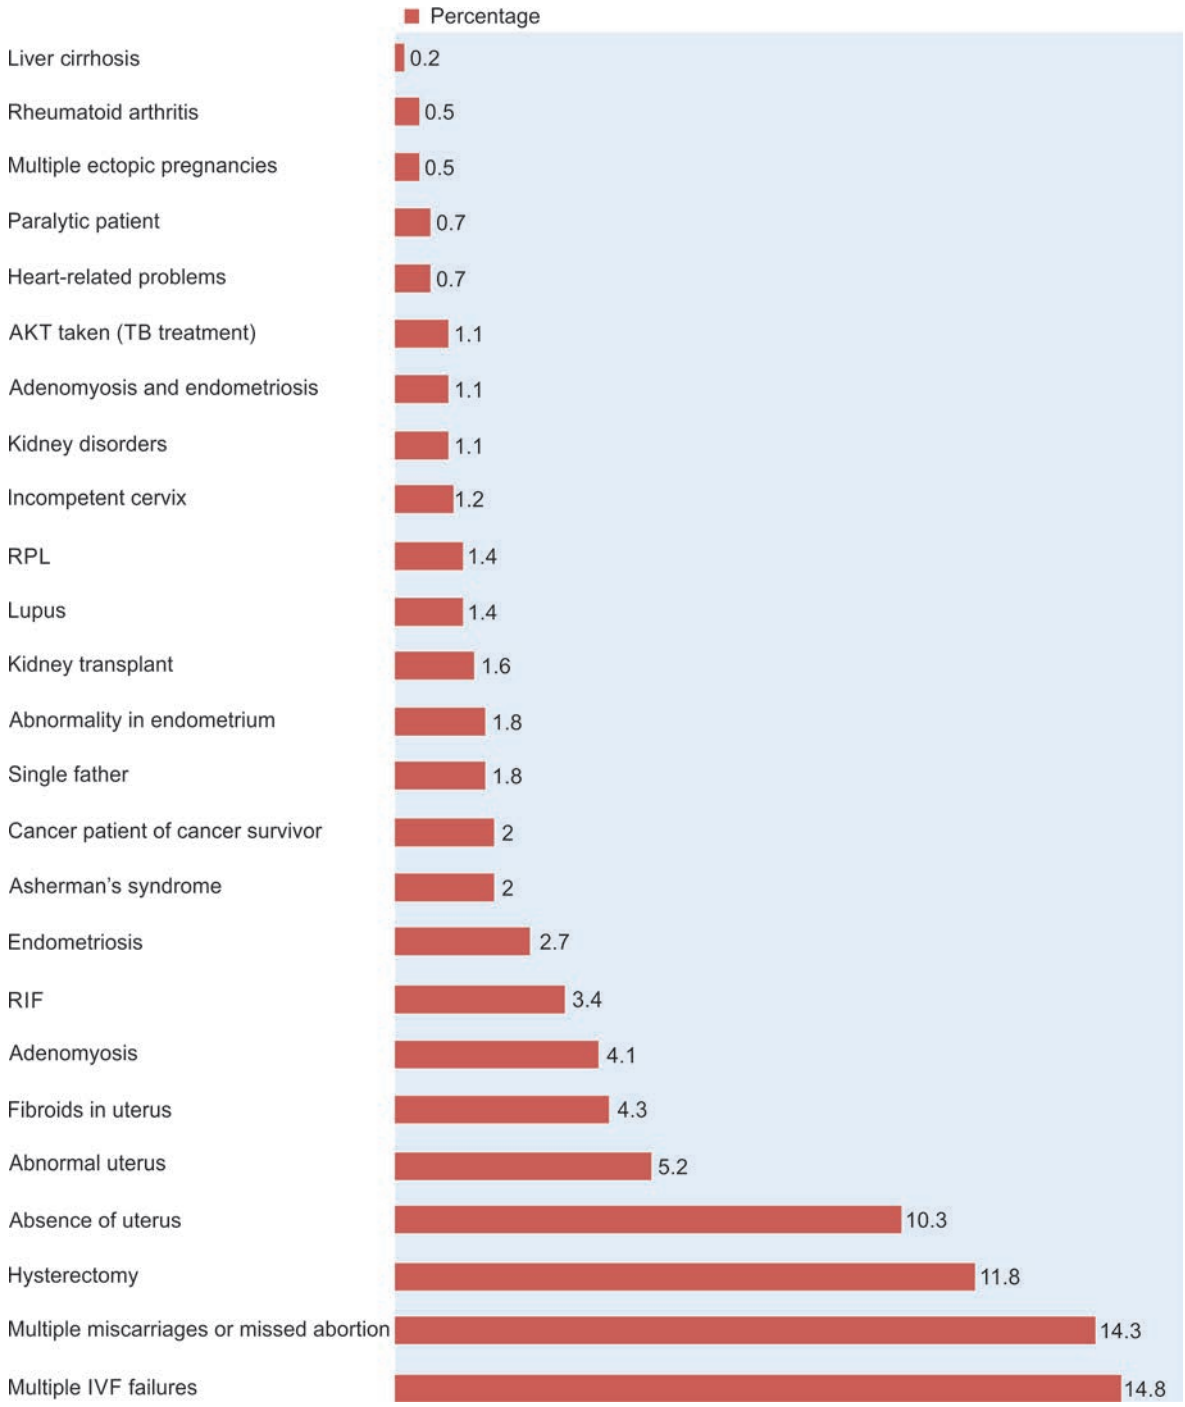

Fig. 1: Indications for surrogacy.
(AKT: assisted reproductive technology; IVF: in vitro fertilization; RIF: repeated implantation failure; RPL: recurrent pregnancy loss; TB: tuberculosis)

4. Intensive counseling—the key factor
5. Legal requirements, financial contracts, and transparency of arrangement
6. Proper controlled ovarian stimulation and IVF technique
7. Preparing the surrogate
8. Synchronizing the cycles of the surrogate and the genetic mother
9. Window period for embryo transfer
10. Obstetrics care of the surrogate.

Selection of Patient

- Patients with a medical indication only are considered for surrogacy. While selecting the patient, consultation and counseling on all aspects of the treatment are carried out.
- Couples and individuals who want to consider surrogacy should research and study surrogacy laws and shall even consult surrogacy professionals to truly understand surrogacy.

Source of Surrogate (Assisted Reproductive Technology Bank)

Surrogates can be selected from the National Registry of Assisted Reproductive Technology Banks in India of the Indian Council of Medical Research (ICMR). A woman from the family or a known person to the couple may act as a surrogate mother. However, she should belong to the same generation as the woman desiring her as a surrogate.

Selection and Screening of Prospective Surrogates[4]

A thorough medical, obstetrical, and psychological screening is mandatory.

- Surrogates are generally 21–35-year-old (25–35 years as per Surrogacy Bill, 2016) married women having one child of their own and a minimum age of 3 years.
- Consent of the surrogate's spouse is mandatory for her to become a surrogate mother.
- An extensive medical and psychological assessment is carried out during the screening process along with a thorough criminal background check.
- Routine tests include a hysteroscopy or other procedures to determine the general health of the surrogate's uterus.
- Tests such as complete blood count, fasting blood sugar, glycated hemoglobin (HbA1c), hemoglobin electrophoresis, human immunodeficiency virus (HIV), hepatitis B surface antigen (HBsAg), hepatitis C virus, and genetic tests are done. Additionally, electrocardiogram, Pap smear, and mammogram are also recommended.
- Pelvic and abdominal ultrasonography is done to evaluate the capability of her uterus to carry a pregnancy to term.
- Medical fitness from a physician.

Intensive Counseling

In-depth counseling of all the parties engaged in surrogacy arrangements is very crucial. They must have trust among themselves, and they must be confident and comfortable with their decisions. Many concerns must be discussed with both the genetic couple and the proposed surrogate, including:

For the genetic couple:

- Consideration of alternative treatment options
- The need for a detailed counseling
- The practical difficulty and cost of treatment of gestational surrogacy
- The psychological risks of surrogacy
- Potential psychological risk to the child
- The possibility of multiple pregnancies
- The possibility of the birth of an abnormal child
- The importance of obtaining legal advice.

For the surrogate:

- Details of undergoing treatment by IVF surrogacy
- The possibility of multiple pregnancies
- The possibility of family and friends being against such treatment
- Risks associated with pregnancy and the possibility of cesarean section
- The possibility of a sense of bereavement while giving baby to the genetic parents.

Legal Requirements, Financial Contracts, and Transparency of Arrangement

A legal contract is drafted and signed by the surrogate and intended parents once they decide to move forward. The attorney of each party ensures that legal interests are represented and protected for everyone.

Documents required from the surrogate: Identity proof in terms of Aadhaar card, voter ID, school leaving certificate, birth certificate for age verification, marriage certificate, divorce certificate if divorced, and death certificate of husband if widow.

Documents required from the couple or single parent: Identity proof of the couple, address proof (Aadhaar card, voter ID, or passport), and marriage certificate.

A financial contract is signed between the intended couple and the surrogate mother as per the ICMR guidelines. As per ART Guideline 2014, funds are transferred to the bank account of the surrogate mother at different stages starting from signing of the agreement till the child/children is/are handed over to the commissioning parents.

Proper Controlled Ovarian Stimulation and In Vitro Fertilization Technique

If women requesting treatment by gestational surrogacy are perfectly normal with regard to their ovarian function, the

management of their IVF treatment cycle is straightforward. Ovarian follicular stimulation, monitoring, and oocyte recovery methods are practiced as previously described.[5] Sperm used in surrogacy cases should be treated in the same way as donor sperm and must be frozen and quarantined for 6 months before use.[6]

With the ovarian stimulation, the job of the infertility specialist doctor is to:

- Select a proper medication protocol and dosing regimen
- Monitor the patient's stimulation progress so that medication doses can be adjusted properly
- Trigger with human chorionic gonadotropin or gonadotropin-releasing hormone agonist at the ideal time.

Preparing the Surrogate

- Start estrogen from D2 or D3 of the recipient's cycle after confirming a thin endometrium (<5 mm) on the scan. The dose of estrogen can vary from 4 to 6 mg/day as per individual preference.
- Follow-up on the 10th day for the scan to see for the growth of the endometrium, a minimum of 8 mm (triple line), is ideal before starting progesterone.
- 5 or 3 days of progesterone is required either intramuscularly (50 mg/100 mg a day) or intravaginally (400 mg/day) before transfer.
- 5 days progesterone for a blastocyst transfer and 3 days for a cleavage-stage transfer
- Various protocols have been suggested; the other popular protocol for surrogate preparation is the leuprolide protocol due to its feasibility and flexibility in adjustment of transfer date with cycle control.
- Here suppression with leuprolide is done along with the previously mentioned endometrial preparation method.
- Either starting from day 21 of the previous cycle agonist injection for downregulation or stopping it at one-fourth dose on their own till the day of progesterone.
- Luteal phase support has to be decided accordingly.

Synchronizing the Cycles of the Surrogate and the Genetic Mother

- The surrogate embryo transfer could be fresh or frozen transfer and is subject to the availability of the gestational carrier. With the advent of excellent vitrification techniques, surrogacy cycles have become less difficult for the ART clinic with good embryology laboratory and freezing facility.
- For a fresh surrogate transfer, the surrogate's and the intended mother's cycle may be synchronized with oral contraceptive (OC) pills or progesterone pills or the surrogate may be put on agonist injection for flexibility of transfer dates.
- The surrogate is started on estrogen tablets from the third day of her cycle for around 10 days before her endometrium is assessed. On reaching a minimum of 8 mm, she is then put on progesterone supplementation for 3 or 5 days before a planned cleavage or blastocyst transfer.

Obstetrics Care of the Surrogate

Once a pregnancy is confirmed in the gestational carrier depending on the facility of the ART clinic, she stays either in the surrogate house or at her home. The concept of surrogate house has recently caught a lot of attention for various reasons. The idea of *surrogate house* was developed from the wish of many surrogates to be provided a shelter during the pregnancy as many of them wish to hide the practice from relatives and friends due to the stigma that prevails in rural areas owing to of awareness of the scientific procedures behind surrogacy. A surrogate house is a place where a surrogate stays for her entire antenatal period till the date of delivery and all her medical and personal requirements are taken care of. The obstetrics care of a surrogate is extensive due to the preciousness of the pregnancy. In the surrogate house, surrogates stay under the supervision of 24-hour nursing staff along with dieticians, physiotherapists, counselors, and gynecologists for their medical care. Surrogates get complete rest and healthy, nutritionally complete meals which turn out to be beneficial for their health during pregnancy. As they stay under one roof, they get a lot of emotional, moral, and psychological support from each other. Also, they are allowed to meet their family and kids and be in constant touch with their families via phone. They can go to their place as and when they want; also, young kids of surrogates are allowed to stay with them at surrogate houses during weekends and school holidays. It is voluntary for surrogates to stay in the surrogate house. Any surrogate who wishes to stay at her home can always do so.

In the surrogate house, she has obstetric assessment every 20 days till the date of delivery: Obstetric scans at 6–8 and 11–13 weeks; anomaly scan at 20–22 weeks (anomaly scan 3D–4D); and growth scan at 28 and 34–36 weeks. Any additional scan is subject to the obstetric needs.

The intended couple is sent regular mail regarding the surrogate's pregnancy in the form of her weight gain, vitals, fetal growth, and antenatal investigation reports and scans. Post delivery, the surrogate is kept under observation for a minimum of 15 days before discharge.

Inducing Lactation in Genetic Mother

The genetic mother is excluded from breastfeeding if she suffers from any malignancy or disease which has the risk of transmission to the infant via breastfeeding.

- "Active" birth control pill each day and 10 mg domperidone 4 times per day for 1 week are started in the intended mother, 6 months before the baby is due. Then the dosage is increased to 20 mg 4 times per day.
- Six weeks before the baby is due, birth control pills are discontinued while continuing domperidone. During

this course, generally mothers experience vaginal bleeding which is normal. Mothers shall be examined for potential pregnancy if she does not experience withdrawal bleeding.
- One month before the baby is due, the mother should pump the milk at least once during the night. Serum prolactin levels reach to peak between 1 and 5 AM.
- After the birth of the baby, the mother should continue the domperidone dosage of 20 mg 4 times per day until she achieves a substantial milk supply. The domperidone shall be decreased slowly once the milk supply is well established.

RISKS ASSOCIATED WITH SURROGACY

The major risks associated with surrogacy are obstetric complications and multiple-order pregnancy, which is most common. Recently, a lot of recommendations have been made by the Association of Reproductive Managers and ESHRE committees for single-embryo transfer, yet only 15–20% of the clinics follow single-embryo transfer norms. But it is an improvement from the previous years and more and more clinics are accepting this policy. Pregnancy, birth, and the postpartum period include complications such as preeclampsia and eclampsia, urinary tract infections, stress incontinence, gestational diabetes, and rare complications such as amniotic fluid embolism and the possibility of postpartum hemorrhage (PPH), but these risks are associated with pregnancy in general and not specific to surrogacy.

Apart from physical risk, surrogacy may be the reason for emotional trauma, surrogate mothers face emotional problems after having to relinquish the child. However, a study by Jadva et al.[7] indicates that although some women experience emotional problems in handing over the baby, these feelings appeared to lessen during the weeks following the birth.

VARIOUS ASPECTS AND CONCERNS INVOLVED IN SURROGACY

- *Ethical aspects:* Surrogacy has raised a large ethical debate in the past. The prime ethical concerns raised in the whole system of surrogacy are regarding exploitation and commodification as women are paid to be pregnant and deliver babies. The commodification arrangement raises the argument of whether women are being given control over their body or being exploited for their individual body parts.[8,9] The other major argument against womb commodification is that it allows the rich to take advantage of the willingness of a poor woman to perform any job as long as she is able to earn a wage.[7] A woman may choose to commodify her womb for money because she is faced with no other possible options for employment.
- *Religious aspects and issues:* Various religions around the world take different stances with regard to surrogacy practice and ART in general. Paragraph 2376 of the Catechism of the Catholic Church states that "Techniques that entail the dissociation of husband and wife, by the intrusion of a person other than the couple (donation of sperm or ovum, surrogate uterus), are gravely immoral." Islam also has a similar approach regarding their Chastity. Jewish religious establishments have now accepted surrogacy only if it is full gestational surrogacy with both intended parents' gametes included and fertilization done via IVF.[10,11] The religious stands for surrogacy are all with regard to traditional surrogacy, as that was the only way during ancient time, but with the advent of IVF and gestational surrogacy, the relevance of these beliefs is being questioned.
- *Psychological impact of surrogacy:* Despite the increasing success rates, surrogacy poses a new complexity on psychological aspects and again requires a multidisciplinary approach. Surrogacy brings to light a cobweb of possible relationships which could sometimes be emotionally taxing. The main element in the success of surrogacy lies in exploring and deeply understanding its psychological arm and the key to it is the quality of relationship between the intended parents and gestational carrier. Unlike the donor egg programs in which the intended parent does not share a relationship with the donor and know only nonidentifying information about her, intended parents working with a gestational surrogate typically share a personal relationship with her that will last throughout the pregnancy and often beyond. Studies have convincingly shown that children through third-party reproduction do well psychologically and developmentally and do not appear to be adversely affected by the lack of a genetic or gestational link to the intended parents.[12,13]

Identity and rights of the child: A child born through ART shall be presumed to be the legitimate child of the couple and shall have legal rights of parental support, inheritance, and all other privileges as of a child born to a couple through natural intercourse. Upon reaching the age of 18 years, the child can ask for any information relating to the donor or surrogate. However, the personal identification of the donor or surrogate may be released only in cases of life-threatening medical conditions which require physical testing or samples of the donor or parents or surrogate. Children born through the use of donor gametes shall not have any right whatsoever to know the identity (name, address, parentage, etc.) of their genetic parent(s).

SURROGACY LEGISLATION: THE INTERNATIONAL SCENARIO

- Surrogacy is not allowed in Austria, Bulgaria, Denmark, Finland, France, Germany, Italy, Malta, Norway, Portugal,

Spain, Sweden, Japan, and Saudi Arabia.[14] However, altruistic surrogacy is allowed in Belgium, Greece, the Netherlands, UK, Australia, Canada, New Zealand, and in many states of USA.

- Poland and the Czech Republic currently have no laws regulating surrogacy.[15,16] Commercial surrogacy is legal in Georgia, Israel, Ukraine, Russia, and California.
- In China, the Ministry of Health banned surrogacy in 2001. However, illegal surrogacy "black market" is still flourishing in China. Anxious about such a situation, strict legislation has been suggested by the political parties.[3] Surrogacy was previously illegal in Bulgaria, but as the procedure is still practiced illegally, the government decided to sanction it. Instead of using the term surrogate, though, Bulgaria calls it the "substitute mother."[17]

SURROGACY IN INDIA AND GUIDELINES FOR SURROGACY

Commercial surrogacy has been legalized in India since 2002. Till the implementation of ART Bill 2015, when surrogacy was allowed for foreigners, overseas citizens of India (OCI), persons of Indian origins (PIOs), and others, India was emerging as a leader in international surrogacy and as a destination in surrogacy-related fertility tourism because of good medical skills, infrastructure, transparency of procedure, favorable guidelines, and relatively low cost. Here, surrogacy was found to be a symbiotic arrangement as infertile couple gets a baby which completes their family and the needy surrogate gets compensation which helps for the betterment of her entire family. Indian surrogates see surrogacy as "Hope for a better future." The common motives for which women in India practice surrogacy vary individually, but most women become surrogates as they want monetary compensation for the education of their children, construction of their houses, start-up of small business, treatment of family members, payment of loans, or other as demonstrated in **Figure 2** (data from a private IVF setup in India).

However, one after the other regulations from the regulatory authority of India is pushing surrogacy practice almost to a ban. The proposed ART Bill 2015 bans foreign nationals from commencing surrogacy in India while an overnight notification in November 2015 restricted OCIs and PIOs as well. The effect of such an approach of government toward surrogacy practice has evidently affected the industry negatively and a reduction in the number of surrogate babies born was noted in private clinics. **Figure 3** depicts data from one private IVF setup to justify this impact. Furthermore, August 24, 2016, has to be considered a Black Day for surrogacy in India, as the Surrogacy (Regulation) Bill 2016 received the cabinet approval. The bill bans the commercial form of surrogacy, allowing only altruistic arrangement with many other constraints on this practice.

Assisted Reproductive Technology Regulation Bill, 2021[18]

- Registration of the ART clinic or ART bank is a must.
- Registration is to be made to the National Registry.

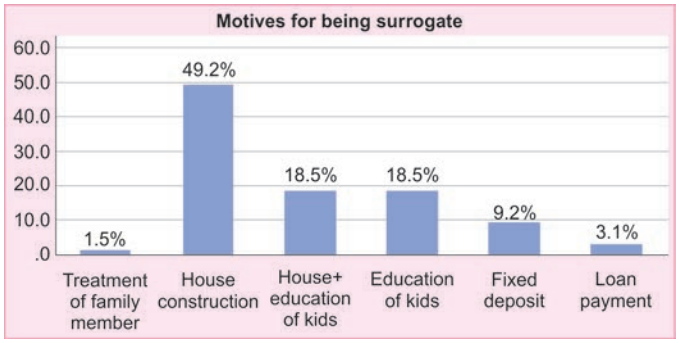

Fig. 2: Motives of surrogate mothers for practicing surrogacy.

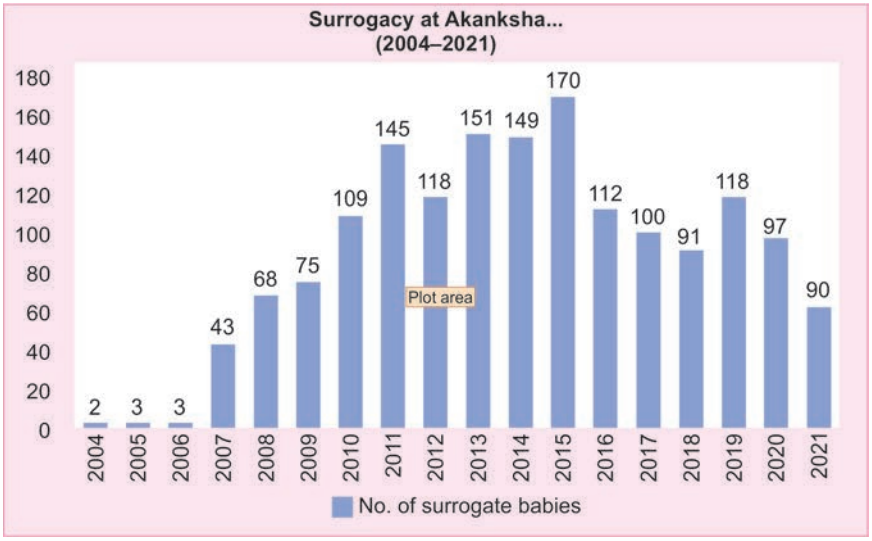

Fig. 3: Yearly frequency of birth of surrogate babies at a private in vitro fertilization (IVF) clinic in India.

- After 60 days of establishment, a clinic or a bank must register itself.
- The registration, if granted, may be renewed for a further period of 5 years by the appropriate authority.
- A national board is to be established for the regulation and to advise the central government.
- A State-Assisted Reproductive Technology and Surrogacy Board (SART and SB) is to be constituted.
- SART and SB will have the responsibility to follow the policies and plans laid by the national board.
- Clinics shall apply the ART services to a woman above the age of 21 years and below the age of 55 years and to a man above the age of 21 years and below the age of 55 years.
- Every clinics and every bank should maintain a grievance cell in respect of matters relating to the clinics/banks.
- No cryopreservation of any human embryo or gamete.
- Clinics to retrieve oocytes as specified by the regulations
- Clinics to not implant/place more than three embryos in the uterus of a woman during the treatment cycle.
- Preimplantation genetic diagnosis (PGD) shall only be used to screen the human embryo for known, preexisting, heritable, or genetic diseases only.
- Regarding donor gametes.
- The banks shall obtain semen from males between 21 and 55 years of age.
- The banks shall obtain oocytes from females between 23 and 35 years of age.
- The sperm or oocytes should not be supplied to more than one commissioning couple.
- An oocyte donor shall donate only once in her lifetime, and not more than seven oocytes shall be retrieved from the oocyte donor.
- All unused oocytes shall be preserved by the banks for use on the same recipient.
- The gamete of a donor or embryo shall be stored for a period of not more than 10 years.
- The use of any human gamete and embryos or their transfer to any country outside India for research is strictly prohibited.
- Harsh fines for offences.
- Sex Selective Assisted Reproductive Technology and Offences and Penalties; whoever contravenes shall be punishable with imprisonment for a term for 5 years but may extend up to 10 years or with fine not less than 10 lakh rupees but may extend up to 20 lakh rupees or both.

(For more details please refer ART Regulation Bill, 2021).

Surrogacy (Regulation) Bill, March 2022[18]

- Medical indications necessitating gestational surrogacy
- Surrogacy can be opted if:
  - A woman has absent uterus or missing uterus or abnormal uterus (such as hypoplastic uterus, intrauterine adhesions, thin endometrium, small unicornuate uterus, T-shaped uterus) or if the uterus is surgically removed due to any medical conditions such as gynecological cancers
  - Intended parents/women have repeatedly failed to conceive after multiple IVF/intracytoplasmic sperm injection (ICSI) attempts (recurrent implantation failure)
  - Multiple pregnancy losses resulting from an unexplained medical reason. Unexplained graft rejection due to exaggerated immune response.
  - Any illness that makes it impossible for a woman to carry a pregnancy to viability or a pregnancy that is life threatening
- The intending couple is in possession of a certificate of essentiality issued by the appropriate authority, after satisfying itself, for the reasons to be recorded in writing.
- The intending couple needs a certificate of proven infertility from a District Medical Board.
- The intending couple have not had any surviving child biologically or through adoption or through surrogacy. Provided if the child is mentally challenged or suffers from life-threatening disorder or fatal illness with no permanent cure and approved by the appropriate authority with due medical certificate from a district medical board.
- Intending couple married and between the age of 23 and 50 years in case of females and 26 and 55 years in case of males.
- Surrogacy is to be done only for altruistic purposes and not for commercial purpose.
- The surrogate should be between 25 and 35 years of age, married, and having a child of her own.
- A woman shall act as a surrogate for *only one successful live birth* in her life.
- Surrogate shall be medically tested for HIV or acquired immunodeficiency syndrome (AIDS) and all other communicable diseases and conditions such as cardiovascular disease and thyroid problem.
- She must not have received a blood transfusion or a blood product in the *last 6 months.*
- *No surrogate* shall undergo *only 1 embryo transfer more than three times* for the same couple.
- A surrogate shall *relinquish all parental rights over the child* or children.
- The couple and the surrogate shall enter into a surrogacy agreement or contract.
- All medical expenses, including insurance of the surrogate, should be given by the commissioning couple.
- Complications that arise during pregnancy (i.e., gestational diabetes, chronic hypertension, etc.), which are likely to continue for the rest of her life, shall be covered under insurance.
- The birth certificate of a baby born through surrogacy shall bear the name of the couple who commissioned the surrogacy, as parents.

- Surrogacy shall be allowed for foreigners but permissible to OCIs, PIOs, nonresident Indians (NRIs), and a foreigner married to an Indian citizen.
- The surrogate mother needs an eligibility certificate issued by the appropriate authority.
- *Registration of surrogacy clinics:* Every certificate of registration shall be valid for a period of 3 years and shall be renewed.
- There shall be established a Registry to be called the National Assisted Reproductive Technology and Surrogacy Registry for the purposes of registration of surrogacy clinics under this act.
- Any intending couple or any person who seeks the aid of any surrogacy clinic, laboratory, or a registered medical practitioner, gynecologist, pediatrician, human embryologist, or any other person for commercial surrogacy or for conducting surrogacy procedures for commercial purposes shall be punishable with imprisonment for a term which shall not be <5 years and with a fine which may extend to 5 lakh rupees for the first offence and for any subsequent offense with imprisonment which may extend to 10 years and with fine which may extend to 10 lakh rupees.
- *ICMR portal for surrogacy bill was open for public opinion till April 2, 2022. [For more details, please refer Surrogacy (Regulation) Bill, March 2022].*

CONCLUSION

In conclusion, surrogacy is a hope for the couples who are facing serious fertility issues which cannot be treated directly. Banning the surrogacy is not a solution for unethical practices rather appropriate regulations can be formulated and implemented to handle the misconduct on surrogates.

KEY POINTS

- Surrogacy is an important method of ART wherein a woman carries a pregnancy for another couple.
- A numbers of couples around the world require surrogacy services for various reasons.
- Since legislation in 2002 till the Surrogacy (Regulation) Bill, 2021, surrogacy in India has traveled a long path.
- Although this arrangement seems to be beneficial for all parties concerned, there are multifarious social, ethical, and legal issues associated with it, which have made this practice unpopular in many parts of the world.
- In recent times, where the need for surrogacy is increasing day by day, delicate issues associated with this practice are ought to be addressed properly. Efforts shall be taken to spread awareness about surrogacy in society to make this arrangement more open and acceptable.
- Formulation of laws, appropriately designed to protect the rights of surrogate mothers, intended parents, and children, can make this practice an approachable and gratifying experience for all the parties involved.
- Banning surrogacy will only give rise to underground arrangements. To solve this issue, national and international frameworks must be set up.
- Proper regulation, ethical practice, and commitment from all the stakeholders can help to solve the associated issues and put an end to all the controversies.

CHAPTER 71

Assisted Reproductive Technology Guidelines

(Brig.) RK Sharma

INTRODUCTION

Infertility, though not life-threatening, causes intense mental agony and trauma that can only be best described by infertile couples themselves. There are no detailed figures of the extent of infertility prevalent in India, but a multinational study carried out by the World Health Organization (WHO)[1] that included India places the incidence of infertility between 10 and 15%. Out of a population of 1,000 million Indians, an estimated 25% (250 million individuals) may be conservatively estimated to be attempting parenthood at any given time; by extrapolating the WHO estimate, approximately 13–19 million couples are likely to be infertile in the country at any given time.

Prevention and appropriate treatment of infertility has been included in the International Conference on Population and Development (ICPD) Program of Action; it follows that alleviation of infertility should be included as a component of the primary healthcare system. Most types of infertility, such as reproductive tract infections (RTIs) and genital tuberculosis, are preventable and amenable to treatment. About 8% of infertile couples, however, need serious medical intervention involving the use of advanced assisted reproductive technology (ART) procedures, such as in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). Such advanced treatment is expensive and not easily affordable to the majority of Indians. Further, the successful practice of ART requires considerable technical expertise and expensive infrastructure. Moreover, the success rate of any ART procedure is below 30% under the best of circumstances. Infertility, especially in our country, also has far-reaching societal implications. Today, infertility is the most common medical problem in 30–40 years age group of couples in India, and ART was valued at $793.27 million in 2020 and is projected to reach $3,721.99 million by 2030, registering a compound annual growth rate (CAGR) of 16.45% from 2021 to 2030. 20,000 ART clinics across the country are providing IVF and intrauterine insemination (IUI) services. However, a fraction of these clinics have applied for registration.[2]

Therefore, with the rapidly increasing use of ART in our country, it has become imperative to ensure their safety and safeguard against their possible misuse.[3]

Scientific societies around the world, such as the American Society for Reproductive Medicine (ASRM), European Society of Human Reproduction and Embryology (ESHRE), and International Federation of Fertility Societies (IFFS), have drawn up guidelines for the safe and ethical practice of ART. The European Union and the governments of several countries such as Australia, the United Kingdom, and the United States of America have taken steps to accredit and supervise the performance of infertility clinics.

The United States notably has few federal or state regulations pertaining to the ART industry. This is in contrast to other developed nations, which provide more extensive regulations on the use of ART, and, in many cases, restrict its use for certain ends, such as reproductive cloning. While some of these regulations may not be ideal, there are steps taken to ensure the health and safety of women utilizing ART and the children resulting from these technologies as well as the ethical use of ART by all participants.[4]

Australia regulates ART at both the federal and the state levels, with the states providing the most regulation. The key federal law is the Prohibition of Human Cloning for Reproduction and the Regulation of Human Embryo Research Amendment Act, 2006. This law prohibits reproductive cloning and allows states to either permit or prohibit research cloning. Research cloning is permitted in Victoria, New South Wales, Tasmania, Queensland, South Australia, and the Australian Capital Territory. Additionally, this law prohibits germline modification and the commercial trading of human eggs, sperm, or embryos. The National Health and Medical Research Council publishes ethical guidelines on the use of ART in clinical practice and research. These general guidelines must be followed for ART centers to be accredited by the reproductive technology accreditation committee. These guidelines encourage limiting the number of embryos created to those needed during the course of treatment, strict recording of the outcomes of ART, and the

prohibition of nonmedical sex selection and commercial surrogacy. Noncommercial or altruistic surrogacy is permitted by some Australian states.[5]

In 2008, after extensive consultations held at both the Indian Council of Medical Research (ICMR) and other national institutions, with scientists, medical practitioners, lawyers, social scientists, and activists, the ICMR developed a draft for ART (Regulation) Bill which was meant to ensure that ART clinics in India are accredited, regulated, and supervised to assure the patients as well as the public that our ART clinics offer services that are at par with those available anywhere in the world and sent it to the Ministry of Health and Family Welfare, which was then revised by the Ministry of Law and Justice as ART (Regulation) Bill, 2013. In 2016, the ART (Regulation) Bill, 2016, came before the Cabinet for consideration. The ART (Regulation) Bill proposed to establish national board, state boards, and national registry of ART in India for accreditation and supervision of ART clinics and ART banks, ensuring that services provided by these are ethical and that the medical, social, and legal rights of all the concerned are protected with maximum benefit to all the stakeholders within a recognized framework of ethics and good medical practices.[6]

The Assisted Reproductive Technology (Regulation) Bill, 2020 was introduced in Lok Sabha on September 14, 2020. On March 19, 2021, Standing Committee Report was formed. On December 1, 2021, it was passed in Lok Sabha, and by December 08, 2021, it was passed by the Rajya Sabha. The Bill seeks to provide for the regulation of ART services in the country.

ART CLINIC AND BANK: MINIMAL PHYSICAL REQUIREMENTS

A well-designed ART clinic of level 1 or level 2[7] should have a nonsterile and a strictly sterile area. Some of the spaces could be used for more than one purpose as long as such a step does not compromise the quality of service. However, the space provision for the sterile area cannot be combined with those for the nonsterile area and vice versa. For level 1B infertility care units,[8] a strictly sterile area will not be required. The space requirement, however, will include a reception area, a waiting room for the patients, and a consulting room for the gynecologist.

The minimum equipment in ART clinics and banks are:[9]

- *ART level 1 clinics:*
  - Microscope
  - Centrifuge
  - Refrigerator
- *ART level 2 clinics:*
  - Microscope
  - Incubator (minimum two in number)
  - Laminar airflow
  - Sperm counting chambers
  - Centrifuge
  - Refrigerator
  - Equipment for cryopreservation
  - Ovum aspiration pump
  - Ultrasonography (USG) machine with transvaginal probe and needle guard
  - Test tube warmer
  - Anesthesia resuscitation trolley
- *ART banks:*
  - Centrifuge machine
  - Incubator
  - Microscope
  - Laminar airflow.

Semen Collection Room

The semen collection room must be a well-appointed room with privacy and an appropriate environment; it should be located in a secluded area close to the laboratory. Such a facility must be available in-house rather than making the patient collect the sample and bring it to the laboratory for analysis as, in the latter case, semen quality and identity are likely to be compromised. Procedures for collection of semen as described in the WHO Semen Analysis Manual must be followed with special reference to the type of container used; these containers must be sterile, maintained at body temperature, and nontoxic. This room must have a washbasin with availability of soap and clean towels. The room must also have a toilet and must not be used for any other purpose.[10]

Semen Processing Laboratory

There must be a separate room with a laminar airflow for semen processing, preferably close to the semen collection room. This laboratory must also have facilities for microscopic examination of postcoital test smears. Good laboratory practice (GLP) guidelines as defined internationally must be followed. Care must be taken for the safe disposal of biological waste and other materials (syringes, glass slides, etc.). Laboratory workers should be immunized against hepatitis B and tetanus.

Sterile Area

The sterile area shall house the operation theater, a room for intrauterine transfer of sperm or embryos, and an adjoining embryology laboratory. Entry to the sterile area must be strictly controlled by an anteroom for changing footwear, area for changing into sterile garments, and a scrub station. The sterile area must be air-conditioned where fresh air filtered through an approved and appropriate filter system is circulated at an ambient temperature (22–25°C).

Operation Theater

The operation theater must be well equipped with facilities for carrying out transvaginal ovum pickup. It must be equipped for emergency resuscitative procedures.

Embryology Laboratory Complex

The embryology laboratory must have facilities for the control of temperature and humidity and must have filtered air with an appropriate number of air exchanges per hour. Walls and floors must be composed of materials that can be easily washed and disinfected; the use of carpeting must be strictly avoided. The embryology laboratory must have the following:

- Laminar flow bench with a thermostatically controlled heating plate
- Stereo zoom microscope
- Routine high-powered binocular light microscope
- "High-resolution" inverted microscope with phase contrast or Hoffman optics, preferably with facilities for video recording
- Micromanipulator (if ICSI is done)
- CO_2 incubator, preferably with a backup
- Hot air oven
- Laboratory centrifuge
- Equipment for freezing embryos in a programmed manner
- Liquid nitrogen cans
- Refrigerator.

Appropriate steps need to be taken for the correct identification of gametes and embryos to avoid mix-ups. All material from the operation room, culture dishes and plastic wares, must bear the name of the patient. In the incubator, identified oocytes and sperm should be kept together on the same tray and double-checked. Pipettes used should be disposed of immediately after use. The embryology laboratory must have a daily logbook in which all the day's activities are recorded, including the performance of the equipment.

Maintenance of the Laboratories

Each laboratory should be maintained by writing standard operating manuals for the different procedures carried out in the laboratory. It should be ensured that there is no "mix-up" of gametes or embryos. The patient's name should be clearly labeled on all the tubes, dishes, and pipettes containing the gametes and embryos. All pipettes should be immediately discarded after use. Laminar flow hoods, laboratory tables, incubators, and other areas where sterility is required must be periodically checked for microbial contamination using standard techniques, and a record of such checks must be kept. A logbook should be maintained which records the temperature, carbon dioxide content and humidity of the incubators, and the manometer readings of the laminar airflow. All instruments must be calibrated periodically (at least once every year) and a record of such calibration maintained.

Power Supply Backup

There should not be any interruption in power supply to the incubator and to other essential services in the clinic. Given the power supply situation in India, it is, therefore, imperative that a power backup in the form of uninterruptible power supply systems and/or a captive power generation system is available in infertility clinics offering ART services.

ART: CLINICS AND BANKS CLASSIFICATIONS AS PER THE ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) BILL, 2021[11]

There shall be two levels of clinics, namely:

- Level 1 ART clinics, where only IUI procedure is carried out as part of treatment
- Level 2 ART clinics, where the procedures, or as the case may be, and techniques that attempt to obtain a pregnancy shall be carried out by any or all of the following, namely:
  - Surgical retrieval of gametes
  - Handling the oocyte outside the human body
  - Using sperms for fertilization of oocytes
  - Transfer of the embryo into the reproductive system of a woman
  - Carryout storage of gametes or embryos or perform any kind of procedure or technique involving gametes or embryos.

Assisted reproductive technology banks shall:

- Be responsible for screening, collection and registration of the semen donor, and cryopreservation of sperms
- Perform screening and registration of oocyte donor
- Operate as semen banks or oocyte banks or both
- Maintain the records or data of all the donors and shall regularly update the National Registry as provided in sections 23, 27, and 28 of the Act.
- Perform screening and registration of surrogate.

ART TEAM: ESSENTIAL QUALIFICATIONS AS PER THE ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) BILL, 2021[12]

- *ART level 1 clinic:* Minimum one gynecologist
  Qualification: The gynecologist shall be a medical postgraduate in Gynecology and Obstetrics.
- *Staffing of ART level 2 clinic:* ART clinic level 2 shall have a minimum of one gynecologist, one anesthetist, one embryologist, and one counselor. The additional staff at

the level of director and andrologist may be employed by the ART level 2 clinics.

- Qualification of staff in ART level 2 clinics shall be as follows:
  - *Gynecologist:* The gynecologist will be a medical postgraduate in Gynecology and Obstetrics and should have a record of performing 50 ovum pickup procedures under the supervision of a trained ART specialist with at least 3 years of working experience in an ART clinic under supervision. (In the case of gynecologists practicing ART or IVF and are working in ART clinics before the commencement of this Act, a postgraduate degree in Gynecology and Obstetrics with at least 3 years' experience and record of 50 ovum pickup procedures shall be acceptable.)

    Or

    A medical postgraduate in Gynecology and Obstetrics with super specialist Doctorate of Medicine or fellowship in reproductive medicine with experience of not <3 years of working in an ART clinic.
  - *Andrologist:* The andrologist in a clinic or a bank will be a MCh or DNB in Urology with special training in diagnosing and treating male infertility.
  - *Embryologist:* From the date of commencement of these rules, clinics will hire embryologists only with the following qualifications and experience, namely: Postgraduate in Clinical Embryology (graduated with full-time program with minimum four semesters) from a recognized university with additional 3 years of human ART laboratory experience in handling human gametes and embryos

    Or

    PhD holder or one with full-time PhD project shall be related to Clinical Embryology or ART or fertility from a recognized university with an additional 1 year of human ART laboratory experience in handling human gametes and embryos

    Or

    Medical graduate (MBBS) or veterinary graduate (BVSc) with a postgraduate degree in Clinical Embryology (full-time program) from a recognized university with additional 2 years of ART laboratory experience in handling human gametes and embryos

    Or

    Postgraduate in Life Sciences or Biotechnology with a minimum of 1 year of on-site, full-time clinical embryology certified training in addition to 4 years of experience in handling human gametes and embryos in a registered ART level 2 clinic.

    Note: As a one-time measure, all embryologists working in ART or IVF clinics before the commencement of these rules, with the below-mentioned qualifications and experience, may be allowed to continue as an embryologist. However, after the commencement of these rules, all clinics will hire embryologists with any of the above-mentioned qualifications and experience as criteria: Graduate in Life Sciences or Biotechnology or Reproductive Biology/Veterinary Science with at least 5 years of working experience in a registered ART or IVF clinic, who have performed at least 500 IVF laboratory procedures (including ICSI and at least 100 cycles of cryopreservation of embryos)
  - *Counselor:* A person who is a graduate in Psychology or Clinical Psychology or Nursing or Life Sciences
  - *Anesthetist:* Anesthetist will be a medical postgraduate in Anesthesia.
  - *Director:* The director shall have a postgraduate degree in Medical or Life Sciences or Management Sciences.
- *ART bank:* The ART bank shall have a minimum of one registered medical practitioner trained in the handling, preparation, and storage of semen samples.

ARTIFICIAL INSEMINATION WITH DONOR SEMEN

The indications for artificial insemination with donor semen (AID) are:

- When there is nonobstructive azoospermia
- When the husband has a hereditary genetic defect
- When the couples have Rh incompatibility

The main advantage of AID is that it enables a couple to achieve pregnancy even though the husband is not the biological father. However, the possible transmission of diseases from the donor to the future child and the risk of consanguinity constitute some drawbacks that must be brought to the notice of the patients. It is necessary to get the informed consent of both the partners after they are counseled about the possible psychological conflict they may face later in their life with the knowledge that one of them is not the biological parent of their child. AID is an ethically acceptable procedure, provided there is a medical indication and psychological confirmation for its use. Also, the normal conditions of anonymity and screening of the donor must be met, and only frozen sperm samples that have passed appropriate quarantining for infectious diseases, such as human immunodeficiency virus (HIV), hepatitis B and C, and syphilis, should be used.

OOCYTE DONATION OR EMBRYO DONATION

Oocyte donation (OD) would necessitate using the husband's semen for fertilization and transferring the resultant embryo to the infertile female partner. Embryo donation (ED) would obviate the necessity of using the husband's semen. The choice of oocytes and embryos for OD or ED would depend entirely on the circumstances prevalent at the time the infertile couple comes for treatment and the access of the infertility clinic to frozen oocytes or embryos.

Indications for Oocyte or Embryo Donation

- Gonadal dysgenesis
- Premature ovarian failure
- Iatrogenic (due to ovarian surgery or radiation, or chemical castration) ovarian failure
- Women who have resistant ovary syndrome or who are poor responders to ovulation induction
- Women who are carriers of recessive autosomal disorders
- Women who have attained menopause

Donors should be healthy (as determined by medical and psychological examination, screening for sexually transmitted diseases, and absence of HIV antibodies) women in the age group of 18–35 years. Oocytes may be obtained for donation, mostly by surgical intervention from women participating in an IVF program or those undergoing elective sterilization or surgery. The recipient should be a healthy woman (determined by medical and psychological examination) having normal genitalia (as determined by physical examination) and uterine cavity (as determined by hysterosalpingography). In case of OD, the semen characteristics of the husband must be determined to see if they are in conformity with those associated with normal fertility. The blood group of the donor should be noted; the donor should also be tested for antibodies to rubella, HIV, hepatitis, *Cytomegalovirus*, gonorrhea, syphilis, *Chlamydia*, *Mycoplasma*, and trichomonas. Ovum or ED can be carried out in menopausal women with no surviving child and desiring to have a child. The endometrium of menopausal women has the ability to respond to sex hormones and provide a receptive environment for the implantation of an embryo. Various protocols are now available to prepare the endometrium of the recipient for OD or ED with estrogens and progestogens until the placenta takes over the function of maintaining the gestation.

Meanwhile, the expansion and proliferation of ART has been facilitated by economic globalization wherein reproductive tissues such as sperm, ova, and uteri are traded like any other commodity to make profit, and India emerged as the surrogacy outsourcing capital of the world.

Due to the proliferation of surrogacy and India becoming a center for medical tourism, some interesting and difficult cases of surrogacy-related legal issues, especially involving foreigners, surrogacy became the most "contentious" issue in the country. It was felt by the government that "there is a need to regulate surrogacy for the time being and that is why it was decided to separate it from the earlier proposed ART Bill so as to get going."

This resulted in the Surrogacy (Regulation) Bill, 2016, by the Health Ministry that proposed to legalize altruistic, domestic surrogacy. The Bill seeks to control exploitation of the surrogate child and mother for unethical purposes.

The Cabinet approved certain amendments in the Surrogacy (Regulation) Bill, 2016, on March 21, 2018. Commercial surrogacy is prohibited, whereas altruistic surrogacy is allowed for the benefit of "needy and infertile" married Indian couples. The Cabinet proposed the formation of a National Surrogacy Board.[13]

KEY HIGHLIGHTS OF THE ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) BILL, 2021

- *Registration:* An application for registration shall be made by the ART clinics or any such health facility which are carrying out procedures related to the ART to the appropriate authority in Form-1 and by the ART banks in Form-2. Every application for registration shall be accompanied with a fee of:[14]
  - ₹ 50,000 for level 1 ART clinic
  - ₹ 200,000 for level 2 ART clinic
  - ₹ 50,000 for ART bank
- Under the Bill, every ART clinic and bank must be registered under the National Registry of Banks and Clinics of India, which will act as a central database for all facilities providing ART services in India.
- *Regulation of ART clinics and banks*: The Bill provides that every ART clinic and bank must be registered under the National Registry of Banks and Clinics of India. The National Registry will be established under the Bill and will act as a central database with details of all ART clinics and banks in the country. State governments will appoint registration authorities for facilitating the registration process. Clinics and banks will be registered only if they adhere to certain standards (specialized manpower, physical infrastructure, and diagnostic facilities). The registration will be valid for 5 years and can be renewed for a further 5 years. Registration may be canceled or suspended if the entity contravenes the provisions of the Bill.
- *National and State Boards*: The Bill provides that the National and State Boards for Surrogacy, constituted under the Surrogacy (Regulation) Bill, 2019, will act as the National and State Boards, respectively, for the regulation of ART services. Key powers and functions of the National Board include (1) advising the central government on ART-related policy matters, (2) reviewing

and monitoring the implementation of the Bill, (3) formulating code of conduct and standards for ART clinics and banks, and (4) overseeing various bodies to be constituted under the Bill. The State Boards will coordinate enforcement of the policies and guidelines for ART as per the recommendations, policies, and regulations of the National Board.

- *Conditions for gamete donation and supply*: Screening of gamete donors, collection and storage of semen, and provision of oocyte donor can only be done by a registered ART bank. A bank can obtain semen from males between 21 and 55 years of age and oocytes from females between 23 and 35 years of age. An oocyte donor should be an ever-married woman having at least one alive child of her own (minimum 3 years of age). The woman can donate oocyte only once in her life and will be minimally stimulated. A bank cannot supply gamete of a single donor to more than one commissioning couple (couple seeking services).
- *Conditions for offering ART services*: ART procedures can only be carried out with the written informed consent of both the party seeking ART services and the donor. The party seeking ART services will be required to provide insurance coverage in favor of the oocyte donor (for any loss, damage, or death of the donor). A clinic is prohibited from offering to provide a child of pre-determined sex.
- *Rights of a child born through ART*: A child born through ART will be deemed to be a biological child of the commissioning couple and will be entitled to the rights and privileges available to a natural child of the commissioning couple. A donor will not have any parental rights over the child.
- *Offenses and penalties*: Offenses under the Bill include (1) Abandoning or exploiting children born through ART; (2) selling, purchasing, trading, or importing human embryos or gametes; (3) using intermediates to obtain donors; (4) exploiting commissioning couple, woman, or the gamete donor in any form; and (5) transferring the human embryo into a male or an animal. These offenses will be punishable with a fine between 5 and 10 lakh rupees for the first contravention. For subsequent contraventions, these offenses will be punishable with imprisonment for a term between 8 and 12 years and a fine between 10 and 20 lakh rupees.
- Any clinic or bank advertising or offering sex-selective ART will be punishable with imprisonment between 5 and 10 years, or a fine between 10 and 25 lakh rupees, or both.
- No court will take cognizance of offenses under the Bill, except on a complaint made by the National or State Board or any officer authorized by the Boards.

OTHER DUTIES OF ASSISTED REPRODUCTIVE TECHNOLOGY CLINIC[15]

- The ART clinic shall ensure that all unused gametes or embryos shall be preserved by the ART clinic for use on the same recipient and shall not be used for any other couple.
- Allow cryopreservation of oocytes, sperms for onco-fertility patients undergoing treatment and for other such conditions, for duration longer than 10 years with the permission from the National Board.
- Ensure the controlled ovarian stimulation of woman in order to prevent ovarian hyperstimulation.
- Ensure that preimplantation genetic testing shall be used to screen the human embryos for known preexisting heritable or genetic diseases and when medically indicated.
- Ensure that no preimplantation genetic testing shall be done for sex selection for nonmedical reasons or selection of particular traits due to personal preferences of the prospective parents or to alter or with a view to alter the genetic constitution of an embryo.
- Maintain consent form to be signed by the couple or woman as specified in Form 6, IUI with husband's semen or sperm as specified in Form 7, IUI with donor semen as specified in Form 8, freezing of embryos as specified in Form 9, freezing gametes as specified in Form 10, freezing of gametes sperm or oocytes and parental consent as specified in Form 11, oocyte retrieval as specified in Form 12, and oocyte donor as specified in Form 13.

NEED FOR ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) BILL, 2021[16]

- *To standardize protocols:*
  - There are so many such ART clinics that have been running without regulation and there are implications on the health of those who undertake the procedure.
  - If there is no regulation, unethical practices will increase.
- *To protect women and children:* The oocyte (a cell in an ovary) donor needs to be supported by an insurance cover. Multiple embryo implantation needs to be regulated and children born through ART need to be protected.

CONCERN FOR ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) BILL, 2021[16]

- *Discrimination in accessibility:* The Bill allows for a married heterosexual couple and a woman above the age of marriage to use ARTs and excludes single men, cohabiting heterosexual couples and lesbian, gay, bisexual, transgender, or queer (LGBTQ+) individuals and couples from accessing ARTs.

- *Duplicity:*
  - Both Surrogacy and ART Bills will set up multiple bodies for registration which will result in duplication or worse, lack of regulation.
  - For example, a surrogacy clinic is not required to report surrogacy to the National Registry.
- *Violates Article 14:*
  - The bill violates Article 14 of India's constitution and is also silent on the rights of children.
  - According to Article 14, equality before law and equal protection of law to any person within India cannot be denied.
- *Cost of the services:* The cost of the procedure should be effectively monitored so that even the poor can avail of its services which may not be possible in third-party reproduction.

EVOLUTION IN SURROGACY LAW—LEGAL INSIGHTS[17]

- *Assisted Reproductive Technology Bill, 2013:* The ART Bill, 2013 was pending for quite a while, which did not allow commercial surrogacy that involves exchange of money for anything other than paying for medical expenses for the mother and the child. The Bill also prohibited couples already having one child, foreigners or overseas citizens of India (OCI), holders as well as live-in-partners, single people, homosexuals, and widows for opting surrogacy.
- *Surrogacy (Regulation) Bill, 2016 and 2019:* In 2016, a Surrogacy (Regulation) Bill was introduced and passed in Lok Sabha, the lower house of the Indian parliament, proposing to permit only Indian heterosexual couples married for at least 5 years with infertility problems to access altruistic or unpaid surrogacy and thereby banning commercial surrogacy. The 2016 Bill lapsed owing to the adjournment of the parliament session. The bill was reintroduced and passed by the Lok Sabha in 2019.
- *Surrogacy (Regulation) Act, 2021:*
  - This Act explains surrogacy as a practice in which if a couple is incapable of producing a child of their own due to infertility or any disease is eligible for the surrogacy process with certain guidelines. It is permitted only for altruistic purposes or for couples who suffer from proven infertility or disease.
  - Altruistic surrogacy includes no money-related pay to the surrogate other than the clinical costs and protection inclusion during the pregnancy. In vitro treatment (IVF) is the most widely recognized and powerful sort of ART. The ART Regulation 2021 gives a framework to the execution of the law on surrogacy by setting up of the National Assisted Reproductive Technology and Surrogacy Board.
  - In order to improve the facilities provided in surrogacy clinics, the Ministry of Health and Family Welfare came up with Surrogacy (Regulation) Rules, 2022, on June 21, 2022, under the ministry of Mansukh Mandaviya, which elaborates the requirement of number of persons employed and the qualifications that they must possess. In addition to that, it also provides for the form and manner in which the registration will take place and the procedure to pay the fees for the surrogacy clinic **(Table 1)**.

TYPES OF SURROGACY

- *Altruistic surrogacy:* It involves no monetary compensation to the surrogate mother other than the medical expenses and insurance coverage during the pregnancy.
- *Commercial surrogacy*: It includes surrogacy or its related procedures undertaken for a monetary benefit or reward (in cash or kind) exceeding the basic medical expenses and insurance coverage.

TABLE 1: Difference between Surrogacy Act and Assisted Reproductive Technology (ART) Act.[20]

Surrogacy Act	***ART Act***
Relates to surrogacy, an infertility treatment, where a third person, a woman, is the surrogate mother	Treatments can be availed by the commissioning couple themselves and it is not always necessary that a third person is involved
Surrogacy is allowed for only Indian married couples	ART procedures are open to married couples, live-in partners, single women, and also foreigners
It prohibits the commissioning of surrogacy in India by foreigners or OCI or PIO cardholders, but NRIs holding Indian citizenship can avail of surrogacy	Foreigners can visit India under medical tourism to avail ART services
There will be a National Surrogacy Board that will be involved in policy making, and act as a supervisory body, and State Boards that will act as executive bodies	The ART Act provides for a National Board, with the powers vested in a civil court under the Code of Civil Procedure
About 1,000 clinics are practicing surrogacy in India according to the Health Ministry	ART practicing clinics are likely >20,000

(NRI: nonresident Indian; OCI: overseas citizens of India; PIO: persons of Indian origin)

ELIGIBILITY CRITERIA FOR COUPLES INTENDING SURROGACY[18]

- Couple is having a proven infertility condition, either male or female suffering from infertility.
- Couple should have Indian citizenship.
- Couple should be married for at least 5 years.
- Age of wife should be between 23 and 50 years old and husband's age between 26 and 55 years old.
- They do not have any surviving child (biological, adopted, or surrogate)—this would not include a child who is mentally or physically challenged or suffers from a life-threatening disorder or fatal illness.
- Not for commercial purposes
- Not for producing children for sale, prostitution, or other forms of exploitation
- For any condition or disease specified through regulations
- Insurance coverage for 16 months covering postpartum delivery complications for the surrogate.

If all the above criteria are met, then only a couple will be issued a certificate of essentiality and a certificate of eligibility by the appropriate authority to make them eligible for the altruistic surrogacy process.

ELIGIBILITY CRITERIA FOR A SURROGATE MOTHER[18]

- A close relative of the intending couple
- Age has to be between 25 and 35 years old
- A married woman
- Already having a child of her own
- Permitted to be a surrogate mother only once in her life
- Possess a certificate of medical and psychological fitness for surrogacy.
- The surrogate mother is not allowed to give her own eggs for surrogacy.
- The surrogate mother should not have any history of miscarriage or complications during her previous pregnancy and childbirth.

ABORTION DURING SURROGATE PREGNANCY

- An abortion of the surrogate child requires the written consent of the surrogate mother and the authorization of the appropriate authority with compliance to the Medical Termination of Pregnancy Act, 1971.
- The surrogate mother has an option to withdraw from surrogacy before the embryo implantation.

OFFENSES AND PENALTIES RELATED TO SURROGACY IN INDIA[19]

In order to stop the exploitation of surrogate mothers and children, some penalties have been established by the Indian government.

- The penalty for such offenses is imprisonment up to 10 years and a fine of up to 10 lakh rupees.
- Undertaking or advertising commercial surrogacy
- Exploiting the surrogate mother
- Abandoning, exploiting, or disowning a surrogate child
- Selling or importing human embryos or gametes for surrogacy.

CIRCUMSTANCES FOR OPTING SURROGACY[17]

- When a woman has no uterus or missing uterus or abnormal uterus or the uterus is surgically removed due to any disease
- Failed to conceive even after multiple IVF or ICSI attempts
- In case of multiple pregnancy losses and the medical reason is unexplained
- If pregnancy is impossible due to some illness.

ANALYSIS OF KEY POINTS OF SURROGACY (REGULATION) RULES, 2022[17]

- Central government, by issuing a notification, declared the eligibility criteria and number of persons required at a registered surrogacy clinic. Further, the details for the minimum equipment required at such clinics are also specifically mentioned.
- The composition of such clinics as per the notification is that any such clinics shall have at least one gynecologist, anesthetist, embryologist, and counselor and the clinic may employ additional staff by the ART level 2 clinics.
- Gynecologist at surrogacy clinics shall be a medical postgraduate in Gynecology and Obstetrics and should have record of performing 50 ovum pickup procedures and at least 3 years of working experience in an ART clinic under supervision of a trained ART specialist.
- ART is defined as "assisted reproductive technology" with its grammatical variations and cognate expressions, means all techniques that attempt to obtain a pregnancy by handling the sperm or the oocyte outside the human body and transferring the gamete or the embryo into the reproductive system of a woman." Henceforth, it is very essential for a gynecologist to have expertise in this technology.
- Form 1 in the notification specifies the application to receive a certificate of recommendation from the board.
- To safeguard the rights of the surrogate mother, the provision for insurance coverage has been introduced, which mandates the intending couple or woman to purchase a health insurance for the surrogate mother for 36 months.
- An affidavit before a Metropolitan Magistrate or a Judicial Magistrate of the first class shall be signed by the woman

or couple with the intention of giving guarantee under section 2 of the Surrogacy (Regulation) Act, 2021.
- The maximum number of attempts of the surrogacy procedure shall not be more than three times.
- The surrogate mother shall give her free consent as per the specifications provided in the form.
- It has been decided that the gynecologist shall implant only one embryo, with an exception of three embryos in special cases.
- In case where a surrogate mother wants to abort the child, the abortion process is to be followed as per the Medical Termination of Pregnancy Act, 1971.

INFERTILITY—A TABOO

Assisted reproductive technology and surrogacy procedures have emerged essentially due to increasing infertility in the society. The current Bill defines infertility as the inability to conceive after 5 years, whereas the previous draft bills defined it as the inability to conceive after 1 year.

The Committee has compared this definition of infertility with that given by the WHO and suggested that "since conception has many interplay functions, a 5-year time bar would add to the misery of already distressed intending couples. The 5-year waiting period is therefore arbitrary, discriminatory, and without any definable logic. The Committee, therefore, recommends that the definition of infertility should be made commensurate with the definition given by WHO. The words "five years" in clause 2(p) and 4 (iii)(c) II, be, therefore, replaced with "one year" and consequential changes be made in other relevant clauses of the Bill."[21]

This suggestion by the Committee is based on the basic fundamental right to reproduction and the right to privacy.

How and when individuals wish to reproduce is their own personal discretion. The government can impose limitations and set criteria; however, the same should be rational and not arbitrary.

Other Suggestions

The Committee made several other laudable suggestions, some of which take root from the previous ART bills and some of which are based on reasonable analysis of the current social–medical scenario. It suggested that "compensated surrogacy" should be allowed and that single parents and live-in partners should be allowed to commission surrogacy.

The Committee also recommended that there should be a provision of breast milk banks for the surrogate child, and a tripartite surrogacy agreement should be entered between the parties instead of separate agreements to make the process easier.

Thus, a Bill to regulate surrogacy is found to have elements far removed from ground realities and certain provisions would need to be recast for it to serve its intended purpose. The committee, which has raised several issues with the Bill, has "strongly" recommended that the ART Bill be brought forth before it.

"The committee failed to comprehend the reasons behind bringing a fresh bill specifically on surrogacy, when a detailed, comprehensive and all-encompassing bill on ART services had already been drafted by the department," the committee stated.

At the same time, it observed that surrogacy could not be a way out for women living in poverty and should not be allowed as a profession—it supported the provision that restricts a woman from becoming a surrogate more than once.

The Bill aims to control exploitation and safeguard interests of poor women who become surrogates for money, but the potential for exploitation is linked to lack of regulatory oversight and legal protection to these women, according to the report.

Despite this, the Bill, in opinion of many ART experts, fails to address various issues, including transparency and fair practices.

One of the major issues is that of lack of screening guidelines of couples based on their socioeconomic background, criminal records in the past, their health, age, and family information check before they are permitted to commission surrogacy. In the absence of such screening guidelines, the surrogate child's interests suffer considerable risk from being put under the guardianship of those who lack credibility or even be detrimental to the child's security.

Although the Bill prohibits and penalizes abandonment, rejection of the surrogate by couple postbirth, it defines "abandoned child" by defining grounds of abandonment as "physical or mental defect or infirmity, or being more than one in number," excluding "sex of the child" among the same. In this aspect, the Bill does not address the plight of such surrogate child found nongenetically connected with either of the parents post birth due to mishaps arising out of switching or swapping of donated frozen gametes of couples in clinics, laboratories, or sperm banks. The Bill is unclear if such a surrogate child is allowed to be abandoned, rejected, or left in adoption home or orphanage.

Among the biggest misses of the Bill is sex-selective surrogacy or family balancing surrogacy done to have child of a predetermined sex, in which the earlier ART Bill prohibited and penalized the same by adding relevant provisions of Prenatal Diagnostic Techniques (Regulation and Prevention of Misuse) Act, 1994, in ART.[22] Among other offenses and punishments, the Bill does not talk about "trafficking or sale, abduction of surrogate child" in the guise of either altruistic

or commercial surrogacy arrangement in any form under the same.

Apart from the above-mentioned aspects, there are various other aspects in relation to the rights of the surrogate mother and the child. The Bill lacks in clarity and transparency required to protect these rights sufficiently in case legal issues arise.

Health experts believe that dealing in surrogacy in isolation and in separation with other important issues such as ART clinics, gamete donation, sperm donation, and IVF practices (which had been earlier the part of the broad ART Bill) will serve no purpose. Earlier, the ART Bill had surrogacy as one of the parts of the Bill and should be taken as such, with more clarification and provisions for surrogacy as it evolves, like other areas of ART. ART, such as all other advances in medical profession, is ever evolving and any legislation or bill will have to be revised as such from time to time, depending on the scientific advancements and societal changes.

ASSISTED REPRODUCTIVE TECHNOLOGY BANK

Facilities for cryopreservation are an essential component of an ART clinic as they are to be used under a variety of conditions.

Freezing Semen

Men who are likely to suffer from psychological stress at the time of ovum pick-up or those who cannot be present at the time of ovum pick-up are recommended to have their semen frozen for use at the appropriate time. One of the important reasons for freezing semen from donors is that any donor semen has to be quarantined for 6 months. The safety of using frozen sperm has been abundantly proven by both experimental work and the actual results in humans. Matters of concern are the donor's health and the necessity to avoid donors who are infected with venereal diseases, hepatitis B or C, or HIV. One of the drawbacks of sperm freezing is an approximate 20% loss in motility after thawing. Donors whose semen is frozen for future use are required to report to the semen bank 6 months after donation to be checked for HIV, hepatitis B or C virus infection, or disease status.[23]

Freezing Embryos

Embryos are routinely cryopreserved to enable storage of supernumerary embryos, as up to a maximum of only three embryos is allowed for transfer to avoid the risk of multiple pregnancies. Embryo freezing is a widespread routine procedure to increase cumulative pregnancy rates. Human embryos can be successfully cryopreserved at any stage from zygote to blastocyst, using 1,2-propanediol (PrOH) or dimethyl sulfoxide (DMSO) for zygotes and cleaved embryos and glycerol for blastocysts. Straws or ampoules used for freezing embryos should be carefully and permanently labeled for identification purpose. Patients should be fully informed before the treatment cycle on the procedure of cryopreservation, the risks and, particularly, what is to be done with their embryos if they do not use them. They should sign a consent form concerning the agreement for embryo freezing as well as for the future use of the embryos.[24] When a serum supplementation is used in the preparation of freezing and thawing solutions, one must carefully avoid any risk of viral transmission to the embryo through the serum.

Oocyte Cryopreservation

This procedure has been successfully used in cases where a large number of immature oocytes have been retrieved during ovum pickup. The oocyte can be thawed at a later date, matured in vitro, and used for OD or similar procedures either on the person from whom the oocytes were retrieved or on other prospective recipients. However, the success rates in terms of fertilization, pregnancy, and live births with the use of cryopreserved oocytes are not very encouraging. ART clinics are the only source of embryonic stem cells. Spare embryos are either frozen or returned to the infertile couple for replacement during a later cycle, or donated to another infertile couple, or discarded after 5 years using a suitable protocol.[25] The stand taken by the foreign governments on embryo research might promote commercial exploitation (selling of embryos) of developing countries that do not have appropriate national guidelines. Therefore, sale or transfer of human embryos or any part thereof, or of gametes in any form, directly or indirectly to any party outside the country, must be prohibited. Within the country, such embryos or gametes could be made available to bona fide researchers only as a gift, with both parties having no commercial transaction, interest, or intent.

CONCLUSION

As India is one of the significant center points of these practices, the Act is surely a positive development, but there are few aspects on which the laws on surrogacy stand contradictory. According to Article 21, "Right to Life" is a fundamental aspect and right to reproduction has been embraced under it. The right for women to have children and the right to bring a pregnancy to term are all included in their reproductive rights. Therefore, it is clearly a violation of Articles 21 and 14 to limit surrogacy while denying reproductive options.

However, it is very crucial to maintain certain standards in the professions where risk to life of a person is involved; with the same motive, the Central Government issued the guidelines to establish quality surrogacy clinics and explained the prerequisites that the surrogacy clinics shall comply with before providing the services. In addition to that,

certain guidelines are also provided for an intending couple or woman who is opting for surrogacy. With these measures, a protective process for a surrogate mother is created.

Since the enactment of new rules and regulations, there have been many debates on the shortcomings of the present bill. There are likely to be some changes to make it more patient friendly. Hence as of today, this is not the last word. Regulated ART and surrogacy will not only be beneficial for the patients but also for the doctors. More deliberations and changes will make this cost effective. Till then, many patients will approach the courts for redressal and the Judiciary will be flooded with such issues.

CHAPTER 72

Adoption

Himanshu Singhal, Anubhuti Patel

INTRODUCTION

Having children has always been important since time immemorial, and the continuity of the family unit has been of major significance in every culture. Infertility affects millions of people of reproductive age worldwide—and has an impact on their families and communities. Estimates suggest that between 48 million couples and 186 million individuals live with infertility globally as per the World Health Organization report in 2020.

Childlessness in India is estimated at around 2.5% (5.5% for the 30–49 year age group and 5.2% for the 45–49 year age group). In absolute terms, it is around 4.9 million, and if secondary infertility is also added, then it increases to 17.9 million.[1]

Due to advancement in fertility treatment, more babies are being born using techniques ranging from minimally invasive medications to assisted conception techniques such as intrauterine insemination (IUI) to in vitro fertilization (IVF).

In vitro fertilization, which is often pursued as the last option, is one of the most complex treatments in infertility with success rates up to 30% which decrease further as women get older.[2]

Dropout rate reaches up to 65% after three cycles of IVF in countries offering free/subsidized cycles[2-4] versus one cycle in self-funded treatment. Various reasons for discontinuation of treatment were found to be financial burden in majority of self-funded cycles, while prognosis being another major factor affecting a patient's decision of continuing the treatment (25% dropout due to poor prognosis). Other reasons for dropout were psychological in 26%, social in 15% (such as marital problems), and physical burden in 6% [ovarian hyperstimulation syndrome (OHSS), infection, and pain due to injections], while it was not related to the cause of infertility.[2,5-7]

Infertile couples undergoing IVF may experience significant psychosocial stress, problems in the marital relationship, divorce, difficulties in sexual adjustment, blame for the infertility, lower self-esteem, loss of hope, and social isolation following the unsuccessful completion of treatment.[3,8-19]

Little is known about their final probability of having a child. 10% of them may conceive spontaneously.[9,20] Another recent study reported live birth rate up to 24% after spontaneous conception in couples who remained childless after treatment.[21] A follow-up study reported women being less satisfied with their lives who remained childless compared with those who were parenting a biological or an adopted child.[12]

After unsuccessful treatment or not achieving parenthood, couples may pass through different stages of grief including denial of them not having children biologically, and then the final stage of acceptance comes when they begin to see adoption as a solution to become parents. Parenthood after discontinuation of IVF in majority (46%) is due to adoption.[22]

Adoption is not a new concept. Its roots may be traced to ancient India. Indian mythology is full of stories about what couples have done in the past to overcome their problem of infertility. One such example of adoption was when Rishi Kanva adopts and raises an abandoned child that he finds in the forest who grows up to be Shakuntala who, when rejected by her husband, Dushyanta, raises her son, Bharata, on her own. The son becomes such a great king that the land he rules comes to be known as "Bharata-varsha," now known as "India."

"The bond that links your true family is not one of blood, but of respect and joy in each other's life."

DEFINITION

Adoption is a social, emotional, and legal process that provides a new family for a child when the birth family is unable or unwilling to parent.[23] It is the creation of a parent–child relationship by judicial order between two parties who usually are unrelated. This relationship is brought about

only after a determination that the child is an orphan or has been abandoned, or that the parents' parental rights have been terminated by court order.[24]

Modern systems of adoption, arising in the 20th century, tend to be governed by comprehensive statutes and regulations.

TYPES OF ADOPTION

Open Adoption

This kind of adoption is open, which means that the adoptive parents and the birth parents keep in touch with each other through letters, emails, phone calls, and may even visit each other, and the birth mother can meet the child.

Advantages

- There is substantial medical information available to the adopted child, which is very important to assess some genetic disorders and other medical purposes.
- The adoptee has an extended family and more people who love and support him.
- The adoptee has access to his ancestry and lineage.

Disadvantages

- There may be a difference in expectations from adoptive or birth parents.
- The boundary issues may occur, where both the parties may struggle with drawing the line.
- The morals and values of both the families may not match, and this may cause confusion.

Semiopen Adoption

This is a kind of adoption that does not involve direct contact between the birth parents and the adoptive parents. However, the mother may keep receiving letters or photographs from the adoptive parents or through the adoption agency she is registered with. This may continue until the child reaches the legal age. At any given point of time, semi-adoption may get converted into an open or closed adoption.

Advantages

- Adoptive parents have access to the medical records and other information of the birth parents.
- This kind of adoption helps you maintain your privacy.
- Birthing parents have the information on how their child is taken care of.
- Adoptees may contact the birthing parents in future.

Disadvantages

- Both parties have to rely on the mediator agency.
- A semiopen adoption may become closed adoption in case the adoption agency goes out of business or stops functioning.
- The communication may stop if either of the party loses contact with the agency.

Closed Adoption

As the name suggests, this kind of adoption involves absolutely no contact between the adoptive parents and the birth parents.

Advantages

- The adoptee will not feel torn between two families.
- There is a sense of closure for both the sets of parents.
- The adoptee will have a close-knit family.
- There will not be any intrusion from the birth parents.

Disadvantages

- The child on knowing that he is adopted may become obsessed with finding birth parents in case of a closed adoption.
- There may be limited medical information available.
- The adoptee may face an identity crisis.

Intra-family Adoption/Relative Adoption

This is a kind of adoption that happens within the family.

Advantages

- The child stays within the biological family.
- The adoptive parents are in full control of taking various important decisions concerning the child.
- The adopted child in most cases gets to keep his original name.

Disadvantages

- The change in relation to the adoptive parents may confuse the child (in case the child is old enough).
- The time to contact and visitation is usually decided by the adoptive parents.

Domestic Adoption

Domestic adoption refers to adoption that happens within the country.

Advantages

- This type of adoption is less expensive as compared to international adoption.
- It also involves lesser paperwork in contrast to international adoption.
- Couples who intend on adopting a newborn baby may adopt him easily.
- The information of the birth parents may be accessible to the adoptive parents.

- You may keep in contact with the birth parents, or the contact may vary as per the requirements of both the parties.
- It does not require any international travel.

Disadvantages

- There may not be enough information on the medical history of the birth parents.
- The rules are very strict, and the eligibility criteria of adoptive parents are very strict.
- Adoptive parents may have to choose from a limited number of children.
- The mother may refuse the adoption, which may amount to termination of adoption.

International Adoption

It involves adopting a child from outside the country or in other words giving a child to the couple (adoptive parents) who are not a native of that country.

Advantages

- International adoption may usually happen with orphaned children, and thus birth parents may not be involved.
- There are a wide variety of children to choose from in terms of sex, race, health, and age.
- There is no interference of birth parents.
- Once the home approval is received, it increases the chances of adoption tremendously.

Disadvantages

- This type of adoption is expensive as the adoptive parents are required to travel to foreign lands.
- There are chances of fraud and scams in international adoption.
- As the adoption procedure may take a while, it may not be feasible to adopt a newborn baby.
- If the child is a bit older, he may take considerable time to adjust to a new setting, new country, and new ways of life.

RULES AND REGULATIONS OF ADOPTION IN INDIA

In India, only agencies recognized by the government can deal with adoption placement. Direct placement by hospitals or maternity homes is not permitted.

Central Adoption Resource Authority

The Central Adoption Resource Authority (CARA) is a statutory body of the Ministry of Women and Child Development, Government of India, and functions as the nodal body, which regulates and monitors in-country and inter-country adoption (in accordance with the provisions of the Hague Convention on Inter-country Adoption, 1993, ratified by Government of India in 2003) of Indian orphan, abandoned, or surrendered children through recognized adoption agencies. In 2018, CARA allowed individuals in a live-in relationship to adopt children from and within India. (For details, we can visit www.cara.nic.in.)

Stakeholders in the adoption process

- *CARA:* It ensures smooth functioning of the adoption process from time to time and issues adoption guidelines laying down procedures.
- *State Adoption Resource Agency (SARA):* It acts as a nodal body within the state to promote and monitor adoption and noninstitutional care in coordination with CARA.
- *Specialized Adoption Agency (SAA):* SAA is recognized by the state government under subsection 4 of section 41 of the Act for the purpose of placing children in adoption.
- *Authorized Foreign Adoption Agency (AFAA):* AFAA is recognized as a foreign social or child welfare agency that is authorized by CARA on the recommendation of the concerned central authority or government department of that country for coordinating all matters relating to the adoption of an Indian child by a citizen of that country.
- *District Child Protection Unit (DCPU):* It means a unit set up by the state government at the district level under section 61A of the Act. It identifies orphan, abandoned, and surrendered children in the district and gets them declared legally free for adoption by the Child Welfare Committee.

Adoption Regulations, 2017

Fundamental Principles Governing Adoption

During the adoption process:

- Child's best interest is of paramount consideration.
- Preference is given to Indian citizens in their own sociocultural environment.
- All the adoptions are registered on CARA and confidentiality is maintained.

Child Eligible for Adoption

- Any orphan, abandoned, or surrendered child declared legally free for adoption by the Child Welfare Committee.
- Child of a relative defined under subsection (52) of section 2 of the Act.
- Child or children of spouse from an earlier marriage, surrendered by the biological parent(s) for adoption by the stepparent.

Eligibility Criteria for Prospective Adoptive Parents

- They shall be physically, mentally, and emotionally stable and financially capable with no life-threatening medical condition.

TABLE 1: Age of adoptive parents to apply for children of different age groups.

Age of the child	*Maximum composite age of prospective adoptive parents (couple)*	*Maximum age of single prospective adoptive parent*
Up to 4 years	90 years	45 years
Above 4 and up to 8 years	100 years	50 years
Above 8 and up to 18 years	110 years	55 years

- Any prospective adoptive parent, irrespective of his marital status and whether or not he has his own biological son or daughter, can adopt a child, but should fulfill the following:
  - Consent of both the spouses is needed in case of a married couple, and they should be in a stable marital relationship for at least 2 years.
  - Single female is eligible to adopt a child of any gender.
  - Single male cannot adopt a girl child.
- The age of adoptive parents shall be counted for deciding the eligibility to apply for children of different age groups as shown in **Table 1**.
- The minimum age difference between the child and either of the prospective adoptive parents shall not be <25 years. The age for eligibility will be as on the date of registration of the prospective adoptive parents.
- Age criteria are not applicable for relative or step-children adoption.
- Couple with three or more children shall not be considered for adoption except in case of special need children and in case of relative adoption and adoption by step-parent.

Procedure Relating to Orphan or Abandoned Children

- Abandoned or orphaned child is first presented to the Child Welfare Committee (within 24 hours) who holds the sole authority to declare the child free for adoption.
- Child's details and the photograph are entered online within 3 days of receiving, and the same can be advertised in a national newspaper to trace biological parents/legal guardians.
- Abandoned or orphan child is free for adoption in 2 or 4 months, in case of child up to 2 or above 2 years, respectively.
- In case biological parents want to relinquish a child, they have to execute a document in favor of adoption agency, witnessed by the authority of hospital and relative. After a waiting period of 2 months given to biological parents to reconsider the decision, the child is free for adoption.

Availability of Child for Adoption

Adoption to resident or nonresident Indian is allowed once the child is legally free for adoption by the Child Welfare Committee.

Intercountry adoption is allowed after:

- 60 days if child is <5 years of age
- 30 days if child is >5 years of age or sibling
- 15 days in the presence of physical or mental illness.

Adoption Procedure for Resident Indians

Such couples have to go to a registered agency licensed by both the state government and CARA.

- *Registration:* Filling online application form, uploading the relevant documents regarding their health, financial status, etc., following which they get a registration number.
- *Home study report:* Within 30 days from the date of submission of requisite documents and remain valid for 3 years.
- Once their adoption is approved, the suitable child is shown, and if accepted placement is legalized.
- *Follow-up of the progress of adopted child:* 6 monthly for 2 years
- In case of an adjustment problem, required counseling is arranged.

Adoption Procedure for Nonresident Indians, Overseas Citizen of India, and Foreign Prospective Adoptive Parents

- Nonresident Indian prospective adoptive parents shall be treated at par with Indians living in India in terms of priority for adoption.
- Nonresident Indian, overseas citizen of India, or foreign prospective adoptive parents, living in a country which is a signatory to the Hague Adoption Convention and wishing to adopt an Indian child, can approach the AFAA or the Central Authority concerned.
- In case there is no AFAA or Central Authority in their country, then the government department or Indian diplomatic mission in that country can be approached.
- After ascertaining their eligibility, a home study report is completed.
- The child can be taken in preadoption foster care for a temporary period within India after issuance of "no objection certificate" by the authority while the court order is pending (Schedule VIII).
- Final custody of the child is received from the specialized adoption agency once the passport and visa are issued to the child after issue of adoption order from the competent court.
- *Follow-up of progress:* On a quarterly basis during first year and on a 6-monthly basis in the second year.

Adoption by Lesbian, Gay, Bisexual, and Transgender

It may be a joint adoption by both partners which is legalized in 26 countries, five countries legalize step-child adoption among lesbian, gay, bisexual, and transgender (LGBT), or it can be adoption by a single LGBT.

CARA does not allow adoption to the same-sex foreigner couples, but many LGBT in India have adopted as single parent. In such cases, their partner does not have any legal rights over the child.

Adoption of Children with Special Needs

- The adoption process for children with special needs to be completed as expeditiously as possible.
- Children with special needs shall be available for adoption by resident Indians and nonresident Indians from the date they are declared legally free for adoption by the Child Welfare Committee.
- These children are available for adoption by overseas citizen of India or foreign adoptive parents, after 15 days from the date they are declared legally free for adoption.
- Adoptive parents are made aware of the exact medical condition.

Procedure for Adoption of a Child from a Foreign Country by Indian Citizens

Necessary formalities for the adoption of a child from a foreign country by Indian citizens shall initially be completed in that country as per their law and procedure.

PEDIATRICIAN'S ROLE

A pediatrician plays a major role in guiding families through the medical aspect of adoption (helping them interpret the information provided to them, risks inherent to international adoption, information on a child's growth and development, ordering essential blood and stool tests, reviewing the immunization, and providing a schedule) as well as helps in improving the health and well-being of children in foster care.

After adoption, a pediatrician helps parents deal with challenges in rearing the adopted child and helps the child in dealing with differences and losses associated with the adoption process.

POSTADOPTION FAMILY CONCERNS

Child Concerns

Children's interest in adoption varies throughout the developmental stages of childhood and adolescence. Parents can facilitate this developmental process by being knowledgeable and supportive and by continuing to retell their child his or her adoption story, thus assisting this natural grieving process.

Infancy and Early Childhood

During this period, a child attaches to and bonds with the primary caregiver. The child must understand that places and people exist outside of his or her immediate environment. Telling a child his or her adoption story at this early age may help parents to become comfortable with the language of adoption and the child's birth story.[25]

School-aged Child

Operational thinking and logical planning start at this age. They realize that most other children live with at least one biological relative[26] and may see themselves as being different from other children, feel abandoned, angry or face withdrawal, and self-image problems. A parent's patience and understanding are crucial at this point of an adopted child's life. School personnel education about the natural grieving issues need to be discussed.[27,28]

Adolescent

Adolescents are in a phase to establish an identity while actively seeking independence and separation from family. Adopted adolescents' search for information about themselves is very normal, and parents should not see this as a threat. Instead, parents' willingness to accept their child's dual heritage of biology and environment will help their child to accept that reality.[27,28]

All adopted children grieve the loss of identity, their biological family, their heritage, and culture at some point in their lives when they learn that they were adopted and may have feelings of depression, anger, anxiety, numbness, or fear.[29] An adopted child wants to learn more about their biological family members and why were they left by their birth parents for adoption. Their grief is real and should not be denied or avoided. Support from knowledgeable healthcare providers is invaluable in helping adoptive parents and their child.

Child Abuse

Child abuse has been estimated to occur in 1% of adoptive families. An Ankeny couple who adopted nine children with disabilities from foster care has been charged for physical abuse. Recently, an Indian–American couple was booked for the death of their adopted daughter. Stringent rules for adoption and follow-up by the regulatory body may help in reducing the same.

Family Concerns

Adoptive parenthood, such as other types of parenthood, can bring tremendous joy and a sizable amount of stress. Some challenges are same that all families—biological and adoptive—face; however, other potential stressors are unique to adoption. Most adoptive children settle in

with their new families, and research shows that the great majority of adoptive parents are satisfied with their decision to adopt.[30] Adoptive parents may worry that they do not "feel" like parents, even after the adoption is complete; a small percentage will have a feeling of "let down" or sadness much like postpartum depression.[31,32]

Number of things can be done to help adjust to the new identity:

- Connect with parents who have completed a similar adoption.
- Establish family traditions or rituals, e.g., bedtime reading or family movie night.
- Create a family story beginning with your own story from childhood through the decision to adopt.
- Connect with your child's birth culture.
- Prepare to respond to outsiders (relatives, friends, or strangers) about the adoption.
- Find support services tailored for adoptive families such as respite care, support groups, counselors or therapists, and educational advocates to help parents of children with special needs.

Most adopted children and families adjust well and lead healthy, productive lives. Disruption rates are higher among children adopted at the older ages and their histories of multiple placements prior to adoption.

KEY POINTS

- Adoption has given and continues to give people the opportunity to lead fulfilling, meaningful lives alongside their children, and in turn provides children opportunities in life once thought unachievable.
- Adoption is a lifelong commitment, and adoption-related issues may arise at any point in the parents' or their child's lifetime.
- A willingness to learn about the issues and seek support if necessary can help to ensure that parents and children experience happy and healthy family lives.

CHAPTER 73

LGBTQ and Fertility

Utpala Sen, Gautam Khastgir

INTRODUCTION

Lesbian, gay, bisexual, or transgender (LGBT) people are a group referred to as the LGBT community and forms a minority section of the society. Not all people consider themselves part of the LGBT community. Homosexual women are known as lesbians, which depicts their sexual identity and sexual behavior regardless of their sexual orientation. Similarly, a homosexual man is referred to as a gay individual. A transgender man is defined as a person who was assigned female at birth but identifies and expresses her gender as male and vice versa. The equality and nondiscrimination guarantee provided by international human right laws applies to all people regardless of sex, sexual orientation, and gender identity or other status. All human beings have the right to express themselves and their identities without fear of violence or retribution. The human rights of this community have been coming into sharper focus around the world, with wider acceptance and legal protection in recent years.

Gender variance is when a person's sex assigned at birth is inappropriate to what they identify themselves to be. These people desire a permanent transition to the sex or gender with which they identify by seeking medical help in the form of hormone therapy with or without sex reassignment surgery (SRS). In 1923, Hirschfeld in Germany first introduced the term trans-sexualismus, which was later translated by Cauldwell into English as transsexualism and transsexual.[1,2] Historically, transsexual people encompassed heterosexual, gay, lesbian, or bisexual. In 1965, John Oliven, for the first time introduced the term "transgender." By early 1990s, transsexual had become a subset of the umbrella term "transgender," which is now more common. The scenario has further altered with evolution of the term "gender dysphoria" in 2013, which has been described as the distress of persons who sense a mismatch between their gender identity with their sex assigned at birth.[3] All transgenders are not gender dysphoric as gender dysphoria is a diagnosis only for those who seek medical treatment, excluding those who have sexual identity disorders without gender concerns.

Those with gender dysphoria have a strong desire to modify her or his appearance and express themselves by doing surgical procedures, taking medicines, and using attire consistent with their gender identity. Transgender persons are subjected to social harassment, discrimination, and abandonment by family or friends, in addition to poor access to healthcare.[4] This psychological suffering leads to psychiatric problems such as self-harming behavior, depressive symptoms, and suicidal ideas. These problems can be lowered by gender-affirming treatment.[5]

The number of LGBT people having babies is unknown in most countries due to lack of published data. In the year 2019, data from Human Fertilization and Embryology Authority (HFEA) and birth registration in the United Kingdom identified that lesbian couples are one of the fastest growing client groups within maternity services seeking fertility treatment. The UK gender clinics have risen proportionally more for transgender men who wish to be parents. Pregnant transgender men may also be a growing population with maternity services.[6]

Over the decades, there has been a distinct paradigm shift in terms of the social existence of LGBT groups globally. A multidisciplinary tailor-made team approach is required to help them with professional assistance to fulfill their reproductive desire. This would help them to enjoy sexual relationship and skills which would strengthen their relationship. Different forms of infertility treatment involving assisted reproductive technology (ART) have been offered to these individuals or couples toward achieving pregnancy and childbirth.

The live birth rate in this group has increased by 15–20% for the past decade. Surrogacy has also shown a similar increase with respect to live birth rate. However, it is unknown what proportion of parents are heterosexual. This uncertainty exists because fertility clinic statistics assume a female partner and report statistics as "male partner, female

partner, no partner, or surrogacy." No figures are available for transgender people becoming pregnant or impregnating their partners.[7]

Universal access to reproductive health is one of the goals of the Millennium Declaration 2000 and the World Summit 2005 of the United Nations.[8] According to the guidelines of the Ethics Committee for the American Society of Reproductive Medicine (ASRM), Endocrine Society, and World Professional Association for Transgender Health, fertility preservation should be discussed before any hormonal treatment or gender-affirming surgery.

The United Nations Human Rights Committee has advocated that it is unlawful to make any discrimination of people, based on their gender and sexual orientation. In 2021, The Ethics Committee of ASRM suggested that fertility programs should be same for single individuals, unmarried couples and LGBT group, and cisgender heterosexual married couples as well.[9] The European Society of Human Reproduction and Embryology (ESHRE) Task Force on Ethics and Law have suggested avoiding the use of double standard in terms of assisted reproductive therapy effect of ART on any of the persons involved, including the future child as well as the surrogate mother or the applicants themselves. All these concerns have to be considered on the basis of available scientific evidence, especially for single women, gay, lesbians, and transgenders.[10]

It is beyond the scope of this chapter to discuss the controversies with regard to the fertility issues of this particular group of people and related legislation. Nevertheless, the authors aim to provide an insight to the readers regarding the global scenario of the fertility options of LGBT groups, including various guidelines and related legislations **(Table 1)**. The changing situation in the Indian subcontinent will also be discussed.

TABLE 1: Fertility options for LGBT community.

Transgender men	Multiple options	• Oocyte cryopreservation • Ovarian tissue cryopreservation • Embryo cryopreservation
Transgender women	Limited options	• Sperm freezing • Testicular tissue cryopreservation
Lesbian	Range of options	• IUI with donor sperm • IVF with donor sperm • Co-IVF with donor sperm
Gay	Limited options	• Ovum donation with surrogacy • Embryo donation with surrogacy

(IUI: intrauterine insemination; IVF: in vitro fertilization; ; LGBT: lesbian, gay, bisexual, or transgender)

TRANSGENDER PEOPLE

Lesbians, gays, and bisexuals are equally concerned about their sexuality, but the problems of transsexuals and transgenders are completely different. Transsexual people often seek medical or surgical consultation, with an intent to satisfy their sexual needs. On the other hand, not all transgender people pursue medical treatment, though they believe that their gender behavior and culture assigned to their sex is not conforming to their gender identity described by the society. Transgender men are biologically born female but wish to be identified as male and vice versa. Fertility potential and options for transgender men and transgender women are distinctly different. A retrospective study in Sweden has reported that 69.5% of trans men and 82% of trans women wished to have parenthood. However, the desire to preserve fertility prior to hormonal or surgical treatment was higher in trans women than trans men.[11]

The process of transition from biological sex to the desired gender starts from early adolescence. Sex reassignment treatment generally starts at a younger age when reproductive desires are not clearly defined. The fertility potential of transgender people may be impaired by gender-affirming hormonal treatment (GAHT) and also suppressed by SRS. Hormonal and surgical treatment may have a devastating effect on the possibility of having a family for these people. GAHT is the most common treatment opted by transgender people to modify secondary sexual characteristics of their desired sex. All medical treatments related to sex reassignment of transgender and intersex people are named as sex reassignment therapy (SRT). A diagnosis of gender identity disorder is the prerequisite to obtain SRT. A multidisciplinary team comprising healthcare professionals, counselors, psychotherapists, and social support groups is required to provide tailor-made treatment to these people according to their wishes. For gender dysphoric children, pubertal suppression with gonadotropin-releasing hormone (GnRH) agonist at puberty can be offered to avoid the development of undesired secondary sexual characteristics.[12]

Fertility preservation should ideally be offered prior to initiation of any hormonal or surgical treatment. In 2021, a French case series has reported that 96% of transgender women who had not started treatment benefitted from sperm cryopreservation compared to 50% who were on GAHT treatment.[13] Therefore, fertility preservation options should be discussed with all transgender people before GAHT or SRS.

The guidelines published by the World Professional Association for Transgender Health are intended to ensure that the clients are adequately informed, having sound psychological health to have realistic expectations. All treatment should be done under supervision of physician and psychiatrist as unsupervised discontinuation of

medicine or even change of dose may lead to physical and psychological health risk.[14]

Gender-affirming hormone therapy facilitates breast growth of thin trans-females, but reduction of breast size in trans-males with such treatment is often suboptimal. Similarly, prompt facial hair growth can be seen on trans men, while regression of hair growth is very rare in trans women. Distribution of body fat and muscle and cessation of menstruation can be achieved by GAHT in trans men. Hormones used for GAHT are testosterone, estrogen, and antiandrogen. Testosterone is used to enhance vocal cord and skin thickness in trans men.

Sex reassignment surgery is done to change the physical appearance and genital anatomy according to their gender identity. Mastectomy along with male chest reconstruction, phalloplasty for trans men, and breast augmentation with vaginoplasty for trans women are common surgeries done in this subset of patients.

For transgender men, the fertility preservation options are oocyte cryopreservation, ovarian tissue cryopreservation, and embryo cryopreservation.[15] Slow freezing cryopreservation of ovarian tissue is the standard method, but vitrification has shown good results in recent years for people who are assigned female at birth. However, in January 2022, Borrás et al. in their study have shown that both cryopreservation techniques are accurate to maintain the number of follicles as well as stromal tissue.[16] Embryo cryopreservation involves fertilization of transgender men oocyte with a donor or partner sperm. They also have the opportunity to preserve their fertility without consenting to a male partner at the time of cryopreservation. However, their future option for fertilizing the egg with another partner or donor would not exist after SRS.[17]

Ovarian tissue cryopreservation is an upcoming experimental method in this group and may be performed during SRS; however, there are limited centers where this option is offered to transgender men. In some centers, it is considered at prepubertal age when ovarian stimulation is not possible. A single case report in 2021 has showed that cryopreservation of mature oocyte is possible for transgender men who are on continuous long-term testosterone therapy.[18]

In 2021, Martin et al. have used letrozole to maintain lower level of estradiol in adolescent transgender men for ovarian stimulation. They reported that low estradiol minimizes pubertal development and possibly prevents gender dysphoria symptoms.[19]

Prolonged use of testosterone in transgender men may lead to follicular atresia, hyperplasia of stroma, and polycystic ovarian look on ultrasonography.[20,21] In 2017, De Roo et al. in their study reported that long-term use of testosterone for 1 year did not induce any significant change in ovarian morphology. In these patients, presence of a large number of primordial follicles ensures potential for in vitro maturation of cumulus–oocyte complexes.[22]

Feigerlová et al. in 2019 reported that 61% of transgender men had testosterone treatment before pregnancy and 88% used the oocytes from their own ovaries. Majority of them became pregnant spontaneously within 4 months, 7% requested fertility drugs, and only 12% required ART [intrauterine insemination (IUI), in vitro fertilization (IVF), and gamete intrafallopian transfer].[23]

There is paucity of evidence with regard to fertility potential for transgender women. The potential for fertility preservation procedures in this group have been questioned though sperm cryopreservation may be an option for them. Experimental techniques including spermatogonium stem cells and testicular tissue preservation are currently under research in prepubertal individuals. There are no reports of such procedures in clinical practice till date. Long-term effects of estrogen and antiestrogen formulations on testicular morphology and function are still not clear. Impaired steroidogenesis and involution of Leydig cells are observed following treatment with combination of estrogen and antiestrogen drugs. A multicenter study on different treatment regimens (antiestrogen with different doses of estrogen, estrogen only, or combination of spironolactone and estrogen) reported unaltered spermatogenesis in 24% of orchidectomy specimens. They also reported that spermatogenic suppression is reversible.[24] Satisfactory recovery of spermatogenesis was observed in 3–4 months after treatment cessation.[25]

LESBIANS

Lesbian single women who wish to have family can opt for IUI with donor sperm if the fallopian tubes are patent with good ovarian reserve (anti-Müllerian hormone and antral follicle count). For older women, IUI may not be the best option. IVF is the option for those lesbian couples where both the partners want to get physically involved in the treatment. Here, one partner may choose to donate egg and the other partner will carry the pregnancy. The partner donating the egg would be stimulated with hormones and have her eggs fertilized with donor sperm and then transferred into the other partner's uterus. This is called co-IVF or reciprocal IVF. They also have the option to donate eggs and the same partner has the embryos transferred. The sperm used for fertilization can be taken from a friend, known donor, or anonymous donor through a sperm bank.

GAY COUPLES

With an increasing number of gay couples willing to have biological parenthood, there is a rise in the demand for IVF. To accomplish this, gay couples need access to fertility clinics, where facility for egg donation and surrogacy is available. Occasionally, insemination may be carried out

with sperms equally shared by both partners. The embryos are transferred into the uterus of the surrogate. The other option for this group is embryo donation, which means that there is no biological involvement of both the partners. Both sperm and egg are collected from the donors and the embryos are put into the surrogate's uterus. Most of the agencies who are providing the service have a customized treatment plan along with legal support, which help the couple to go through the journey smoothly.

SCENARIO IN INDIA

LGBT rights in India have been attracting more social and administrative attention over the past decade, with increasing tolerance and social acceptance. Nevertheless, discrimination still exists, especially in the rural areas where these people face rejection from their family and the society at large. The concept of gender is generally beyond the understanding of common people, who often consider the terms "gender" and "sex" to be synonymous.[19] According to the human rights campaign, gender is defined as the innermost concept of self as male, female, absence of both, or neither depending on how individuals perceive themselves and what they call themselves. There are many genders outside of just men or women that people can identify with. It can be the same as what was assigned at birth or may be entirely different.[26]

Historically, exclusion of LGBT community from the rest of the society was legalized by section 377 of the Indian penal code in 1860. It took one and a half century to change this law when the Supreme Court of India decriminalized all consensual sex among adults including homosexual sex in 2009 and subsequently in 2018.[27] In a landmark ruling by the Supreme Court of India in 2014, transgender has been recognized as a legal third gender. Transgender people now have constitutional rights to change their legal gender and to register themselves under a third gender following a reassignment surgery.[28] Legislations with regard to same-sex marriage are also emerging. The first marriage in lesbian community was officially recognized by the Gurgaon High Court in 2017.[29] In April 2022, private member's bill was introduced to legalize same-sex marriage under the Special Marriage Act, 1954.[30]

Despite the emerging Indian legislations and strong political movements in favor of LGBT rights, a large section of Indian citizens is yet to come out of the social stigma and generally disapprove such changing practice in the society. In addition, the LGBT community often face violence and discrimination in employment, education, and healthcare services. In 2014, Badgett has reported that 41% of Indians do not want their neighbor to be homosexual and 64% believe that homosexuality is not justified.[31] A public opinion poll in 2019 showed that 25% of Indians were still objecting to same-sex relationship.[32]

In India, when single parents and live-in couples with children are facing burdensome battle, the discrimination against lesbian, gay, bisexual, transgender, or queer (LGBTQ) parents is not even a part of public conversation. The right to parenthood for people of this group is not recognized or accommodated by law or even by society. Most laws and rights that fall in the domain of family law in India including adoption, surrogacy, guardianship, and assisted reproductive therapy are all tied to marriage. Adoption regulation in India, published officially by Central Adoption Resource Authority in 2017 for couple who have been married for at least 2 years, states that a single woman can adopt a child of any gender while a single man is eligible only to adopt a male child and there is no mention about live-in couples, same-sex couples, and transgender individuals. Until April 2022, when LGBT people could not get married legally, they were forced to find all sorts of other ways such as adopting in one partner's name instead of together. Currently, there is no law that unequivocally stops or supports adoption by LGBTQ people in India, and it needs to be more clarified as now the marriage is legal in this group.

The recent ART bill, 2021, strictly says that married heterosexual couple and a woman above the age of marriage can opt for ART treatment. However, single men, cohabiting heterosexual couples, and LGBT individuals and couples have been excluded. The surrogacy bill in 2022 is also far from clear in terms of the legal rights of LGBT individuals who seek treatment for childbirth and parenthood.

SUPPORT GROUPS

In the continued struggle for this particular community throughout the world to get their choice and rights accepted legally and socially, various support groups have had substantial contributions.

LGBT Mummies

The purpose of this organization is to support LGBT women and people globally on the path to motherhood or parenthood. They passionately campaign for LGBT family through their recommendation, training and conversation with government, National Health Service (NHS), corporate and charitable organization to improve support for LGBT families in healthcare, law, and society. They provide guidance on the different family creation pathways through their social media and support groups and also provide access to their global community to meet like-minded families. Their mission is to acquire true equality and equity for LGBT families to that of their heterosexual counterparts.

TwoDads (UK)

This organization commenced operation in 2004 by two male partners who are now dads to three children. They

have their own networks of clinics, surrogacy agencies, family lawyers, surrogacy experts, egg banks, counselors, and regulators.

Pride

LGBT pride is a social group who promotes the dignity and equality of this group of people across the world. Pride supports LGBT-themed organizations and foundations by lending its name.

CONCLUSION

LGBT community is a component of human civilization, which has emerged over past centuries. However, this particular community has been underrepresented in the area of human rights throughout the world. Though there has been a significant revolution with regard to legal and social acceptance of this particular group of the global community, very little has been done so far regarding their fertility options being legalized. In some parts of the world, partnership rights or marriage have been extended to same-sex couples. Advocates of same-sex marriage believe that a range of benefits are denied to unmarried live-in partners. This includes immigration, health care, inheritance and property rights, and other family obligations and protections.

In summary, there has been a distinct paradigm shift in terms of the social existence and enhanced human rights of this group of people globally. New legislations and novel fertility management protocols are evolving which would pave the way forward for this community to fulfill their dream to have a child.

KEY POINTS

- LGBT community forms a minor section of the society.
- This section of people are subjected to social harassment, discrimination, and abandonment by family or friends.
- LGBTQ subjects face challenges while looking for options to have offspring.
- Fertility options for these people are limited but evolving.
- Tailormade medical treatment reinforced by social and administrative support is crucial.

CHAPTER 74

Transgender Population and Fertility

HK Nagaraj, Arjun N

INTRODUCTION

Gender dysphoria is a term used to define the psychological distress experienced by transgender people because of the incongruence between the birth assigned sex and one's gender identity. However, transgender is a term used to denote a person whose birth assigned sex differs from their gender identity.

As per the 2011 census, India's transgender population is around 4.88 lakh. In Karnataka, the total population of transgenders is about 20,266, with a literacy rate of 58.82%. This population has lesser access to jobs, education or community/family support and hence these people are subject to inequality in their social and economic status.

There has been an increased demand for gender affirmation surgery and specialized care to meet the expanding needs for this specific population, but only a small portion of them undergo both chest and genital surgeries. This indicates that the needs of the patient may be varied may it be surgical or otherwise.

GENDER AFFIRMATION SURGERY

In gender dysphoria, gender affirmation surgery is often the last and most considered step in the process of treatment as compared to the other modalities.

It includes a large selection of procedures which can be broadly classified into male-to-female (MTF) or female-to-male (FTM). The most common procedures opted for are given in **Tables 1 and 2**.

TABLE 1: Common surgical procedures for male-to-female (MTF).

Surgical procedures for MTF	***Process***
Chest surgery	Breast augmentation
Genital surgery	Penectomy, orchidectomy, vaginoplasty
Others	Facial feminization surgery, esthetic procedures, hair reconstruction, liposuction/lipofilling, thyroid cartilage reduction

TABLE 2: Common surgical procedures for female-to-male (FTM).

Surgical procedures for FTM	***Process***
Chest surgery	Bilateral mastectomy
Genital surgery	Hysterectomy, salpingo-oophorectomy, metoidioplasty, phalloplasty, vaginectomy, scrotoplasty, insertion of prosthesis
Others	Facial reconstruction, pectoral implants, esthetic procedures

Criteria for Gender Affirmation Surgery

At our institute we follow certain criteria that the patients have to fulfill before they are deemed to be considered for surgery. Any patient who comes for sex reassignment procedures would be referred to the department of psychiatry for diagnosis, counseling and confirmation of gender dysphoria. After the patient has undergone the requisite counseling, letters of recommendation are requested from the mental healthcare professionals for the surgical procedure considered.

Among others, a recommendation letter from one mental health professional is required for chest surgery and letters from two mental health professionals is required for genital surgery.

Hormone therapy is a prerequisite for surgery in the case of genital surgery for a minimum continuous period of 12 months, however not so in the case of chest surgery as per the *WPATH guidelines*.

The two major goals of hormonal therapy are:

1. To reduce endogenous sex hormone levels to reduce the secondary sex characteristics of the individual's designated gender, and

TABLE 3: Hormone regimes for transgender females [male-to-female (MTF)].

Antiandrogens

- GnRH agonists – leuprolide depot – 3.75 mg subcutaneously monthly or 11.25 mg subcutaneously 3 monthly
- If the patient cannot afford GnRH agonists then, the following can be given
- Spironolactone 100–200 mg/day (up to 300 mg)
- Cyproterone acetate 25–50 mg/day

Estrogen

- *Oral estradiol:*
  - Estradiol valerate 2–6 mg/day, initially low doses are started, then increased every 2–3 months
- *Transdermal estrogen:*
  - Estradiol patch 0.025–0.2 mg/d (new patch placed every 3–5 d)
- *Parenteral:*
  - Estradiol valerate or cypionate
    - 5–30 mg IM every 2 weeks
    - 2–10 mg IM every 2 weeks

BOX 1: Hormonal therapy for transgender males [female-to-male (FTM)].

Testosterone:

- *Parenteral testosterone (IM or subcutaneous)*
- Testosterone enanthate or cypionate 100–200 mg every 2 weeks or 250 mg every 3–4 weeks
- Testosterone undecanoate 1,000 mg every 12 weeks

Transdermal testosterone:

- Testosterone gel 1% w/v 5 g: 50–100 mg/d
- Testosterone transdermal patch: 2.5–7.5 mg/d

2. To replace endogenous sex hormone levels consistent with the individual's gender identity by using hormone replacement therapy of the identified gender

The hormone replacement therapy routinely used at our institute is given in **Table 3 and Box 1**.

Additionally, we also get an affidavit done with relevant declarations through the legal process prior to surgery. Below we will discuss a few procedures involved in gender affirmation surgery.

Surgical Procedures in Male-to-Female

This includes breast augmentation, orchidectomy, feminizing urethroplasty, vaginoplasty, etc. **(Table 1)**.

Vaginoplasty includes creation of a neovagina of adequate depth and width which can be done in various techniques. An average depth of around 12–15 cm is achievable by using the penile skin technique. The procedure involves bilateral orchidectomy and creation of the neo-vaginal canal initially. The neovaginal canal is made in a space in-between the urethra along with the bladder superiorly and the rectum inferiorly. The penis is separated into its component parts, after which based on the type of the vaginoplasty, the procedure is taken forward. The skin of the penis is used to

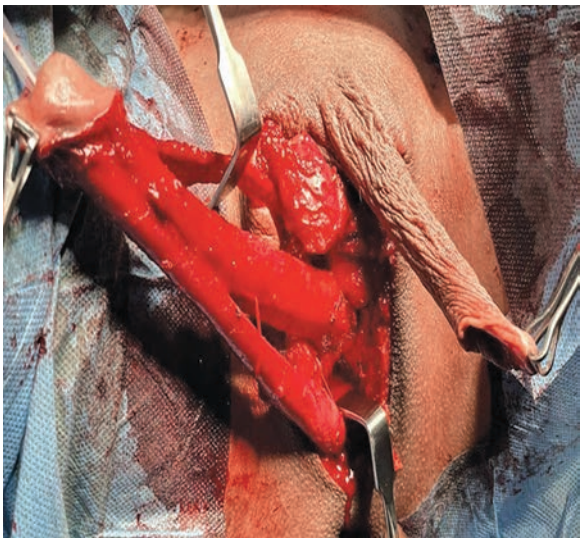

Fig. 1: Components separated showing the penile skin, urethra, corpora cavernosal bundles and neurovascular bundle with glans penis. Retractor showing the neovaginal canal.

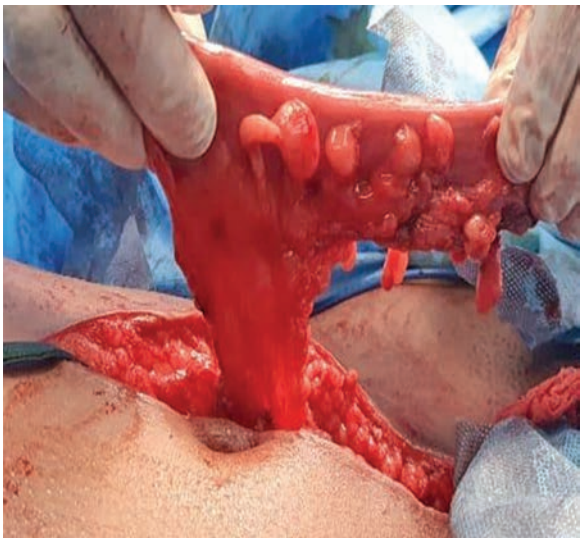

Fig. 2: Colon segment used for vaginoplasty.

cover the neovaginal canal when doing a penile skin inversion vaginoplasty, the urethra is shortened and feminizing urethroplasty is done and the neovascular bundle along with a part of the glans is used to create the neoclitoris.

Vaginoplasty can be done in various methods including the penile skin inversion vaginoplasty as described. Others include using pedicled intestinal segments such as sigmoid colon, ileum, etc. Also we can include a peritoneal or skin flap and partial or full thickness skin grafts for the same among others **(Fig. 2)**.

Reconstruction is done using the available tissue along with the scrotal skin. Postoperatively patients are given vaginal dilators for up to 6 months for regular dilatation of the neo vaginal canal based on the procedure they have undergone **(Figs. 1 to 4)**.

Fig. 3: Neovaginal canal created.

Fig. 4: Vaginal dilators.

Majority of the Indian patients do not opt for a vaginoplasty but only removal of the male genitalia with a feminizing urethroplasty or a zero depth vaginoplasty.

Other Procedures

The other common procedures include breast augmentation which is done either by using breast implants or by fat augmentation, facial feminization surgery, aesthetic procedures, hair reconstruction, liposuction/lipofilling, thyroid cartilage reduction, etc.

Surgical Procedures in FTM

This includes bilateral mastectomy, hysterectomy, salpingo-oophorectomy, metoidioplasty, phalloplasty, etc., as discussed in **Table 2**.

Bilateral Mastectomy (Chest Surgery)

This includes removal of breast tissue bilaterally usually via a periareolar incision, inframammary incision, double incision, transaxillary being some of the methods used.

Fig. 5: Bilateral mastectomy.

The procedure used is dependent on the size of the breast and is evaluated preoperatively and the patient is counseled accordingly **(Fig. 5)**.

Metoidioplasty and Phalloplasty

Metoidioplasty is a one stage procedure for the creation of a microphallus. The patient is required to undergo a minimum of 1 year of hormone replacement therapy prior to the procedure. This ensures an adequate growth of the genital tissues which can be used for reconstruction required for metoidioplasty. Metoidioplasty of an adequate length ensures that the patient can micturate in the standing position. However, it is not adequate for the purpose of intercourse. This can be done with phalloplasty.

Phalloplasty is one of the most challenging procedures in gender affirmation surgery. It involves creation of a neophallus using a well vascularized flap. It can be combined with other procedures such as reconstruction of the urethra, closure of the vaginal canal, creation of scrotum, implants, etc., in a single stage or a two stage procedure.

Various flaps are used for the purpose of phalloplasty including radial artery forearm free flap, anterolateral thigh flap, latissimus dorsi flap, abdominal flap, etc., based on the patient requirements and body habitus. The length of the neo phallus depends on the flap taken.

Below we have described the procedure of a radial artery forearm free flap phalloplasty in brief. The flap was marked as shown. The radial artery and cephalic vein were identified and divided. Centrally, the neourethra was planned as shown and tubularized. This would be connected later on with the native urethra along with tissue obtained from the vagina and labial skin to gain adequate length of the urethra for anastomosis. The flap is wrapped around the neo urethra to form the neophallus. The corona is fashioned on the neo phallus. The neophallus is brought to the recipient site and the neourethra is anastomosed to the native reconstructed urethra over a Foleys catheter. The arterial and venous

Fig. 6: Radial artery free flap marked, raised and tubularized.

Fig. 7: Flap after anastomosis.

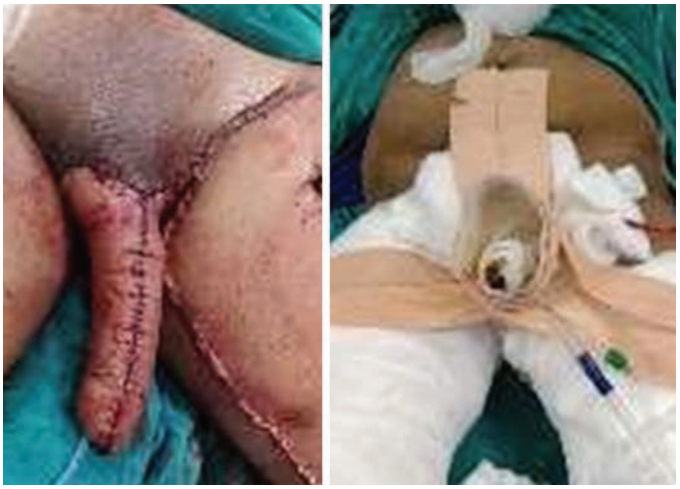

Fig. 8: Created neophallus and dressing.

anastomoses are done. We use a saphenofemoral AV loop, which is made to facilitate the arterial and venous anastomosis. The left ilioinguinal nerve was coapted with the lateral antebrachial cutaneous nerve. The flap inset is completed and the vagina is closed. The donor forearm site is covered with a skin graft. We usually plan for placement of penile and scrotal implants at a second stage **(Figs. 6 to 8)**.

Other Procedures

The other commonly done procedures include hysterectomy with or without bilateral salpingo-oophorectomy which may be done by the open abdominal, vaginal, laparoscopic or robotic method. The other procedures include supplemental or esthetic procedures, facial reconstructive procedures, etc.

COMPLICATIONS OF GENDER AFFIRMATION SURGERY

The purpose of gender affirmation surgery though done regularly comes with a set of complications that the patient has to be counseled and aware of. Depending on the type of surgery the complications may vary. In chest surgeries, the most commonly encountered complications are that of wound infection, necrosis of the nipple areola complex in mastectomy, complications of the breast implants including infection of the implant and capsular fibrosis are seen. In both, scarring may be a significant feature with keloid formation at the incision site in a few.

In genital surgeries, the more serious complications include neovaginal canal stenosis **(Fig. 9)**, rectal or bladder fistulas with the neovaginal canal, urethral stenosis in the case of vaginoplasty. As with phalloplasty, urethral strictures, necrosis of the neophallus and urethrocutaneous fistulas are the more morbid complications usually requiring a second procedure for correction. The above are just a few of the complications encountered during gender affirmation surgery **(Fig. 10)**.

The most common problem in the present scenario arises with patients who undergo these procedures in the hands of surgeons or others who are not trained to do these procedures, those who do not follow guidelines for the same or procedures done at low volume centers. In many cases, there is no diagnosis of gender dysphoria or the patient has not undergone hormone replacement therapy. This leads to a significant morbidity to the patient in terms of a bad

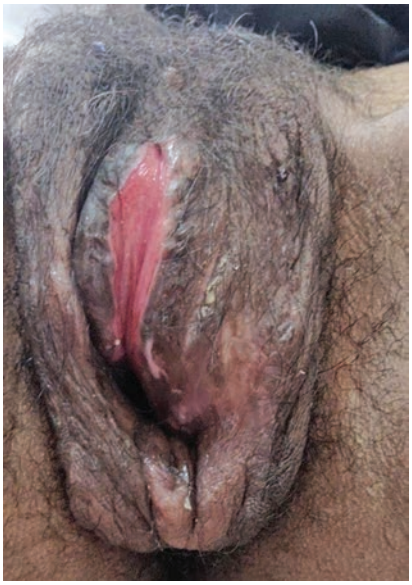

Fig 9: Stenosis of neovaginal canal.

Fig. 10: Necrosis of neophallus.

Fig. 11: Complications of surgery with urethral injury.

reconstructive procedure or long-term implications to the patient for the same. This leads to added procedures, health risks and an additional financial burden to these patients. Most commonly encountered are shown in the images **(Fig. 11)**.

Urethral stenosis is a very commonly seen complication of urethroplasty in gender affirmation surgery. The patients usually realize the thinning of urinary stream with recurrent urinary infections and some patients tend toward home-made solutions for the purpose of urethral dilatation with the use of thin metal rods/wires, clove, hair accessories, etc. The treatment of the same includes urethral dilatation as a temporary procedure or meatoplasty as a permanent measure. An adequate spatulation of the urethra during

Fig. 12: Urethral stenosis with clove inserted by patient for dilatation.

Fig. 13: Urethral injury with stenosis.

Fig. 14: Urethral stenosis postsurgery.

reconstruction with adequate skin flap cover are a few techniques utilized to prevent this complication. The other complications include infection and necrosis of the surgical flaps which require debridement and secondary reconstruction in certain cases **(Figs. 12 to 14)**.

There are incidents in certain patients living within transgender communities wherein they are made to under genital mutilation procedures using knives or other sharp instruments which require an additional reconstructive procedure either in the short- or long-term periods as shown in **Figure 13**.

FERTILITY PRESERVATION

After a patient undergoes orchidectomy or oophorectomy for gender affirmation, fertility is a concern as it causes irreversible effects in the patient. Hence the fertility preservation should be discussed with the patient before they undergo any treatment for the same. The methods of fertility preservation in transgender patients have been discussed here.

Fertility Preservation in MTF Transgender Patients

Hormonal interventions for transgender people down-regulate the HPG axis and the estrogen therapy causes reduced testosterone and in turn reduced sperm count and motility and surgical orchidectomy would be irreversible. Methods for fertility preservation in MTF include sperm cryopreservation. Cryopreservation of testicular tissue for intracytoplasmic sperm injection is an experimental option but feasible in azoospermic men. The collection is ideally done before hormone therapy is started as studies have shown azoospermia in around 75% of men who have been started on hormone therapy after 6 months of use.

Fertility Preservation in FTM Transgender Patients

Embryo and oocyte cryopreservation are first-line methods in postpubertal women. Metaphase II oocyte cryopreservation is the preferred option. Oocyte cryopreservation, embryo

cryopreservation and ovarian tissue cryopreservation are the three methods for fertility preservation in FTM transgender patients of which ovarian tissue cryopreservation is in an experimental stage. Oocyte cryopreservation includes a controlled ovarian hyperstimulation but the patient will need to stop hormone therapy for the same. Embryo cryopreservation is similar to oocyte cryopreservation, but once mature oocytes are retrieved, they are inseminated on the same day to create embryos and then vitrified for future use.

There is a need for further studies in this area with the focus on transgender population. With breakthrough examples such as uterine transplantation in the field of reproductive medicine which has been proven to be successful in a controlled setting, there is a need for detailed discussion with the patient regarding fertility preservation prior to the commencement of any therapy for gender dysphoria.

CONCLUSION

Gender dysphoria and gender affirmation surgery involves multiple considerations which may be different for each individual. It is necessary to be aware of the options available and the protocols to be followed so that proper guidance can be given in this aspect.

KEY NOTES

- There is an increasing awareness for gender dysphoria with an increasing population of transgender patients requiring specialized treatment.
- Gender affirmation surgery is always followed by the diagnosis of gender dysphoria with relevant counseling and hormone treatment when necessary.
- The main modality of fertility preservation in MTF is sperm cryopreservation.
- Fertility preservation in FTM mainly includes oocyte cryopreservation, embryo cryopreservation and ovarian tissue cryopreservation.

Outcome Following Assisted Reproductive Technique

CHAPTER 75

Maternal and Fetal Outcomes Following Assisted Reproductive Technique

Navya V, Amit J Upadhyay, Kamini A Rao

INTRODUCTION

Infertility is defined as an inability to conceive after 1 year of attempting pregnancy.[1] Infertility itself acts as an independent predictor of adverse pregnancy and perinatal outcomes.[2-4] Assisted reproductive techniques (ARTs) contribute to 1.4–7% of total pregnancies.[5] ART helps couples suffering from primary or secondary infertility.[6] But nowadays, it has been extended to help patients undergoing gonadotoxic treatments for fertility preservation,[7] to help same-sex couples, single women, and men to conceive and have their biological children,[8] and to facilitate the services of surrogate gestational carriers. The global incidence of multiple pregnancies is on the rise due to ART and advancing maternal age.[9,10]

The ART involves any procedure which includes handling of human gametes outside a body such as in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), cryopreservation, donor gamete usage, assisted zona hatching (AZH), preimplantation genetic screening (PGS), and intrauterine insemination (IUI).[11] In the initial days, success of ART was a primary concern now with an exponentially escalating number of children born through ART poses multiple challenges on maternal as well as fetal outcomes.

POSSIBLE CAUSES OF ADVERSE OUTCOMES AT VARIOUS LEVELS

- Specific IVF-related outcomes **(Table 1)**[11]
- Perinatal risks
  - Multiple gestations
  - Preterm birth
  - Low birth weight and small for gestation age (SGA)
  - Congenital anomalies
  - Perinatal mortality
- Long-term outcomes of children
- Other maternal morbidity
  - Maternal age
  - Recipients of donor oocytes
  - Polycystic ovary syndrome (PCOS).

ADVERSE OBSTETRIC AND PERINATAL OUTCOME IN COUPLES WITH DELAY IN TIME TO PREGNANCY BUT WITHOUT ANY TREATMENT

Approximately, one in seven couples experiences a certain period of subfertility during their reproductive life.[12] About 50% of these couples have chances of conceiving spontaneously whereas others may require some or other form of infertility treatment.[13-15] The chances of having high obstetric and perinatal adverse outcomes are more in subfertile population when compared to women who are fertile.[16,17] There are evidences showing the increased risk of obstetric complications and interventions in women with subfertility, which are independent of age, parity, and fertility treatment. The risk of preterm delivery and low birth weight is high among ART-born babies.[18] In comparison with women in the general population,

TABLE 1: Specific in vitro fertilization-related outcomes.[11]

At gamete level	*At embryo level*	*At embryo transfer level*	*At endometrial level*
• Maternal and paternal age • Environment • Genetics • Male factor • Ovarian stimulation • In vitro maturation	• Culture systems • Assisted hatching • Blastomere biopsy	• Number of embryos transferred • Day of transfer • Quality • Cryopreservation • Imprinting disorders • PGD/PGS	• Endometrial receptivity • Placentation • Maternal health • Uterine environment • Gestation order

(PGD: preimplantation genetic diagnosis; PGS: preimplantation genetic screening)

there is a twofold increased risk of preeclampsia, placental abruption, cesarean section and vacuum extraction, and a fivefold increased risk of placenta previa in spontaneous singleton pregnancies in women with a history of infertility.[18]

MULTIPLE PREGNANCY AND ADVERSE OBSTETRICAL AND PERINATAL OUTCOMES

Multiple pregnancy is the most debatable issue associated with ART. Multifetal gestations are considered as high-risk pregnancies with higher perinatal morbidity and mortality rate. The prime determinant of pregnancy and its long-term sequelae depends on whether the pregnancy is a singleton or multiple gestation, irrespective of whether it is a natural or assisted conception.[19,20]

Worldwide, there is a drastic increase in the multiple-order births associated with advancing maternal age due to increased focus on career orientation and seeking fertility treatment.[21,22] Following ovulation induction with drugs and controlled ovarian hyperstimulation, multiple gestation rates range between 5 and 40%.[23] The 2011 published rate of multiple pregnancies as a result of IVF reported by the Canadian Assisted Reproductive Technologies Register (CARTR) in Canada is approximately 30%.[24]

The risk of adverse outcomes increases with high-order gestation and even worsens with monozygous gestation as it poses two- to threefold increased risk when compared to natural conceptions although the incidence of monozygotic twins, even after IVF, remains very low.[25]

Approximately, monozygotic twinning (meaning having a monochorionic placentation) accounts for 0.4% of live births among pregnancies which are conceived spontaneously when compared to 0.9–2% of IVF pregnancies.[25-27] The percentage of monozygotic twinning is almost 6% after transferring day 5 blastocyst in IVF pregnancies when compared to day 3 cleavage embryo transfer which accounts for 2%.[28]

One of the recent systematic reviews in 2009 compared the live birth rate of elective double embryo transfer (DET) with that of elective single, triple, or quadruple embryo transfer. The review concluded that a single cycle of elective single embryo transfer (eSET) resulted in a lower live birth rate than DET, but that the cumulative live birth rate in a fresh eSET cycle followed by a frozen eSET was not significantly different from a single DET cycle.[29]

A meta-analysis by Grady et al. in 2012 compared perinatal outcomes between DET and eSET pregnancies. eSET is associated with decreased risks of preterm births and low birth weight compared with DET but poses a high risk when compared to singleton pregnancies conceived spontaneously. They found a randomized controlled trial (RCT)-based relative risk of 0.37 (0.25–0.55) for preterm birth <37 weeks and an RCT-based relative risk of 0.25 (0.15–0.45) for birth weight <2,500 g in the eSET group.[30]

As evidence in the literature shows, there may be a sevenfold increase in mortality among twins and 20-fold increase in mortality among triplets when compared to singletons.[31-33] The risks of perinatal mortality, growth restriction, cerebral palsy, and congenital anomalies are also increased in multiple-order gestation than in singletons, not only in monochorionic twins but also in dichorionic twins.[22,34,35]

Multiple-order gestation involves higher perinatal complications including fetal anomalies, fetal demise, intrauterine growth restriction, prematurity, polyhydramnios, and oligohydramnios.[36]

Some rare complications such as twin oligohydramnios-polyhydramnios sequence (TOPS), twin-to-twin transfusion syndrome (TTTS), acardiac twins, conjoined twins, co-twin demise, and heterotopic pregnancies, which affect both maternal and perinatal outcomes negatively, are seen with multiple gestations.[37]

Nowadays, adopting eSET in assisted reproductive technologies demonstrates a rapid downfall in unnecessary complications to mother such as preeclampsia and cerebral palsy for fetus.[38]

PRETERM DELIVERY

Various meta-analyses in the literature showed that singleton pregnancies born through assisted reproductive technologies after single-embryo transfer or multiple-embryo transfer are 1.8–2.1 times more prone to the risk of preterm delivery when compared to pregnancies which are conceived spontaneously.[39-42]

De Neubourg et al. study compared single-embryo transfer versus spontaneous singletons, which found a 10% risk of preterm delivery in the single-embryo transfer group compared to a 6.8% risk among spontaneously conceived singletons.[43]

Hayashi et al. concluded that infertility itself is a risk factor of preterm delivery and also there is no significant difference in the risk of prematurity between various methods of infertility treatment groups such as ovulation induction, IUI, and IVF. He also derived a conclusion that prematurity risk is more in the infertility-treated singleton groups in comparison to singletons born in fertile groups.[44]

According to Adam et al. study, the production of high levels of steroid hormones and other protein peptides resulting after ovarian stimulation during IVF also increases the risk of prematurity, hence performing an embryo transfer in artificially prepared luteal cycles after cryopreservation of embryos was shown beneficial. Along with ovarian steroid hormones, maternal serum relaxin, which is produced from the corpus luteum also known to be increased after controlled superovulation, which is associated with an increased risk of preterm delivery in singleton.[45]

In view of Maheshwari et al., there is a lower risk of preterm deliveries in singleton pregnancies conceived with frozen embryo transfer when compared to fresh embryo transfer cycles. In this study, following frozen thawed transfer, singleton pregnancies were 16% less likely to deliver before 37 weeks in comparison to those pregnancies following fresh IVF cycles.[46]

Therefore, it is well documented that ART singleton pregnancies have a little increased risk of preterm compared to singleton from spontaneous conceptions. Preterm birth after ART is considered as a syndrome with multifactorial etiology.

LOW BIRTH WEIGHT

In the literature, all systematic reviews showed that IVF pregnancies are associated with low birth weight babies.[40,42,47-49] Sazonova et al. performed logistic regression analysis between 2002 and 2006 on 8,941 singleton pregnancies, and four major outcomes were investigated such as very preterm birth, SGA, placenta previa, and placental abruption. Maternal factors such as age, parity, body mass index (BMI), smoking, and years of infertility and other variables such as number of oocytes retrieved, number of embryo culture days, number of transferred and cryopreserved embryos, and "vanishing twin" were studied and it was concluded that primiparity, smoking, BMI, and the vanishing twin phenomenon increased the risk of preterm birth and that maternal age, smoking, BMI, and duration of infertility increased the risk of low birth weight.[50]

Various studies compared fresh versus cryopreserved embryos, which showed that frozen embryo transfers result in higher birth weights and decrease the chances of low birth weight infants in addition to preterm births.[51-54] A systematic review analyzed that the risk of low birth weight can be unchanged or improved with frozen embryo transfers whereas the risk of preterm births is either unchanged or decreased.[55]

An interesting study of 292 singletons examined serum estradiol levels during IVF cycles adjusted for patient's age, BMI, parity, number of embryos transferred, day of transfer, and gonadotropin dose, and high serum estradiol levels (>3,450 pg/mL or >90th percentile) were associated with preeclampsia [odds ratio (OR) 4.8; 95% confidence interval (CI) = 1.6–14.8] and SGA (OR 9.4; 95% CI = 3.2–27.5).[56]

The most recent data from a cohort of 25,777 births documents a significant difference in birth weight of 90.9 g in singletons conceived in frozen versus fresh transfer cycles.[57] The Society for Assisted Reproductive Technology (SART) report comparing 60,037 standard IVF cycles with 10,176 donor egg cycles and 1,180 gestational carrier cycles found an adjusted odds ratio (aOR) of 1.21 (95% CI = 1.13–1.30) for birth weight <2,500 g and 1.28 (95% CI = 1.10–1.49) for birth weight <1,500 g when comparing donor egg with autologous egg IVF cycles.[58]

PERINATAL MORTALITY

A prospective follow-up study of 20,166 singleton pregnancies at Denmark compared the risk of stillbirths between fertile women, subfertile women (time to natural conception >12 months), and women pregnant after fertility treatment (IVF and non-IVF ART).[59] Women who conceived with IVF had a statistically significant fourfold increased risk of stillbirth as compared with fertile women. However, this is in contrast to the findings from three studies of perinatal mortality in singletons conceived naturally following a prolonged time to conception, which found a two- to three-fold increased risk of perinatal death compared with singletons naturally conceived without a prolonged time to conception.[60-62]

OTHER OBSTETRICAL OUTCOMES

A prospective cohort study that included 1,000 ART pregnancies when compared to 2,593 spontaneously conceived pregnancies, where all women were screened for first-trimester screening, showed that false-positive rates in ART groups were significantly higher when compared with the control population which is 9 versus 6%.[63]

Other adverse outcomes of ART conceptions include the placentation abnormalities, which indirectly lead to low birth weight babies, preeclampsia, abnormal placentation, placenta accreta, antepartum hemorrhage (APH), and postpartum hemorrhage. One of the retrospective studies showed that the association of placenta accreta and IVF pregnancies, which showed higher chances of developing the same in IVF pregnancies, may be related to the altered endometrial environment, repeated curettages, advanced maternal age, and multiparity.[64]

A large retrospective cohort study between 1990 and 2004 in Australia compared the occurrence of placental conditions such as placenta previa, placental abruption, APH, and primary postpartum hemorrhage in women, 6,730 IVF/ICSI cycles versus 24,619 general population, 2,167 non-ART population, and 779 gamete intrafallopian transfer (GIFT). Logistic regressions and exploratory analysis showed that obstetric hemorrhages are common in IVF, ICSI, and GIFT cycles which can be attributed to the defective endometrial environment around implantation due to fresh embryo transfers in controlled stimulated cycles, endometriosis, and hormone treatments.[65]

Postpartum depression is another outcome, which is significantly increased in a group of pregnancies conceived with ART, showed by a systematic review. Small study samples and a lack of psychiatric history lead to further research in this area.[66]

The procedures such as induction of labor, operative deliveries, cesarean sections, perinatal complications, neonatal deaths, and neonatal intensive care unit (NICU) admissions tend to be more associated with the ART conceptions, which can be explained with the occurrence of maternal complications such as APH and preeclampsia.[67]

CONGENITAL ANOMALIES

Among 3–5% of total congenital anomalies are associated with ART pregnancies which contribute to 30–40% more in comparison with natural conceptions. Common anomalies include gastrointestinal, cardiovascular and musculoskeletal, cardiac septal defects, etc.[47,68,69]

According to one retrospective cohort study in IVF/ICSI cycles, the prevalence of cardiac septal defects is around 1.1% more when compared to spontaneously conceived infants, which was around 0.4% which can be attributed to an increased BMI of >30 kg/m^2.[70]

Meta-analysis showed that there is no difference in occurrence of congenital anomalies between IVF and IVF/ICSI pregnancies.[71]

CHROMOSOMAL DISORDERS

Compared to ART pregnancies as a whole, the rate of occurrence of chromosomal anomalies is around 0.2% in spontaneously conceived pregnancies, and in IVF/ICSI cycles, it is around 1%.[72]

Women conceived with ICSI are at a higher risk of chromosomal aberrations, including sex chromosomal abnormalities; hence, diagnostic testing should be offered after appropriate counseling.

Various studies observed that there are no major significant differences between nuchal translucencies among ART pregnancies and spontaneously conceived pregnancies.[73]

IMPRINTING DISORDERS

Nowadays, with increasing technology, industrialization, career orientation, advanced maternal age, and availability of ART techniques everywhere, the percentage of babies born through ART was around 1.7–4%.

Imprinting is a process of modification of complete deoxyribonucleic acid (DNA) structure by methylation or histone that occurs over a period of time by which that gene becomes nontranscriptable but with no alteration in actual DNA coding sequence **(Table 2)**.[74-76]

Most probable mechanisms include the composition of media, culture conditions, gas phase in incubators, oil overlay, superovulation, hypomethylation of maternal and paternal genes, underlying conditions of infertility, etc.[77]

Due to reduced imprinting gene activity leading to dysregulation in tumor suppression causing malignancies in later stages of life has to be followed up with long-term follow-up studies.[76]

TABLE 2: Human phenotypes identified and associated with imprinted genes.[76]

Maternal and paternal uniparental disomy	2, 14, 16
Turner	X

PREIMPLANTATION GENETIC SCREENING

Preimplantation genetic screening is a procedure where an adequate number of blastomeres are taken for biopsy to study the whole genome. The role of most recent advances, which include PGS/PGD (preimplantation genetic diagnosis) usage in indicated cases such as increased maternal age, recurrent miscarriage, repeated IVF failures, and testicular sperm extraction using the latest technologies such as whole genomic analysis using comparative genomic hybridization which studies all sets of chromosomes to detect the aneuploidy rates to be done in large samples of population, are required to know the long-term effects. One of the recent reviews showed that there is no significant difference found in birth weights and major anomalies among infants born after PGS.[78]

BLASTOCYST CULTURE

According to systematic review and meta-analysis, the probability of having a live birth is almost 40% higher with blastocyst transfer when compared to cleavage transfers.[79] Monozygotic twinning is considered to be one of the common complications after blastocyst transfer. According to Papanikolaou et al., the monozygotic twinning is not increased after a single blastocyst transfer when compared with a single cleavage transfer.[80-82] Some other authors concluded that there is an increased risk of monozygotic twinning after blastocyst transfer.[83] However, the reason might be related to the usage of various culture media during ART. In the near future, to avoid complications, eSET will be an effective option.

However, blastocyst transfer ensures good embryo selection and also encourages single embryo transfer. Two systematic reviews and meta-analyses on perinatal outcomes after blastocyst versus cleavage embryo transfers

which included >100,000 singletons born with fresh cycles found that preterm, very preterm, and SGA babies are comparatively less with blastocyst transfer.[80-82]

FRESH VERSUS FROZEN

According to recently published randomized controlled studies which compared fresh versus frozen embryo transfer; the mean birth weight, preterm birth, and birth defects were same in both groups, but while safety is concerned, elective frozen embryo transfer (eFET) significantly reduces the risk of moderate-to-severe ovarian hyperstimulation syndrome.[80-82]

Cryopreservation techniques reduce the risk of ovarian hyperstimulation syndrome, and an effective synchronization between the embryo and endometrium is possible, thus reducing the incidence of prematurity.

VITRIFICATION VERSUS SLOW FREEZING

There were no significant negative effects of either of the cryopreservation techniques except for a slight risk of preterm deliveries with vitrification. However, vitrification or ultrarapid cryopreservation method seems to be reassuring.[80-82]

ASSISTED HATCHING

Sometimes, because of the inability of blastocyst to escape from its thick shell called zona, implantation failure and conception may result. Assisted hatching is a procedure where an aperture is created in zona which facilitates the embryo to get implanted. This method appears to increase the clinical pregnancy rate whereas the live birth rates and take-home baby rates are yet to be proven. Long-term sequences are yet to be studied in larger study groups.[84,85]

IN VITRO MATURATION

In vitro maturation (IVM) is a process where immature oocytes are collected and cultured in vitro to change them to metaphase II oocytes, and then ICSI is conducted. This procedure has a promising role in fertility preservation, patients with PCOS, etc. As the number of babies born through IVM worldwide are less, their long-term their long-term sequences are yet to be reported. As such, there are no major significant neurological disturbances noted in children born with IVM in the study reported by Söderström-Anttila et al.[86-88]

Intracytoplasmic Sperm Injection versus In Vitro Fertilization

Some researchers strongly believe that ART complications are due to many manipulation factors such as using ovulation induction drugs, addition of many nonphysiological operations in ART, composition of culture medium, storage time in culture medium, freezing process of the embryo, and blood levels of hormones at the time of implantation; these factors play a role in pregnancy outcomes.[87,88]

LONG-TERM CONSEQUENCES IN ASSISTED REPRODUCTIVE TECHNIQUE BORN CHILDREN

According to many studies, there is no significant difference between language, neuromotor skills, and cognition among children born from ART when compared to naturally conceived children.[89]

Ceelen et al. reported various cardiometabolic diseases, variations in systolic and diastolic blood pressures, and fasting sugars among children born through ART.[90]

Therefore further studies are mandatory which include adolescents and adults born through ART studying various metabolic disorders, cardiovascular disorders, obesity, etc.

OTHER MATERNAL FACTORS WHICH INFLUENCE THE OUTCOME

In this modern era, with the increase in the average age of marriage and conception increases, maternal and perinatal complications have increased too. Complications which may be related to infertility, miscarriages, APH, postpartum hemorrhage, operative deliveries, pregnancy-induced hypertension, and gestational diabetes may increase. As comorbidities improve along with age, pre-IVF counseling and screening should be offered in routine for couples opting for ART.

Polycystic ovary syndrome being one of the main causes of infertility poses a long-term risk for diabetes, cardiovascular disorders, obesity, neonatal complications including preterm births, low birth weight babies, increased perinatal mortality, operative deliveries, cerebral palsy, etc. Hence, this mandates a very well-explained thorough preconceptional counseling for women who are associated with PCOS and emphasis is to be imposed on lifestyle changes and weight management.[91]

With increasing usage of donor, oocyte programs among women with increased maternal age, and premature ovarian failures, an increased risk of maternal and perinatal complications is seen; however studies has to be done to show the longterm sequelae of children born after ART.[92]

Barker's hypothesis showed that baby's nourishment before birth and during infancy manifests in patterns of fetal and infant growth and may program the various risk factors such as raised blood pressure and glucose intolerance which are the key role players of coronary heart diseases **(Fig. 1)**.[93,94]

Preexisting maternal medical conditions were present in 15.1% of women, with a consistent increase from 9.7% in women <31 years old to 27.8% in women >40 years.

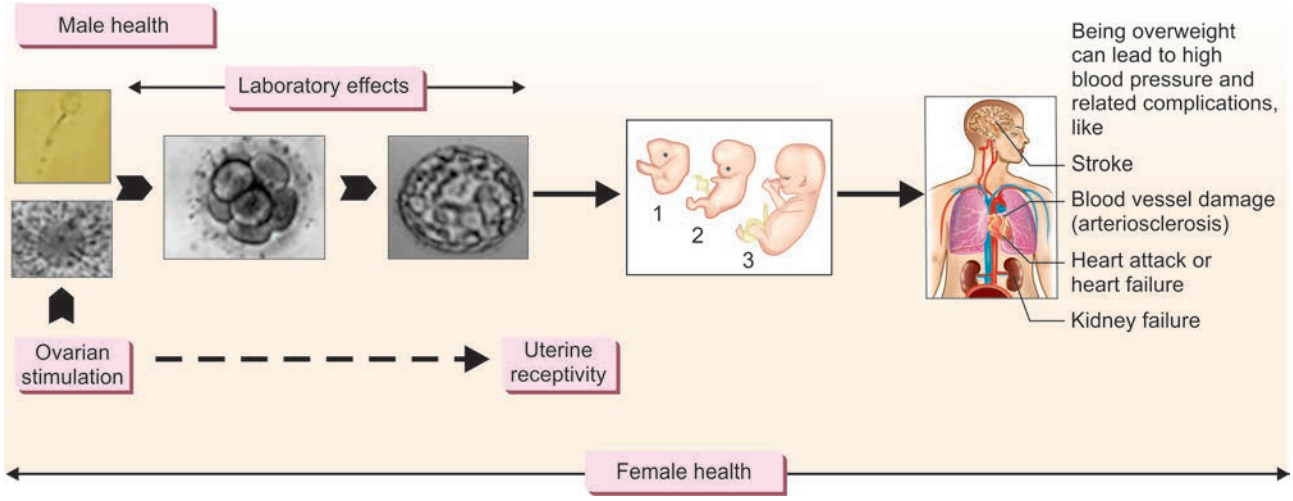

Fig. 1: Barker's hypothesis.[93,94]

INTRACYTOPLASMIC SPERM INJECTION WITH EJACULATED VERSUS NONEJACULATED SPERM

The evidence shows that there is no major difference in the rate of birth defects in children conceived with ICSI using non-ejaculated sperm compared with ICSI using ejaculated sperm.[95]

Genetic counseling plays a pivotal role in those individuals who have oligozoospermia, azoospermia, aspermia, etc.

KEY POINTS

- As ART is always evolving because of its dynamic and ever-changing nature, there will be newer developments at each and every step.
- ART poses a clear high risk of adverse perinatal and maternal outcomes; proper counseling about IVF, the risks involved in it, and assessment of risk during the antenatal period with an apt time of referral are very important.
- Constantly ongoing studies on larger populations are always required, and continuous fine-tuning of the technologies and its application become mandatory.
- Continuous supervision after ART is needed to ensure safety and quality, especially when new techniques are introduced.
- In conclusion, women who undergo ART may have an increased risk of obstetric and perinatal outcomes due to multiple pregnancies; hence, eSETs are strongly recommended.

CHAPTER 76

Early Pregnancy Scan

Srividhya GK

INTRODUCTION

The availability of the modern ultrasound technology has increased the understanding of early pregnancy development and antenatal management. The high-frequency transvaginal probe improves the image quality in such a way that detailed imaging of the embryonic morphology has become possible. Early human embryo changes its anatomical appearance rapidly with uniform development and continuous growth. Hence, first trimester defines the most critical period of human development.[1]

The duration of first trimester is from conception up to 12 weeks of gestation. The accurate method to calculate the duration of pregnancy is by knowing the date of conception. As most women are not aware of the date of conception, the last menstrual period (LMP) date is noted to calculate the gestational age (GA) and expected date of delivery (EDD). The embryological age of the gestation is calculated from the conception date and is usually 2 weeks less than the menstrual age.[2]

Ultrasonography is used in the first trimester for the pregnancy confirmation, its location, molar pregnancy, first-trimester vaginal bleeding, or pain in the abdomen, to determine the GA, to assess multiple gestations and its chorionicity, to assess fetal viability, as an adjunct to invasive procedures such as chorionic villus sampling (CVS) and fetal reduction, and to evaluate adnexal masses or uterine abnormalities. The diagnostic ultrasound is considered safe during all trimesters of pregnancy and has no harmful bioeffects demonstrated. However, a fundamental principle for the safe usage of ultrasound is to use the lowest power output and the shortest scan time for acquiring the required diagnostic information. This is called ALARA principle (i.e., as low as reasonably achievable). The serum beta-human chorionic gonadotropin (β-hCG) levels and ultrasonography make the diagnosis of pregnancy more specific and help in identifying women with abnormal or high-risk pregnancies.[3] Furthermore, with the introduction of three-dimensional and four-dimensional ultrasound, the fetal embryological developments are still more accurately documented.[3]

It is important to understand normal development and to appreciate the rapid and critical sequential changes that are occurring and thus helps us to identify normal and abnormal sonographic findings in early pregnancy.

NORMAL SONOEMBRYOLOGY

Sonoembryology is defined as the description of the normal embryonic anatomical relations as visualized by ultrasound. To make the diagnosis of an anomaly, the knowledge of the normal embryonic development is needed. The GA is subclassified into distinct gestational periods. The first 2 weeks of prenatal development are referred to as the *preembryonic stage*. The conceptus phase is from 3 to 5 weeks, embryonic phase is from 6 to 10 weeks, and fetal phase is from 10 weeks onward.

First 3 Weeks of Development

The duration of pregnancy from the LMP is an average of 280 days to delivery. This period consists of:

- *Ovulation and oocyte migration:* The oocytes fertilize in the tube within 24 hours of ovulation.
- Fertilization and zygote migration
- *Implantation:* It is the process of attachment and invasion of the endometrium by the blastocyst (conceptus). Implantation occurs about 9 days after ovulation, ranging between 6 and 12 days. hCG produced by the trophoblasts enters the maternal circulation approximately 2 weeks postconception.

On ultrasound, a gestational sac develops after implantation.

- *Gastrulation:* The inner cell mass forms and it consists of two layers—an upper epiblast and a lower hypoblast. Gastrulation converts this bilaminar disk into three layers: (1) Upper ectoderm, (2) middle mesoderm, and (3) lower endoderm **(Fig. 1)**.

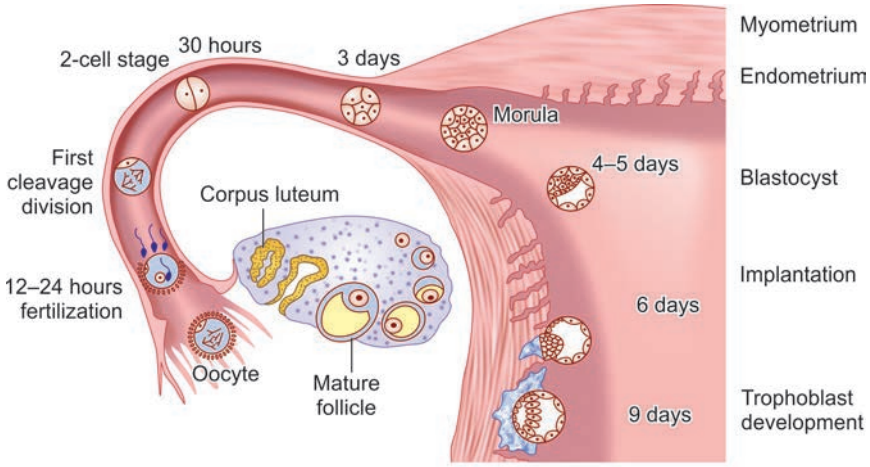

Fig. 1: Sequence of ovulation, fertilization, and early development of the embryo.

FIRST-TRIMESTER ULTRASOUND: NORMAL LANDMARKS

The chronologic developmental features of the embryo or fetus are well defined in an orderly manner like the visualization of gestational sac, then the yolk sac, and then the embryo with heartbeat at a given number of days from the onset of the LMP. These features help us in identifying the structural defects as early as the first 12 weeks of pregnancy. These can be identified during the first-trimester scan, thus differentiating the pregnancy into a normal and at-risk pregnancy **(Table 1)**.

Gestational Sac

Gestational sac is seen as a round, fluid-filled area with echogenic rim. The central fluid is the chorionic cavity, and the echogenic rim is due to the chorionic decidual complex. The growth rate of the sac is 1 mm/day. The sac is usually round in shape initially and later becomes oval. The gestational sac measurements are taken as the mean sac diameter (MSD). The measurements from three orthogonal planes [anterior–posterior (AP), transverse, and longitudinal] are averaged. The calipers are placed at the inner margin of the sac for measuring the MSD **(Figs. 10A to C)**. It is measured in all pregnancies <10 weeks of gestation. The GA can be calculated by using MSD when the pregnancy is <6 weeks of gestation or until the crown–rump length (CRL) is seen. There is a percentile graph available for the gestational sac at different GA.[4,5]

The sac must be distinguished from other cystic areas seen in the cavity, such as nabothian cyst in the upper cervix, decidual cyst, decidual cast, or pseudogestational sac (hypoechoic cystic area in the cavity without echogenic rim due to fluid). The sac may become irregular in shape due to fibroid uterus, focal myometrial contraction, large subchorionic hemorrhage (SCH), and distended bladder.[3]

The lowest β-hCG level by which a normal intrauterine sac is possibly visible is called *threshold level*. The level of β-hCG above which a gestational sac should be visualized is called *discriminatory level*. Nyberg et al. described the discriminatory level as 1,000 mIU/mL for a transvaginal scan (TVS).[5]

Yolk Sac

During early pregnancy, the yolk has nutritive, metabolic, endocrine, immunological, and hematopoietic functions. It is a well-defined echogenic rim with anechoic center and is round in shape. It identifies the true gestation sac. The yolk sac is seen by TVS by 5–6 weeks of GA and when the sac diameter is 8 mm. The yolk sac normally grows 0.1 mm/day to a maximum of 5 mm **(*see* Figs. 10A to C)**.[3]

Embryo

The embryo is initially seen as an echogenic line next to the yolk sac by 5 weeks. It is measured from crown to rump and termed "crown–rump length" (CRL)," the most precise method for assessing the GA in the first trimester. The fetal pole should always be seen when the sac is around 25 mm.

An amniotic sac separates the embryo from the extraembryonic celom (chorionic cavity), and the obliteration of the celomic cavity happens by 14–16 weeks. There is a proportional growth of the chorionic cavity, amniotic cavity, and CRL in normal gestation till about 10 weeks of gestation. Later, the fetal urine production disproportionately enlarges the amniotic cavity, and hence obliteration of chorionic cavity. The percentile chart for the CRL and GA is available in the literature and has to be used to assess the fetal growth.

Embryonic morphology is featureless till about 7–8 weeks. At approximately 8 weeks of gestation, the cranial portion is well defined and thus differentiated from the body. The rhombencephalon (which develops into hindbrain) is an important structure seen at >7 weeks of gestation. It is seen

TABLE 1: Embryonic developmental landmarks and sonoembryology.

Sonoembryology	***Embryonic developmental landmarks***
 **Figs. 2A and B:** (A) Formation of the mesoderm after implantation; (B) On ultrasound, small gestational sac with good choriodecidual reaction seen within the endometrium.	*Menstrual age—4th week* **(Figs. 2A and B)**: • The first feature on ultrasound is the presence of a decidualized endometrium with vascular corpus luteum • A small regular and spherical sac seen in the mid-to-upper uterine cavity. (approximately 2–5 mm in size) • The threshold value for the gestational sac to be seen on TVS is when the beta-human chorionic gonadotropin values are 1,000 mUI or above
 **Figs. 3A to D:** (A) The mesodermal migration around endodermal pouch creates yolk sac; (B to D) On ultrasound, gestational sac appears regular with echogenic trophoblastic rim and a small yolk sac is seen within.	*Menstrual age—5th week* **(Figs. 3A to D)**: • MSD is around 7–10 mm in size • Yolk sac (YS) is visible • The embryo appears as a thickened linear structure adjacent to the yolk sac ("=" sign) and measured as crown–rump length (CRL). The embryo appears more echogenic when the size is around 2 mm – Cardiac activity can be seen within the embryo on real-time imaging
 **Figs. 4A to C:** (A) The embryonic disk bulges into the amniotic cavity at the head fold; (B) On ultrasound, fetal pole is well visualized and measured as CRL. Fetal pole and yolk sac appear floating in the chorionic cavity; (C) FHR increases with gestational age.	*Menstrual age—6th week* **(Figs. 4A to C)**: • The fetal pole can be easily identified and it measures around 2–4 mm in length • Cardiac activity when measured at this gestation is around 90–120 BPM • The fetal pole and YS appear floating in the chorion cavity • The fetal pole needs be seen when the MSD is of 18 mm (on TVS) and 25 mm (on TAS) • The fetal pole is measured as crown–rump length (CRL) • The embryo grows at the rate of around 1 mm/day

Sonoembryology	***Embryonic developmental landmarks***
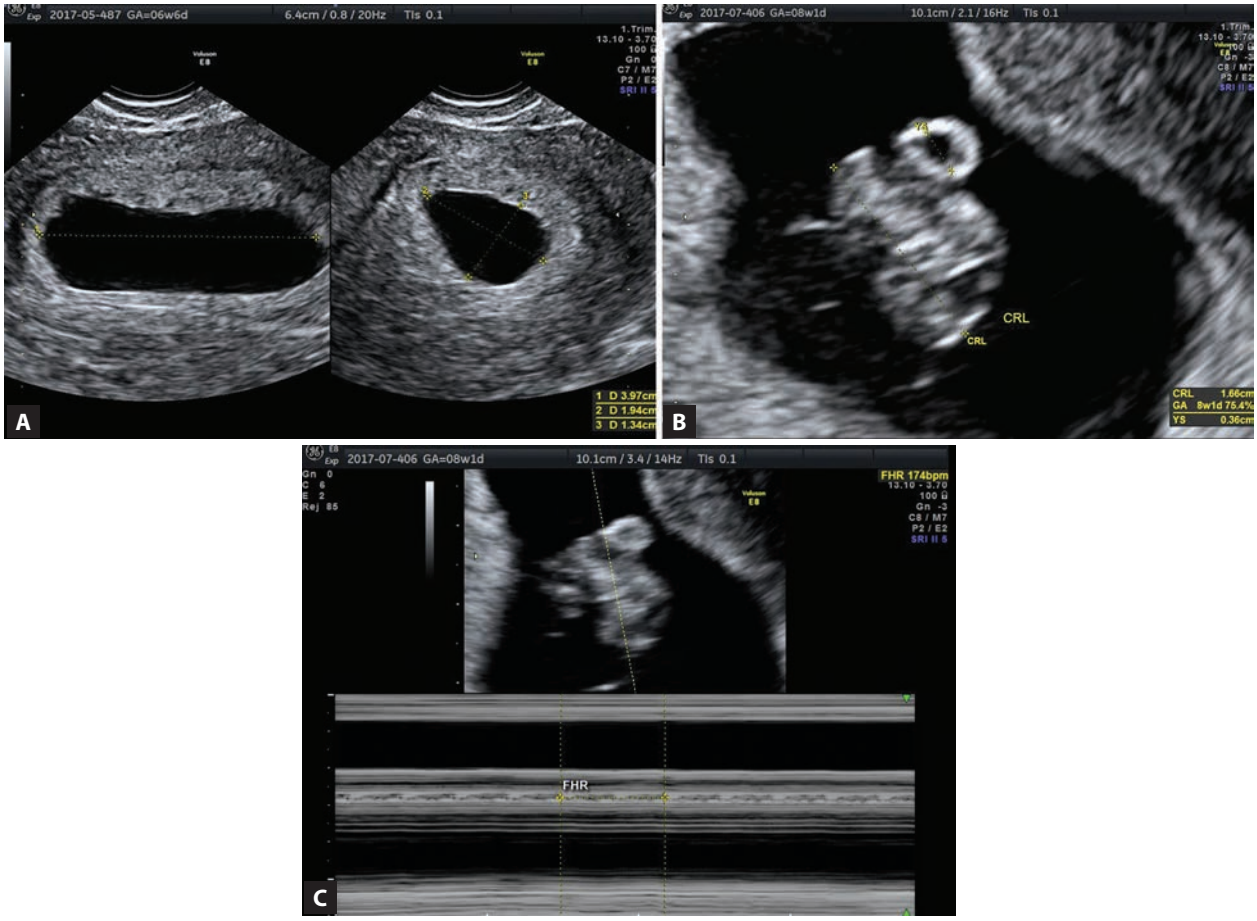
 **Figs. 7A and B:** On ultrasound, (A) Cephalic portion is about one-third of the body. Fetus is seen within the amniotic cavity and the yolk sac within the chorionic cavity; (B) The limb buds increase in length and the hand and feet are distinct now.	*Menstrual age—9th week* **(Figs. 7A and B)**: • CRL measures around 23–32 mm • The limb buds increase in length and the hand and feet are distinct now • FHR increases to 170–180 BPM • The cephalic portion is about one-third of the body. The echogenic falx and choroid plexuses are prominent in the cranium • Distinct frequent body movements are seen
 **Figs. 8A and B:** (A) Amniotic cavity rapidly expands and fills the uterine cavity. Fetus is connected to the placenta by cord; (B) On ultrasound, CRL is measured in sagittal section.	*Menstrual age—10th week* **(Figs. 8A and B)**: • The fetus grows and fills around one-third of the sac space • CRL is around 32–41 mm and the craniocaudal curvature becomes more • The lateral ventricles are completely filled by choroid plexus • The three segments of the limbs are well defined
 **Figs. 9A and B:** (A) Ultrasound image of the fetus in mid-sagittal section with magnification of head and thorax portion and measurement of the NT; (B) 3D image of the fetus.	*Menstrual age—11–13 + 6 weeks* **(Figs. 9A and B)**: • The CRL is >42 mm at around 11 weeks and reaches to about 76 mm by 13 weeks • Detailed anatomical survey is done, the cerebral, cardiovascular systems, digestive and urinary tracts. Stomach, bladder, and the kidneys are visible. The hernia returns into the abdominal cavity • NT scan is done when the CRL is around 45–84 mm • The important aneuploidy markers are nuchal translucency (NT) and nasal bone. The normalcy of the Doppler flow across tricuspid valve and ductus venosus needs to be established • Fusion of the two decidual layers happens by the end of first trimester (parietal and capsular) and nonfusion of which is abnormal

(FHR: fetal heart rate; MSD: mean sac diameter; TAS: transabdominal scan; TVS: transvaginal scan)

as a cystic space (diamond shaped) within the head. The limb buds are prominently seen. The body movements are seen as early as 8–9 weeks of gestation.[5]

The CRL is the measurement of the maximum length of an embryo **(Figs. 10A to C)**. Prior to 7 weeks of gestation, the mean of three CRLs should be obtained. Later, as the GA advances, CRL should be measured in the sagittal section and as a straight line. The magnification should be such that the sac and the embryo occupy most of the width of screen. The endpoints should be clearly made out. Beyond 10 weeks as the fetal curvature increases, the fetus should be measured in neutral position.



Figs. 10A to C: (A) Measurement of gestational sac; (B) Yolk sac and crown–rump length (CRL); (C) Fetal heart rate (FHR) in M mode.

Cardiac Activity

Cardiac pulsation is seen at around 5–6 weeks of gestation. The cardiac activity is always seen by CRL of 7 mm and larger and thus enables in diagnosis of early pregnancy loss. During the first trimester, fetal heart rate is always recorded by M-mode and it varies with GA.

The heart rate increases over the first 6–8 weeks of gestation. The lower limit of normal is 100 BPM at around 6 weeks of gestation and reaches to 120 BPM at 6–7 weeks of gestation. The heart rate reaches to 170–180 BPM by 8–9 weeks of gestation.[5]

Assessment of Gestational Age

Accurate dating is a very essential part of the first-trimester scan and helps in proper follow-up of the pregnancies. It is one of the main indications of ultrasound in the first trimester. Ultrasound CRL measurement determines GA, and it is based on the assumption that the size of the embryo is consistent with its age. Biological variation in the size of the embryo is less during the first trimester compared to later gestations.[6,7]

Dating of the pregnancy can be done by two different methods. The age calculated from the conception date is referred to as conception/fertilization age. The GA calculated from the LMP is referred to as "menstrual age," which is commonly used. Only in case of in vitro fertilization (IVF)-assisted reproduction pregnancies, the day of conception is determined reliably. Else, the true GA is established accurately by ultrasound. All the guidelines recommend that the early pregnancy ultrasound should be advised to all pregnant women to determine the GA.

The CRL up to 84 mm size is the most precise in dating the pregnancy or determining the GA, and the difference is usually ±5–7 days in 95% of cases. The period for CRL assessment for assigning the GA is between 7 and 13 + 6 weeks by either a transabdominal or transvaginal sonography.[8] After that, head circumference is used to calculate GA as it is more precise than biparietal diameter (BPD). The American College of Obstetricians and Gynecologists (ACOG) committee's expert opinion is that when the CRL is at least 10 mm (i.e., by 7 weeks), the reliability and measurability are best. Nomograms are available for the singleton and are also applicable in multiple pregnancy.[6]

Dates are reassigned when:

- In case of spontaneous conception and assisted reproductive technologies (ART) except for IVF:
  Expected delivery date (EDD) should be changed to correspond with the ultrasound age when:

  - *11–14 weeks period of gestation:* When CRL and the menstrual age differ by >7 days.
  - *7–10 weeks period of gestation:* When CRL and the menstrual age have a discrepancy of >5 days.
- If the patient does not know her LMP, EDD is assigned as per the ultrasound examination, and the earliest CRL measurement is the most reliable.
- In case of an ART–IVF pregnancy, the conception date should be used to assign the EDD. For example, in an IVF pregnancy, the delivery date is assigned by the embryo age and the date of transfer, i.e., when the embryo is transferred on for the day-5/fifth day after fertilization, the EDD is 261 days from the embryo transfer (ET) date. Likewise, for a day-3 embryo/third day after fertilization, EDD is 263 days from the ET date.[7]

Assessment of GA in twin pregnancy: The CRL of both the fetuses is measured. The larger CRL is used for assigning or confirming the GA. Differences of >1 week between the fetuses in the first trimester should be noted. These fetuses need to be monitored with serial ultrasound scans. The discrepancy is often due to constitutional differences, but however, the early onset fetal growth restriction (FGR), structural, and/or karyotype abnormality need to be excluded.

MULTIPLE PREGNANCY

The incidence of multiple pregnancy is increasing, mainly due to widespread use of assisted reproduction techniques. Ultrasound examination in the first trimester tells us about the number of fetuses and the chorionicity of pregnancy. It is important to determine the type of twining.

The fertilized egg is termed "the zygote." If there is ovulation and fertilization of two eggs, it results in dizygotic twin, and in case of a single oocyte, it leads to monozygotic twin. All dizygotic twins have two placentas and hence have two chorionic sacs and two amniotic sacs. They are called "diamniotic dichorionic" twins. The *monozygotic twin* divide at different stages of development, resulting in three types of monozygotic twins:

- *Dichorionic diamniotic (DCDA twin):* They will have two placentas (chorion) and two amniotic cavities (when the embryo splits within the first 48 hours). They are similar to dizygotic twins but will be of the same sex and constitute around one-third of monozygotic twins.
- *Monochorionic diamniotic (MCDA twin):* There is one placenta (chorion) and two separate amniotic cavities (when the embryo splits after 72 hours but within 8 days). Majority of the monozygotic twins are MCDA (around two-third).
- *Monochorionic monoamniotic (MCMA):* They have one placenta and one amniotic cavity (when the embryo splits between 9 and 12 days). It constitutes <1% of monozygotic twins.

All dizygotic twins are dichorionic and not all monozygotic twins are monochorionic. Dizygotic twins can be either of same sex or of different sex, but all monozygotic twins are of same sex.

Ultrasound Assessment of Multiple Pregnancy

Multiple gestation can be seen as singleton during early scans (from 4 to 5 weeks). All twin pregnancies seen in the early GA might not result in twin live birth. The twin conception rate is usually high, but unfortunately, the early single embryo or fetal loss is approximately around 30% in the first trimester.

The visualization of two different gestational sacs on ultrasound before 6 weeks of gestation confirms the diagnosis of dichorionicity; however, it could be either dizygotic or monozygotic. The number of sacs is not used as a predictor of the number of future embryos as the sac might contain more than one embryo. Many a time, an empty sac in twin gestation regresses spontaneously, and it is known as "vanishing twin" phenomenon (20% of multiple pregnancies).

Presence of two or more embryos in a sac by 6–7 weeks of gestation confirms the diagnosis of monochorionic multiple pregnancy. But however, the amnionicity is established only by 8–9 weeks of gestation as the amount of amniotic fluid increases, thus facilitating the visualization of amniotic membrane by ultrasound **(Table 2)**.

Ultrasound Labeling of Twins

On ultrasound, each fetus or fetuses has to be identified correctly to ensure proper fetal assessment throughout the pregnancy. The position of the sac in relation to the cervix remains almost constant throughout the gestation and hence is used for labeling of the multiple pregnancies.

The fetus in the sac closer to the cervix is identified as twin/fetus 1 or A and the twin in the sac further from the cervix as fetus/twin 2 or B. In case of multiple pregnancy (multiple order), further labeling goes anticlockwise from fetus one, two, and so forth. This notation should be strictly applied from the very beginning of pregnancy **(Figs. 12A to C)**.

Establishing Chorionicity and Amnionicity

Ultrasound between 10 and 14 weeks of gestation is the ideal time for multiple pregnancy as dichorionic (DCDA) or monochorionic (MCDA/MCMA) twin pairs.

DCDA twin: The presence of two placentas in the later gestation is diagnostic of a dichorionic twin pregnancy. However, the presence of a single placenta on ultrasound can indicate either a dichorionic pregnancy with adjacent implantation of the two placentas or a monochorionic pregnancy with a single placenta. It is important to establish

TABLE 2: Ultrasound diagnosis of type of twin pregnancy.

Gestational age (weeks)	*Dichorionic diamniotic*	*Monochorionic diamniotic*	*Monochorionic monoamniotic*
5	Two separate sacs **(Fig. 11A)**  **Fig. 11A:** Two separate sacs.	Single sac **(Fig. 11B)**  **Fig. 11B:** Single sac with two yolk sacs.	Single sac **(Fig. 11C)**  **Fig. 11C:** Single sac with one yolk sac.
6	Two sacs with embryo in each **(Fig. 11D)**  **Fig. 11D:** Two sacs with embryo in each.	Single sac with two embryos **(Fig. 11E)**  **Fig. 11E:** Single sac with two yolk sacs and two embryos.	Single sac with two embryos **(Fig. 11F)**  **Fig. 11F:** Single sac with one yolk sac and two embryos.
9	Two sacs with embryo and amniotic cavity in each **(Fig. 11G)**  **Fig. 11G:** Two sacs with embryo and amniotic cavity in each.	Single sac with two embryos in two amniotic sacs **(Fig. 11H)**  **Fig. 11H:** Single sac with two embryos in two amniotic sacs. the chorionicity correctly for further antenatal management, as monochorionic pregnancy is associated with more complications than dichorionic pregnancy. The dichorionic placenta will demonstrate *the "twin peak" sign* or *"lambda" sign* **(Figs. 12A to C)**. It comprises the two amniotic and two chorionic membranes separated slightly at the insertion site by a tongue of placental tissue.

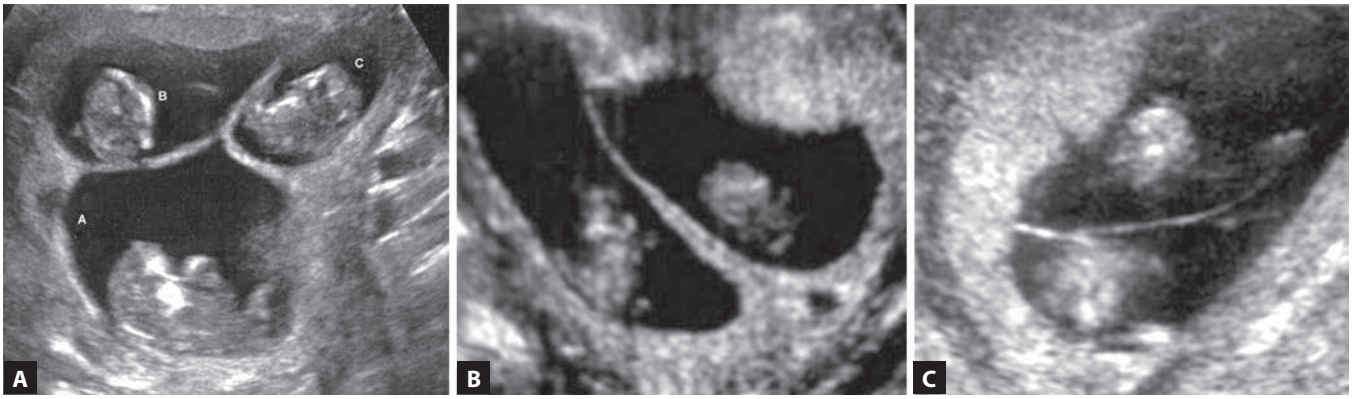
MCDA twin: A monochorionic placenta will demonstrate the "*T sign*" when the two amniotic membranes insert into the shared placenta **(Figs. 12A to C)**.

MCMA twin: If there is no dividing membrane seen between the fetuses, MCMA twins have to be suspected. The confirmation is always to be made in the late first trimester or early second trimester.

FIRST-TRIMESTER COMPLICATIONS

The fetal demise, empty sac, and disproportionate fetal growth can be a feature of abnormal development in early pregnancy. The vaginal bleeding and pain in the abdomen are symptoms of early pregnancy loss but could also be seen



Figs. 12A to C: (A) Labeling of fetuses in multiple pregnancy; (B) Twin peak sign in dichorionic diamniotic (DCDA) twin; (C) T-sign in monochorionic diamniotic (MCDA) twin.

in normal gestation. The ultrasound helps in identifying the first-trimester complications and thus to prognosticate the pregnancy. A detailed medical history, examination, sonography, and serum β-hCG help in making a more specific diagnosis.

Approximately 40% of early pregnancies can result in early pregnancy loss. The causes of miscarriages could be due to unknown causes, chromosomal defects, viral infections, uterine malformation, maternal endocrine problems, autoimmune antibodies—immunologic factors, and maternal systemic disease. As the pregnancy advances, the risk of miscarriage decreases.[3]

Early Pregnancy Loss

The criteria for diagnosing an early pregnancy loss by ultrasound were reported in the early 1990s, immediately after vaginal sonography was widely available. Based on the ultrasound findings, the miscarriages are labeled as threatened, missed, incomplete, and complete.

Complete and Incomplete Miscarriage

The experience of the operator is important in the diagnosis of complete and incomplete miscarriage. The clinical history plays an important role in the diagnosis of complete or incomplete miscarriage. Ultrasound should always be combined with clinical and biochemical assessment. When the endometrium is thin, regular, and comparable to that of early proliferative phase on ultrasound, probability of complete miscarriage is high.

The ultrasound diagnosis of incomplete miscarriage is difficult. The diagnostic criteria of endometrial thickness vary between 5 and 15 mm. Using fixed cutoff values are difficult as blood clots cannot be always differentiated from retained conception products within the cavity at the time of miscarriage. Therefore, subjective assessment is preferred over quantitative assessment. The retained conception products appear as a well-defined hyperechoic area within the cavity as opposed to blood clots which are more irregular. Clots are seen sliding within the cavity when pressure is applied by the transvaginal probe. However, the Doppler examination may not add much value to the diagnosis of incomplete miscarriage.[9]

Threatened Miscarriage

Threatened miscarriage is associated with vaginal bleeding with or without abdominal cramps, and ultrasound gives valuable information about the prognosis and the treatment options. The cervical os is closed. It occurs in about 20% of the recognized pregnancies. The subchorionic hematoma does not always predict poor outcomes **(Figs. 13A to C)**.[9]

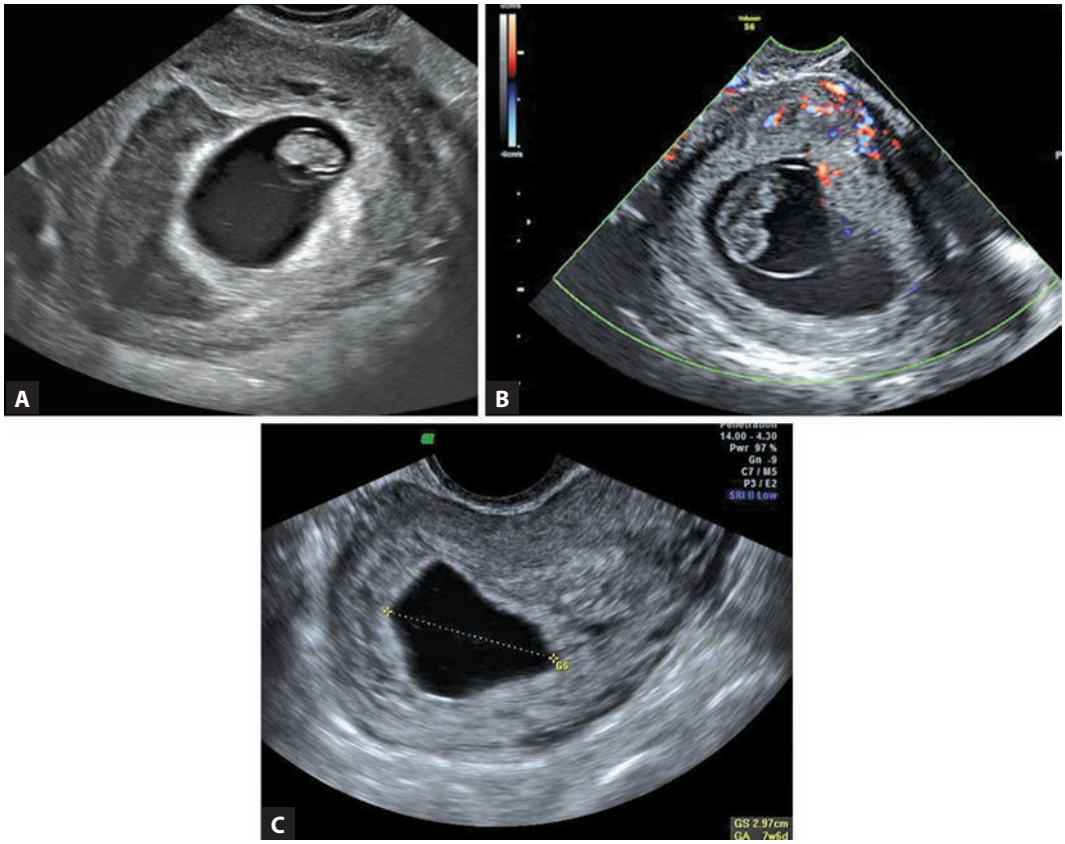
Anembryonic Miscarriage

Anembryonic miscarriage is defined as an empty gestational sac, previously known as blighted ovum **(Figs. 13A to C)**.

Missed Miscarriage

Missed miscarriage is defined as embryonic demise or early fetal death in utero. Absence of cardiac activity in the embryo or fetus on ultrasound aids in the diagnosis of missed miscarriage. The cardiac activity either does not develop (up to CRL of 7 mm) or appears and then later disappears **(Figs. 13A to C)**.

According to the previous studies, the diagnostic criteria to confirm early pregnancy loss were either a CRL of 5 mm without a cardiac activity or an empty sac with a diameter of 16 mm.[10-12] In the recent time, two large prospective studies challenged these cutoffs.[13,14] In one of the studies, when the CRL cutoff of 5 mm was used for diagnosis of early pregnancy loss, the false-positive rate was 8.3% and for CRL cutoff of 7 mm, a false-positive rate was decreased with high specificity.[13] Similarly, the authors said that when the MSD cutoff of 16 mm was used for early pregnancy loss, the false-positive rate was 4.4%. An MSD cutoff of 25 mm (without an embryo and with or without a yolk sac) was used to achieve 100% specificity for the early pregnancy loss. However, the authors also concluded that if the sac remained



Figs. 13A to C: (A) Threatened miscarriage; (B) Absent cardiac activity suggestive of missed miscarriage; (C) Empty gestational sac suggestive of anembryonic miscarriage.

empty after reassessment in 7 days, then it was labeled as pregnancy loss.[14]

Based on these studies, the Society of Radiologists in Ultrasound Multispecialty Panel on Early First Trimester Diagnosis of Miscarriage created guidelines which are more conservative than the previous guidelines and has a strict cutoff for the diagnosis of early pregnancy loss.[15]

Individualizing these guidelines according to the patient circumstances is very important. According to the ACOG committee opinion, few criteria are considered suggestive of early pregnancy loss but not diagnostic, and these are listed in **Table 3**. Examples of slow fetal heart rate at 7–8 weeks of gestation are associated with early pregnancy loss. When these findings are present, it warrants repeat ultrasound in 7–10 days.[15]

Pregnancy of Unknown Location

When there is no sign of intrauterine or extrauterine pregnancy on transvaginal ultrasound, in spite of the pregnancy test being positive, it is defined as pregnancy of unknown location (PUL). It is a transient situation and not a final diagnosis. At this stage, the differential diagnoses are early intrauterine pregnancy (IUP), ectopic pregnancy, and complete miscarriage. Serial ultrasound evaluation and also serum hCG are necessary for the follow-up, especially for localization of pregnancy. In women with an hCG result below the discriminatory level, it may be too early to visualize the gestational sac. In a multiple pregnancy, serum β-hCG levels are high at the early gestation when compared with those in a singleton pregnancy. The possibility of ectopic pregnancy is high when there is no intrauterine sac and β-hCG is above the discriminatory level, particularly if the level is >3,000 IU/L. The Doppler finding of focal low-resistance arterial trophoblastic flow may not be useful as it can have adverse effect on the IUP.

There is a small intrauterine collection seen in PUL, which could be a decidual cyst or localized intrauterine fluid. When a patient with PUL is hemodynamically stable, it is less harmful to wait. It is recommended that serum β-hCG levels and endovaginal scan need to be repeated after 7–10 days.[4] The combination of ultrasound findings and quantitative β-hCG levels help in the diagnosis of normal IUP, nonviable IUP, and ectopic pregnancy.

ECTOPIC PREGNANCY (FIGS. 14A TO C)

Implantation of the embryo outside the uterine cavity is defined as an ectopic pregnancy. Majority of the ectopic pregnancies are tubal (93%). The rate of ectopic pregnancy is 11/1,000 pregnancies, with a maternal mortality of 0.2/1,000 estimated ectopic pregnancies.[16] Clinically, a patient

TABLE 3: Society of Radiologists in Ultrasound Guidelines for Transvaginal Ultrasonographic Diagnosis of Early Pregnancy Loss*—ACOG, Committee Opinion Number 700, May 2017.

Findings diagnostic of early pregnancy loss†	***Findings suggestive, but not diagnostic, of early pregnancy loss‡***
Crown–rump length of 7 mm or greater and no heartbeat	Crown–rump length of <7 mm and no heartbeat
Mean sac diameter of 25 mm or greater and no embryo	Mean sac diameter of 16–24 mm and no embryo
Absence of embryo with heartbeat 2 weeks or more after a scan that showed a gestational sac without a yolk sac	Absence of embryo with heartbeat 7–13 days after an ultrasound scan that showed a gestational sac without a yolk sac
Absence of embryo with heartbeat 11 days or more after a scan that showed a gestational sac with a yolk sac	Absence of embryo with heartbeat 7–10 days after an ultrasound scan that showed a gestational sac with a yolk sac
	Absence of embryo for 6 weeks or longer after last menstrual period
	Empty amnion (amnion seen adjacent to yolk sac, with no visible embryo)
	Enlarged yolk sac (>7 mm)
	Small gestational sac in relation to the size of the embryo (<5 mm difference between mean sac diameter and crown-rump length)

*Criteria are from the Society of Radiologists in Ultrasound Multispecialty Consensus Conference on early first-trimester diagnosis of miscarriage and exclusion of a viable intrauterine pregnancy, October 2012.

†These are the radiologic criteria only and do not replace clinical judgment.

‡When there are findings suspicious for early pregnancy loss, follow-up ultrasonography at 7–10 days to assess the pregnancy for viability is generally appropriate.

Source: Doubilet PM, Benson CB, Bourne T, Blaivas M, Society of Radiologists in Ultrasound Multispecialty Panel on Early First Trimester Diagnosis of Miscarriage and Exclusion of a Viable Intrauterine Pregnancy, Barnhart KT, et al. Diagnostic criteria for nonviable pregnancy early in the first trimester. N Engl J Med. 2013;369:1443-51.

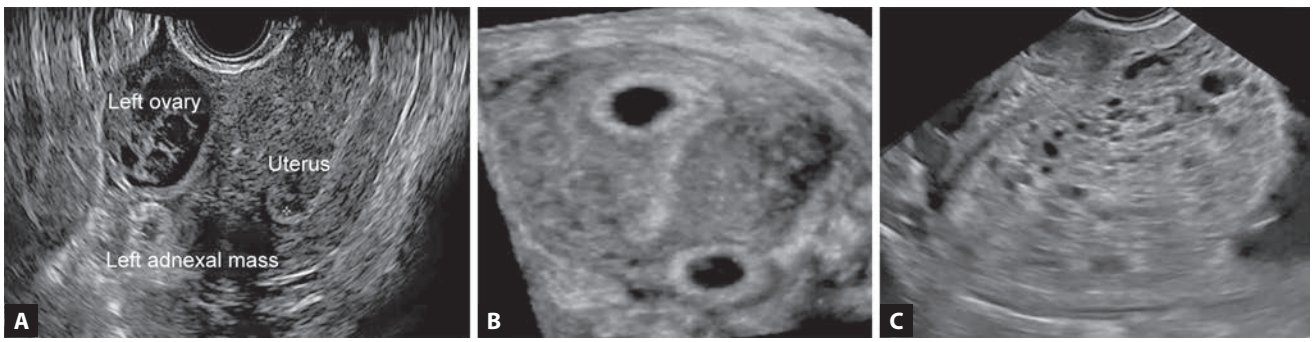
may present with abdominal pain with or without vaginal bleeding.[9]

Usually, the finding of pregnancy test being positive and on ultrasound, no IUP suggests ectopic pregnancy. On TVS, majority of the ectopic pregnancies can be visualized at the initial ultrasound scan; however, index suspicion should be high. A sac-like structure within the uterus, known as pseudosac, is seen in around 10–29% of ectopic pregnancies and should not be mistaken for an early gestational sac. In longitudinal section, the gestational sac is round, and pseudosac is elongated in appearance. Absence of good choriodecidual reaction and vascularity on Doppler helps in differentiating pseudosac from gestational sac.[16]

In about 78% of the cases, ectopics are on the same side as the corpus luteum, and few times it is difficult to differentiate corpus from the ectopic. The "sliding sign" helps to distinguish a corpus luteum from an ectopic pregnancy. In this technique, a gentle pressure is applied with the tip of the transvaginal probe to observe whether the mass moves separately from the ovary. In addition to the adnexal mass, presence of internal hemorrhage which is indicative of tubal abortion or a ruptured ectopic has to be noted. On ultrasound, hemorrhage is seen as hyperechoic fluid in the pouch of Douglas **(Table 4)**.

Differential diagnosis of an ectopic (false positive diagnosis) is static bowel loop, hydrosalpinx, adhesions, or an endometrioma. Direct visualization of the adnexal ectopic mass facilitates the diagnosis and helps to decide the best management option. The ultrasound appearance of ectopic pregnancies varies and the diagnosis depends on the quality of the equipment and the experience of the sonographers.

Interstitial pregnancy is defined as implantation in the interstitial portion of the fallopian tube. On ultrasound, gestational sac or the mass is seen in the upper lateral aspect of the uterus and outside the uterine cavity, surrounded with a thin myometrial mantle. A *cervical pregnancy* occurs when the conceptus is implanted in the cervical canal. The ultrasound diagnostic criteria for the diagnosis of cervical ectopic are no evidence of an intrauterine gestational sac,



Figs. 14A to C: (A) Transvaginal scan showing an adnexal mass adjacent to left ovary—left-sided ectopic pregnancy; (B) 3D rendered image of heterotrophic pregnancy shows presence of intrauterine and extrauterine gestational sac; (C) Transvaginal scan image showing homogeneous distribution of cystic areas within the uterine cavity. Suggestive of complete molar pregnancy.

TABLE 4: Ultrasound (transvaginal scan) findings of tubal ectopic pregnancy.

Intrauterine	*Adnexal findings*
• Empty uterus with or without increased endometrial thickness • Fluid collection within the uterine cavity (i.e., pseudosac, must be differentiated from an intrauterine sac, which is identified by the presence of an eccentrically located hypoechoic structure with a double decidual sign in the endometrium) • Concurrent intrauterine pregnancy	• Adnexal mass, moving separate to the ovary (sometimes called the "sliding sign"): – Comprising a gestational sac with a yolk sac or fetal pole (with or without fetal heartbeat) or an empty gestational sac (described as a "tubal ring" or "bagel sign") – A complex, inhomogeneous adnexal mass moving separate to the ovary • Moderate or large amount of free fluid collection is seen in the peritoneal cavity or pouch of Douglas, suggestive of hemoperitoneum

Source: Ectopic pregnancy and miscarriage: diagnosis and initial management (update) (NG126) April 2019.[17]

ballooning of the cervical canal (hourglass uterine shape), the presence of a gestation sac within the cervical canal, and internal os is closed. Ovarian ectopic can be diagnosed on scan when the gestation sac is seen within the ovary or when sac cannot be separated from the ovary. It is essential that the corpus luteum is identified separately from the gestational sac to avoid misinterpreting the corpus luteum as an ovarian pregnancy.

HETEROTOPIC PREGNANCY (FIGS. 14A TO C)

When there is an intrauterine gestational sac along with an ectopic pregnancy, it is termed "heterotopic pregnancy." The incidence of heterotopic pregnancy is high in women undergoing assisted reproductive treatment, and in the general population it is about 1:6,000. The diagnosis of a normal IUP thus cannot rule out a concomitant ectopic pregnancy. A careful and thorough examination has to be made to exclude the presence of heterotopic pregnancy in a symptomatic patient and a high index of suspicion is necessary for the diagnosis.

MOLAR PREGNANCY

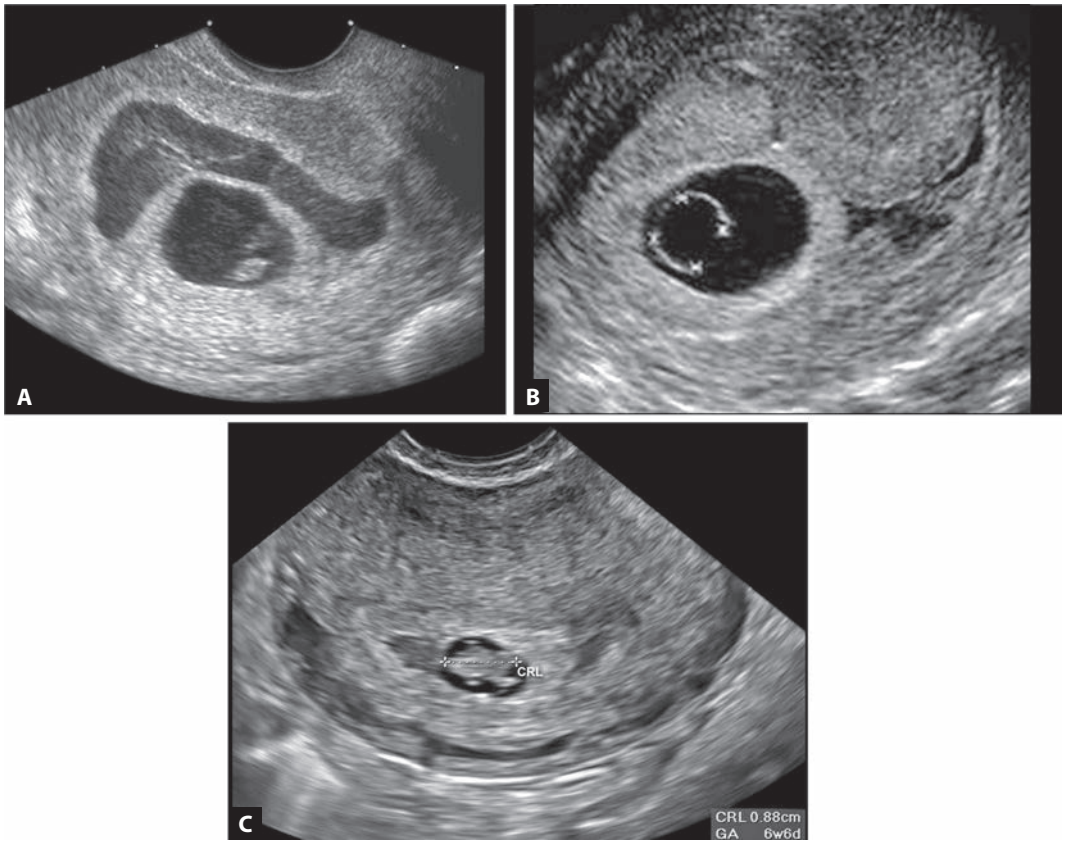
The generalized swelling of the chorionic villous and diffuse trophoblastic hyperplasia in the absence of embryonic or fetal tissue are the features of complete molar pregnancy. The ultrasound appearance of molar pregnancy is described as "snowstorm appearance," i.e., homogenous distribution of cystic areas within the uterus. The gestational sac or fetal pole is not separately seen **(Fig. 14C)**. Serum hCG will be high in these women, usually >2.5 multiples of median (MoM), and will continue to increase as the pregnancy advances.

Partial hydatidiform moles are characterized by focal swelling of the villous tissue and focal trophoblastic hyperplasia in the presence of embryonic or fetal tissue. The sonolucent areas seen within the placenta might represent either a partial mole or a twin pregnancy with one conceptus normal and the other complete mole. In partial moles, the molar structures are dispersed inside the placental mass. With triploid partial moles, major fetal abnormalities or severe intrauterine growth restriction are most commonly present.

RISK FACTORS FOR EARLY PREGNANCY FAILURE (FIGS. 15A TO C)

- *GA:* An inverse relationship exists between GA and an adverse outcome.
- *SCH:* Intrauterine collections of blood are found in many women with first-trimester threatened miscarriage as well as some asymptomatic patients. Bleeding in the early pregnancy period occurs in about 5–25% of all pregnancies. During very early pregnancy, bleeding could be implantation bleed. Later, it is likely due to venous bleeding associated with separation or abruption of the placental margin or marginal sinus. The blood dissects along paths of least resistance and ultimately can be located in a variety of positions relative to the developing sac and placenta. The echogenicity of the blood depends on its age and the amount of associated clot. *Subchorionic hematoma is defined as hypoechoic or anechoic areas between the chorionic membrane and the myometrium adjacent to gestational sac.*[18-21]

  The SCH can be quantified by measuring the volume of the hematoma. The volumes can be estimated by measuring the anteroposterior, longitudinal, and transverse diameters and multiplying these values by 0.523 (the ellipsoid formula). However, the *size of the hematoma can be assessed relative to the gestational sac because this method is simple and well-established.*
  - *Small:* When SCH encircles less than one-third of the gestational sac.
  - *Moderate:* When SCH encircles around one-third to half of the gestational sac.
  - *Large:* When SCH encircles around one-half to two-thirds or greater of the gestational sac.
- *Growth delay:*
  - *CRL:* A smaller-than-expected first-trimester CRL measurement reflects early growth restriction that persists throughout pregnancy and is associated with low birth weight, premature delivery, and an increased risk for miscarriage, approximately 25%. It is not surprising when a small sac is present; other adverse prognostic indicators such as embryonic



Figs. 15A to C: (A) Large subchorionic hemorrhage; (B) Large yolk sac; (C) Small gestational sac with small amniotic cavity. (CRL: crown–rump length; GA: gestational age)

bradycardia, maternal bleeding, or delay in embryonic growth may also be present.[22]

- *Yolk sac:* The size and characteristics of the yolk sac should be assessed in early pregnancy. An abnormal-appearing yolk sac is also associated with early pregnancy failure. Sporadic case reports suggest that yolk sacs that are abnormally shaped, calcified, echogenic, or double (vitelline duct cyst) are associated with either antecedent or subsequent embryonic demise. Despite an abnormal-appearing yolk sac, whenever cardiac activity is present, follow-up imaging is recommended because, in rare and exceptional cases, the pregnancy may continue to term.[22,23]
- *Cardiac activity:* When embryonic cardiac activity is first detected between 5 and 6 weeks' GA, the rate is relatively slow. The mean heart rate increases to approximately 140 BPM by 9 weeks' GA. Bradycardia is defined as <90 BPM after 6 weeks of gestation. There is a 25% risk of fetal demise by the end of the first trimester.

  Analysis of first-trimester bradycardia also confirms an association with structural and chromosome abnormalities, especially trisomy 18 and triploidy. In contrast, other chromosome defects, including trisomy 21, and especially trisomy 13 and Turner syndrome, have all been associated with first-trimester tachycardia (determined at 10–14 weeks of GA).[23-28]
  - *Maternal factors:* These factors that may increase the risk of spontaneous miscarriage include age, smoking, structural uterine abnormalities, and a history of miscarriages.

Adnexa

The anatomical area adjacent to the uterus is called adnexa, and it contains the fallopian tube, ovary, associated vessels, ligaments, and connective tissue. The incidence of adnexal masses in pregnancy is around 1 in 81 to 1 in 8,000 pregnancies. Usually, the diagnosis is incidental. The adnexal mass is commonly complicated by torsion, rupture, or bleeding/infection. Ultrasound allows stratification of risk in women with adnexal mass during pregnancy without compromising maternal or fetal safety. The adnexal mass in pregnancy is classified as simple, complex, solid-benign, and solid-malignant. Functional cyst and corpus luteum account for 13–17% of all cystic adnexal masses in pregnancy. Other adnexal masses seen in pregnancy are benign masses (dermoid cyst, serous cystadenoma, mucinous cystadenoma), ovarian malignancy (approximately 1–8% of adnexal masses in pregnancy), endometrioma, hydrosalpinx, and leiomyoma. Complications such as torsion of the ovary

have no definitive ultrasound features. The ovary may appear congested, edematous, and markedly enlarged ovary. However, Doppler may show the absence of blood flow in case of torsion, though this is not universal as torsion may be complete or intermittent. Both transabdominal scan and TVS should be used together as complementary techniques. However, the detailed morphological assessment of the mass is better with TVS, especially in early pregnancy. The color Doppler imaging significantly improves the ability to distinguish benign from malignant masses.[29]

KEY POINTS

- The TVS and the quantitative β-hCG levels are the great tools available for the diagnosis of normal and abnormal early pregnancy.
- The Society of Radiologists in Ultrasound 2012 consensus panel of radiologists, obstetricians, and emergency medicine physicians has established new terminology and a new set of discriminatory criteria for the diagnosis of the abnormal early pregnancy and would improve patient care and reduce the risk of inadvertent harm to potentially normal pregnancies.
- The aim of these guidelines is to protect the mother and baby by providing accurate and correct interpretations of the ultrasound findings. Therefore, sonologists should have a knowledge of the progression of normal early pregnancy ultrasound features and abnormal first-trimester ultrasound findings.
- The importance of using the accepted terminology in reporting helps the referring physicians to understand the findings and treat the patients safely.

CHAPTER 77

Recurrent Pregnancy Loss: From Diagnostic Dilemmas to Clinical Decisions

Smitha AP, Sushma Baxi, Sushma Madhuprakash

DEFINING PREGNANCY LOSS AND RECURRENT PREGNANCY LOSS

Recurrent pregnancy loss (RPL) is a rising concern today. Most of the clinicians face ambiguity as to defining RPL. With more and more couples facing infertility, may be it is time to redefine RPL.

The term "miscarriage" is applied to many complications of early pregnancy, and it is important to be clear on terminology. A pregnancy loss that occurs after a positive urinary human chorionic gonadotropin (hCG) or a raised serum beta-hCG but before ultrasound or histological verification is defined as a "biochemical loss" [the European Society of Human Reproduction and Embryology (ESHRE) 2005]. In general, these occur before 6 weeks of gestation. The term clinical miscarriage is used when ultrasound examination or histological evidence has confirmed that an intrauterine pregnancy has existed. Ectopic, biochemical, and molar pregnancies are thus not included. Clinical miscarriages may be subdivided into early clinical pregnancy losses (before gestational week 12) and late clinical pregnancy losses (gestational weeks 12–21).

The new sonographic diagnostic criteria for early pregnancy loss [the American College of Obstetricians and Gynecologists (ACOG)] are shown in **Table 1**.

TABLE 1: New sonographic diagnostic criteria for early pregnancy loss.

Absent embryonic cardiac activity	*Gestational sac diameter*	*Empty gestational sac with no yolk sac/fetal pole on a repeat scan >1 week*
• CRL cut off 5–5.3 mm • False positive reduced from 8.3 to 0%	• 21 mm without embryo • False positive reduced from 4.4 to 0%	Always associated with pregnancy loss

Prompt reevaluation of both clinical and sonological parameters is warranted within a week where there is evidence of a subchorionic hematoma or a slow fetal heart of <100 beats per minute (bpm).

There is no consensus on the number of pregnancy losses needed to fulfill the criteria for recurrent miscarriage (RM), but ESHRE guidelines define RM as three or more consecutive pregnancy losses before 22 weeks of gestation.

In primary RPL, a woman has multiple losses with no previous viable pregnancies, whereas, in secondary RPL, it occurs in a woman who had a pregnancy beyond 20 gestational weeks. In tertiary RPL, multiple pregnancy losses occur between normal pregnancies **(Fig. 1)**.

Recurrent pregnancy loss has been redefined as two or more clinical pregnancy losses, which are not necessarily consecutive [American Society for Reproductive Medicine (ASRM) 2012].

TIP OF THE ICEBERG

Recurrent pregnancy loss encompasses a wide spectrum from nonviable intrauterine pregnancy for early pregnancy loss to midtrimester abortions and more complex late intrauterine devices (IUDs). The workup and evaluation for each of these presentations vary with specific treatment directed at the primary pathology.

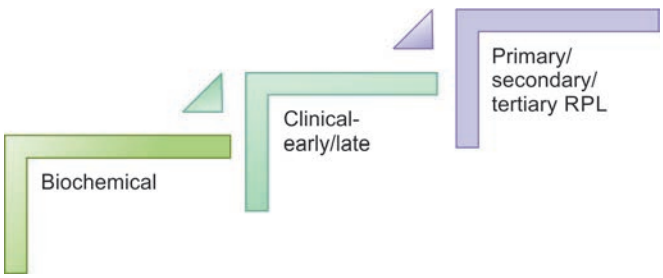

Fig. 1: Spectrum of pregnancy loss.
(RPL: recurrent pregnancy loss)

TABLE 2: Etiological features of recurrent pregnancy loss.

Uterine factors	• *Anatomic defects congenital:* Septate, bicornuate, unicornuate, arcuate, didelphic • *Acquired:* Intrauterine adhesions, myoma, endometrial polyps • *Chronic endometritis*
Thrombophilias	• *Inherited:* Factor V Leiden (FVL), prothrombin gene (PT G20210A) mutation, protein C and protein S deficiency (PSD), antithrombin III (ATIII) deficiency, and methylenetetrahydrofolate reductase (MTHFR) mutation • *APS:* Lupus anticoagulant, anticardiolipin antibody, and anti-β2 glycoprotein I
Endocrine factors	Hyperprolactinemia, hypothyroidism, PCOS, uncontrolled diabetes
Environmental and psychological factors	High BMI, smoking, high caffeine consumption >300 mg/day, excess alcohol intake, and cocaine
Genetic factors	Embryonic aneuploidy, balanced translocations (reciprocal/Robertsonian)
Unexplained	

(APS: antiphospholipid syndrome; BMI: body mass index; PCOS: polycystic ovarian syndrome)

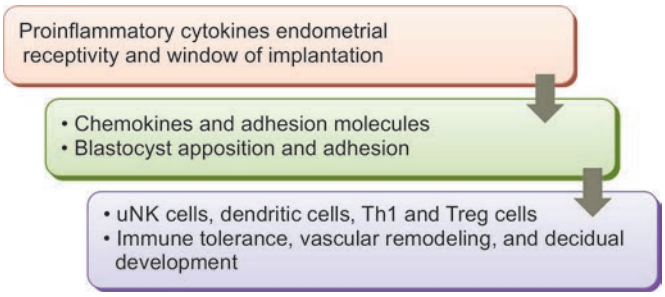
TABLE 3: Etiological features: Diagnostic tests and treatment options.

Etiology	*Diagnostic tests*	*Treatment options*
Uterine factor	3D USG, HSG, hysteroscopy, MRI	Myomectomy, hysteroscopic removal of polyp, septum, adhesion
APS	aCL, anti-β2 glycoprotein, lupus anticoagulant	Heparin, aspirin
Endocrine abnormality	TSH, prolactin, FBS/ HbA1c	Appropriate therapy
Genetic	Karyotype of POC parental karyotype	PGD for balanced translocation

(aCL: anticardiolipin; APS: antiphospholipid syndrome; FBS: fasting blood sugar; HbA1c: glycated hemoglobin; HSG: hysterosalpingography; MRI: magnetic resonance imaging; PGD: preimplantation genetic diagnosis; POC: products of conception; TSH: thyroid-stimulating hormone; USG: ultrasonography)

The turmoil a couple go through facing RPL is beyond description, and it is futile to run a whole plethora of tests on them and add to their agony. Targeted tests to identify the primary pathology and specific treatment plans ensure optimal outcomes. In more than half of couples facing RPL, there is no discernible cause, and tender loving care (TLC) plays a crucial role as proven time and again in achieving clinical end points, at times probably the only evidence-based treatment in such couples **(Tables 2 and 3)**.

Flowchart 1: Immunological milieu in recurrent pregnancy loss.



(Treg: regulatory T; Th1: T helper 1; uNK: uterine natural killer)

IMMUNOLOGICAL MILIEU IN RECURRENT PREGNANCY LOSS

Disproving the historical statement that pregnancy is a state of immunological suppression with inhibition of T helper 1 (Th1)-mediated cytotoxic responses. The newer theory defines that pregnancy encompasses a state of altered immunological milieu with pro- and anti-inflammatory phases during specific stages in pregnancy. A complex network of receptors and cytokines orchestrate an intricate communication between the fetus and the maternal immune cells, which ultimately results in a successful pregnancy **(Flowchart 1)**.

NATURAL KILLER CELLS: FRIEND OR FOE?

Maternal–fetal interface is a site of intense immunological activity. The natural killer (NK) cells present here are not a threat to pregnancy but are recruited and harnessed by the trophoblast favorably for promoting trophoblast invasion and vascular remodeling. Reduced decidual NK (dNK) cells mark limited trophoblast invasion, a hallmark of fetal growth restriction **(Fig. 2)**.

Decidual NK cells communicate with the invading extravillous trophoblast (EVT). Paternal human leukocyte antigen (HLA)-C is the major histocompatibility complex (MHC) class I molecule that is expressed by the EVT, which binds to killer immunoglobulin-like receptor (KIR) on NK cells. This triggers the release of angiogenic growth factors, thereby promoting trophoblastic invasion and spiral artery remodeling.

Extravillous trophoblast-mediated expression of Fas ligand (FasL) causes apoptosis of Fas-bearing activated $CD3^+$ T cells and endothelial cells (ECs), thereby protecting against the maternal immune system. Failure of any of these mechanisms predisposes to preeclampsia **(Figs. 3A and B)**.

Regulatory T Cells

Regulatory T (Treg) cells play an important role by recognizing self and nonself antigens. They help in recognizing fetal tissue and are responsible for maternal

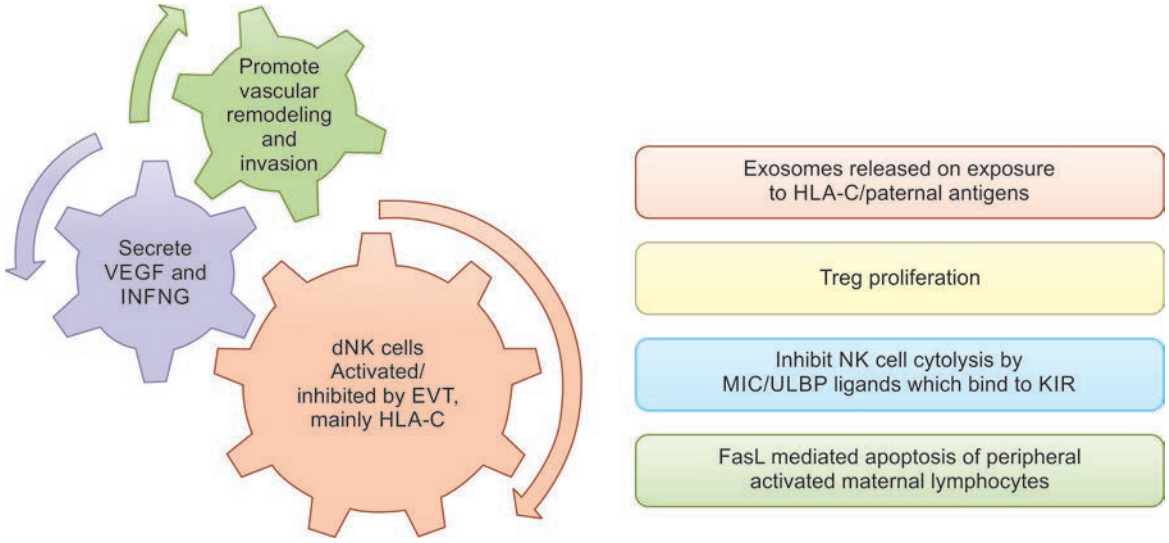


Fig. 2: Features of natural killer (NK) cells as well as decidual NK (dNK) cells.
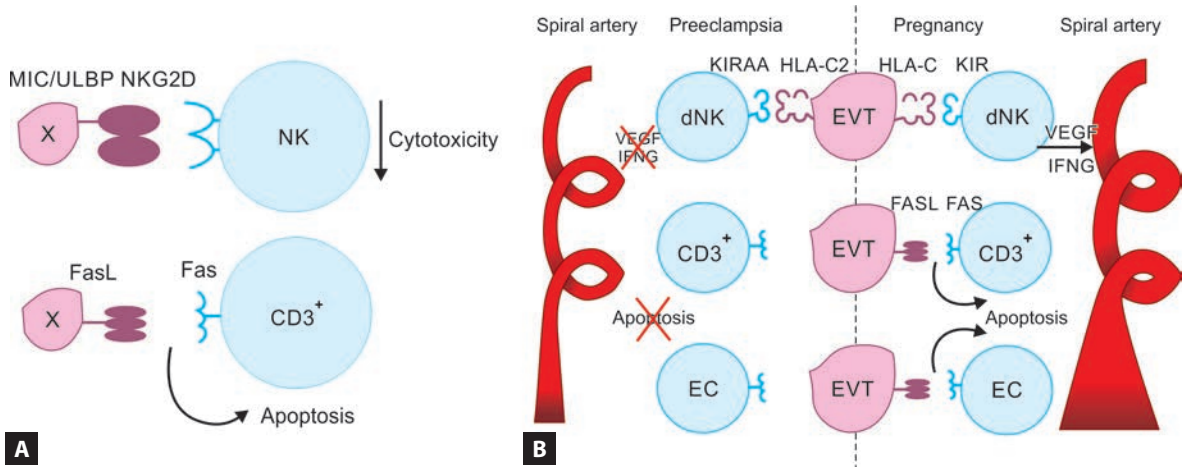
(EVT: extravillous trophoblast; FasL: Fas ligand; HLA: human leukocyte antigen; INFNG: interferon gamma; KIR: killer immunoglobulin-like receptor; MIC: MHC class I related chain; Treg: regulatory T; ULBP: UL16-binding proteins; VEGF: vascular endothelial growth factor)



Figs. 3A and B: (A) Maternal periphery; (B) Extravillous trophoblast-mediated expression of Fas ligand (FasL).
(dNK: decidual natural killer; EC: endothelial cells; EVT: extravillous trophoblast; HLA: human leukocyte antigen; INFNG: Interferon gamma; KIR: killer immunoglobulin-like receptor; KIRAA: combination of two KIR A haplotypes; MIC: MHC-I class-related chain; NK: natural killer; NKG2D: natural-killer group 2, member of CD94/NKG2 family an activating receptor; ULBP: UL16-binding proteins; VEGF: vascular endothelial growth factor)

immune tolerance. They secrete transforming growth factor (TGF)-β and interleukin (IL)-10 and mediate both Th1 and Th2 responses. Granulocyte colony-stimulating factor (G-CSF) may reduce the incidence of miscarriage by promoting the proliferation of these Tregs by recognizing HLA-C on extravillous cytotrophoblasts.

In autoimmune diseases, there is evidence of Treg dysfunction. Overexpression of Th1 with low levels of Tregs has been found in RPL and primary infertility.

Angiogenesis and trophoblast invasions are immunologically active processes; rather than passively "escaping" maternal recognition, the fetus actively harnesses the maternal immune surveillance system to facilitate its survival and growth.

PLASTICITY OF REGULATORY T AND T HELPER 17 CELLS (FIG. 4)

Genetic Factors (Flowchart 2)

More than half of early pregnancy losses are the consequence of chromosomal abnormalities. These can arise de novo as commonly encountered or can be of parental origin.

Accounting for 2–4% of cases of RPL, balanced translocations are the most common parental causes and account for more than double than those seen in the general population.

Unbalanced translocations are found in more than a third of miscarried embryos. Most couples with balanced translocations have healthy live births.

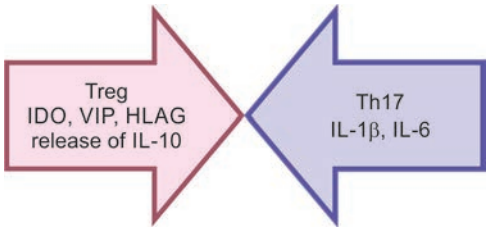


Fig. 4: Plasticity of regulatory T (Treg) and T helper 17 (Th17) cells. (HLAG: human leukocyte antigen-G; IDO: indoleamine-2,3-dioxygenase; IL: interleukin; VIP: vasoactive intestinal peptide)

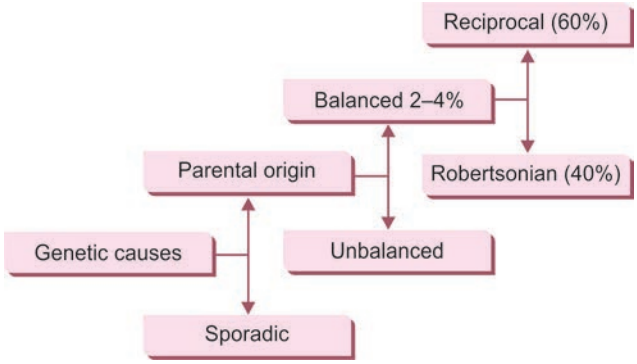
Flowchart 2: Genetic causes.



Embryonic aneuploidy, most commonly seen (60–70%) in early pregnancy loss <10 weeks, is generally numeric, namely trisomy (60%), monosomy X (20%), and polyploidy (20%). They are less likely to occur with a higher number of miscarriages.

Genetic Workup (Flowchart 3)

How Soon is Too Soon?

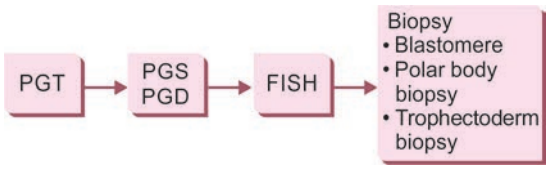
Selective RPL evaluation could be a tool to cut down expenses involved in evaluating a couple which is done if second miscarriage is euploid and <10 weeks.

Based on this concept, genetic evaluation of couples with RPL can be done, thereby enabling early diagnosis and targeted treatment and minimizing the valuable time for these couples.

Preimplantation genetic screening (PGS) is offered to couples with RPL for global assessment of the embryo, unlike the more specific preimplantation genetic diagnosis (PGD) where more specific genetic abnormalities are looked at. PGS use is yet controversial in couples with RPL.

Among the other modalities, comparative genomic hybridization (CGH) is gaining popularity in present day as it can be used even when conventional cytogenetic analysis and cell culture fails or when maternal contamination is present or in tissues preserved in formalin or embedded in paraffin. However, it has its own limitations as in balanced structural chromosome rearrangements cannot be identified, and flow cytometry is required to detect polyploidy. Array CGH (aCGH) testing of products of conception (POCs) do not need live cells, cell culture, or

Flowchart 3: Genetic workup.



(FISH: fluorescent in situ hybridization; PGD: preimplantation genetic diagnosis; PGS: preimplantation genetic screening; PGT: preimplantation genetic testing)

cell division. It is more rapid and flexible. Single nucleotide polymorphism (SNP) chromosomal microarray analysis can detect the overall distribution of microdeletions and microduplications across a genome. SNP arrays can also be used with CGH to detect aneuploidies and single-gene disorders through linkage analysis.

Next-generation sequencing (NGS) for preimplantation embryo assessment may provide information to such intricacies whose clinical relevance is questionable. With the dawn of "omics," deploying noninvasive technologies for PGS, such as transcriptomics, epigenomics, metabolomics, and mitochondrial function tests, may prove to be a promising future for couples facing RPL.

INTERVENTIONS IN RECURRENT PREGNANCY LOSS

Unexplained Recurrent Pregnancy Loss

In more than half of the cases with RPL, there is no underlying pathology detected. The concept of genetic predisposition to RPL is emerging as it is higher in siblings of patients with unexplained RPL (URPL). Most commonly associated with RPL are the IL genes, especially IL-1β, IL-6, IL-10, and IL-18. More studies on establishing HLA haplotypes in couples with URPL are required. Immune dysregulation has long been postulated with various immune modulatory therapies such as the use of synthetic corticosteroids and more recently hydroxychloroquine sulfate (HCQS).

Hydroxychloroquine Sulfate

Hydroxychloroquine sulfate is a lysosomotropic amine and interferes with lysosomal acidification, which in turn inhibits proteolysis, chemotaxis, phagocytosis, and antigen presentation. As a result, cells are not able to proceed with endocytosis, exosome release, and phagolysosomal fusion in an orderly manner. It could probably prove to be the "wonder drug" in URPL by its various methods of action as enumerated in **Figure 5**.

Aspirin or/and Low-molecular-weight Heparin

Aspirin

Aspirin has been used widely in the prevention of preeclampsia and in RPL secondary to antiphospholipid

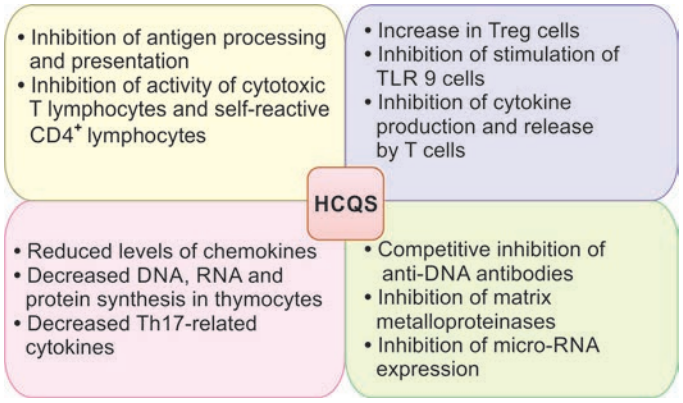


Fig. 5: Various methods of action of hydroxychloroquine sulfate (HCQS).
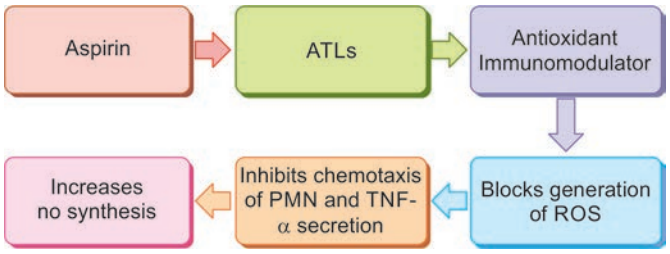
(DNA: deoxyribonucleic acid; RNA: ribonucleic acid; Th17: T helper 17; TLR: toll-like receptors; Treg: regulatory T)

Flowchart 4: Method of action of aspirin.



(ATLs: aspirin-triggered lipoxins; PMN: polymorphonuclear; ROS: reactive oxygen species; TNF: tumor necrosis factor)

syndrome (APS). The mechanism is not a mere reduction of prostaglandins/thromboxanes but the production of aspirin-triggered lipoxins (ATLs) **(Flowchart 4)**.

Low-molecular-weight Heparin

Though low-molecular-weight heparin (LMWH) use is rampant in clinical practice, unfortunately, its benefits have not been reflected in randomized controlled trials (RCTs). LMWH might regulate in vitro trophoblast invasiveness and placental production of matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs). Heparin significantly enhanced both pro-MMPs and the active forms, and increased the invasiveness of EVT. The increase in trophoblast invasion by heparin is probably due to a specific protein playing a role in placental invasion. Treatment with LMWH and low-dose aspirin in high-risk patients with low pregnancy-associated plasma protein-A (PAPP-A) has shown improvement in overall clinical outcomes as well.

Synthetic Corticosteroids

Synthetic corticosteroids have been the gold standard in the treatment of RPL because of their known immunosuppressive effect. Prednisolone effectively reduces the number of uterine NK cells in women with RPL and is most widely used in this patient population. Though some studies showed an improvement in live birth rate (LBR) when prednisolone was combined with aspirin or LMWH, their safety in the first trimester is of concern albeit its effect on increasing risk of maternal hypertension, diabetes, and prematurity. What makes the scenario complex is the presence of multiple confounding factors, thereby masking each individual component from being assessed for the efficacy of this drug. Their use should be limited in women with proven immunological backgrounds for RPL.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIg) has long been used in women with URPL despite several trials failing to show any positive impact. A recent meta-analysis of 11 randomized trials in women with URPL showed no difference in LBR between IVIg and placebo. IVIg is, therefore, not recommended for women with URPL.

TUMOR NECROSIS FACTOR-ALPHA ANTAGONISTS

Tumor necrosis factor-alpha (TNF-α) is involved in fetal loss via thrombotic and inflammatory factors. TNF-α antagonists, such as adalimumab, have been used for URPL. Improved LBRs were found when a combination of adalimumab and IVIg was added to anticoagulants compared to anticoagulants alone in a retrospective analysis of 75 patients. Further studies are required for supporting their use in RPL.

Intralipids

Intralipids have immune modulatory properties and act by inhibiting NK cell activity.

Granulocyte Colony-stimulating Factor

Granulocyte colony-stimulating factor is a cytokine that stimulates neutrophilic granulocyte proliferation and differentiation and is produced by decidual cells. G-CSF administration significantly increased LBR in women with URPL compared to placebo (82.8 vs. 48.5%, $p = 0.006$) without major side effects in one trial. However, G-CSF use in clinical practice warrants evidence from larger trials.

Sperm Deoxyribonucleic Acid Fragmentation and Unexplained Recurrent Pregnancy Loss

Sperm DNA fragmentation (SDF) is commonly tested using terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay, the sperm chromatin dispersion test, and the sperm chromatin structure assay. A meta-analysis of 16 cohort studies involving 2,969 couples found

a significant increase in miscarriage in patients with high SDF. Sperm DNA fragmentation testing should be offered to couples with otherwise unexplained RPL. Besides advanced paternal age, many environmental factors, such as cigarette smoking, obesity, exogenous heat, and exposure to toxins, have been associated with increased SDF. Testing for SDF could aid in bringing necessary lifestyle modifications.

Progesterone Supplementation for Unexplained Recurrent Pregnancy Loss

Progesterone supplementation has been proposed as a treatment for URPL and has proven beneficial. What makes the situation complex is the numerous preparations, routes, doses, and duration of therapy. A meta-analysis of 10 RCTs, including 1,586 women with URPL, found a significantly lower risk of RM [RR: 0.72, 95% confidence interval (CI): 0.53–0.97] and a higher chance of live birth (RR: 1.07, 95% CI: 1.02–1.15) following supplementation with progesterone. However, natural and micronized progesterone had no impact, whereas the use of synthetic progestogens made the difference. In a more recent observational cohort study, vaginal micronized progesterone started 3 days after the urinary luteinizing hormone (LH) surge resulting in improved pregnancy rates in women with URPL.

Overall, progesterone administration seems to be beneficial for women with URPL. But to answer our questions on the ideal progestogen, its dose and route of administration, further studies are required.

RECENT ADVANCES

Chronic Endometritis

Chronic endometritis has been seen in 7–58% of women with RPL. However, prevalence is largely influenced by the method of detection. Antibiotics have been found to be effective in treating endometritis with an apparent improvement in the live birth rate.[1] More studies are required to validate these evidences in clinical practice.

Endometrial Decidualization

Endometrium acts as a checkpoint for embryo quality with decidualization for normal embryos and rapid demise of endometrium with abnormal embryos. Abnormal endometrial decidualization leads to an excessively permissive endometrium to implantation of embryo and not sustenance.[2]

Chromosomal Microarray on Products of Conception

These tests offer more clarity on the etiology in 90% of cases. This not only gives answers to the questions of the couple and the treating doctor but also minimizes the cost of empirical therapy and the emotional turmoil of uncertainty.[3]

CONCLUSION

A couple with RPL needs evaluation with the right tools and management with appropriate interventions. These interventions could be as minimal as TLC and as complex as involving genetic workup with PGS or use of therapeutic agents altering immunologic mechanisms of RPL. Although more than half of these patients conceive on their own in due course of time, these interventions are required to minimize time lag and ensure successful outcomes. Over vigorous workup draining the couple financially, on a superseded emotional turmoil, triggers anxiety and apprehension. Avoidance of blanket therapy with judicious use of the available parameters and evidence-based approach is warranted. Optimization of complex clinical situations into pleasant pregnancy with definitive end points of "healthy mother and a healthy baby" become a reality for these couples sailing through troubled waters.

STRONG PRACTICE RECOMMENDATIONS IN RECURRENT PREGNANCY LOSS

- Optimal BMI: Neither obesity/underweight is recommended.
- aCGH is recommended.
- Thyroid screening and anti-thyroid peroxidase (TPO) antibody testing are recommended.
- Assessment of uterine anatomy is mandatory.

Recent Advances

CHAPTER 78

Bioengineered Human Endometrium In Vitro

Satish Patki, Ujjwala Patki, Shweta Patki

INTRODUCTION

Since the birth of the first test tube baby in 1978, many technological advances have taken place in the field of assisted reproductive technology (ART). In spite of these advances, the implantation rate in all the ART procedures is 25–30%.[1] The problem of failure of implantation is due to the difficulties in getting the process of synchronization between the competent embryo and the receptive endometrium.[2] It is now proved that in 65% cases of the failure of implantation, the cause is the nonreceptive endometrium, while in 35% cases, the poor embryo is the cause. The research in the field of creating a good-quality embryo "in vitro" is evolving rapidly by the use of different culture media, advanced incubators, and monitoring systems such as embryo scopes and metabolomics. However, the research in the field of endometrial assessment is not progressing with a similar pace. Animal studies cannot mimic the human "in vivo" conditions. In mice, natural killer (NK) cells are not present in the nonpregnant endometrium, decidualization occurs only after implantation, and during pregnancy, there is minimal trophoblastic invasion.[3] To understand the cellular and molecular events in the human endometrium, especially during the process of implantation, the procedure of getting the endometrial tissue by biopsy itself is invasive and cannot be performed repeatedly. The procedure of endometrial biopsy cannot be performed during the conception cycle. Hence, most of the data on endometrial receptivity are based on noninvasive procedures such as assessing endometrial thickness and blood flow by vaginal sonography. However, their positive predictive value is limited.[4,5] Doing repeated endometrial biopsies in the preembryo transfer cycle and assessment of the endometrial gene expression by the procedures of endometrial receptor array (ERA) tests are expensive and also have limitations.

Thus, there is a need for a process to develop a bioengineered human endometrium in a Petri dish for the following reasons:

- Such bioengineered endometrium will be at hand any time and can obviously avoid the traumatic procedures of repeated endometrial biopsies, especially to study the sequential changes in the endometrium during the window of implantation (WOI).
- It will avoid animal model studies, which are scientifically never matching the human physiological processes.
- Such bioengineered endometrium will be useful to study the effects of hormones or drugs at a cellular level.
- It will be easier to study the morphological and molecular status of the bioengineered endometrium available in Petri dish.
- The bioengineered endometrium will be helpful as a model for implantation research.
- Finally, the embryos cultured on this autologous bioengineered endometrium will be sensitized for the process of implantation, before they are actually transferred to the uterus. This will definitely increase the implantation rates of the procedures of ART following their transfer.

INDICATIONS OF THE CULTURE OF ENDOMETRIUM

The indications for endometrium culture are as follows:

- As a research tool for the evaluation of the process of implantation
- It is more useful in the management of the patients with previous implantation failure with a high index of suspicion of inadequate endometrial receptivity.

Tissue Culture Protocol for the Development of Bioengineered Endometrium in Culture Dish

The entire procedure has to be performed in a class 10,000 tissue culture laboratory, well equipped with air management by air handling unit (AHU). The cells handling should be performed in a laminar flow with class 100 atmosphere. All the disposable ware should be made up of tissue culture grade polypropylene of BD Falcon make, and

the culture media used should be from Sigma-Aldrich. The patients undergoing in vitro fertilization (IVF) procedures are posted for diagnostic hysteroscopy and endometrial scratch during the cycle prior to IVF cycle in the proliferative phase. After the hysteroscopy, the endometrial samples are obtained by sharp curettage. Even in a situation where hysteroscopy is not planned, blind endometrial biopsy from the uterine fundus is adequate. The endometrial bits should be placed in a beaker containing phosphate buffered saline (PBS).

CONTRAINDICATIONS

The procedure is contraindicated in patients with genital tuberculosis, Asherman's syndrome, where the amount of endometrium obtained for culture is usually inadequate. Similarly, patients with pelvic inflammatory disease and large hydrosalpinges are also not good candidates as their endometrium may be contaminated and hence difficult to culture.

THREE-DIMENSIONAL CULTURE SYSTEM

Human endometrium is a layered tissue with basically three components **(Fig. 1)**:

1. The surface epithelium which invaginates down to form the glands.
2. The stroma underneath the epithelium actually keeps the glands intact and supports the vessels.
3. The coiled vessels running in the stroma between the glands.

It is relatively easy to culture the stromal cells in vitro but to culture and propagate the epithelium, glands, and vessels are extremely difficult and need a three-dimensional (3D) culture system. Scientists have made attempts to culture both glandular epithelial and stromal cells in the canine endometrial model[6] and rabbit endometrial model.[7]

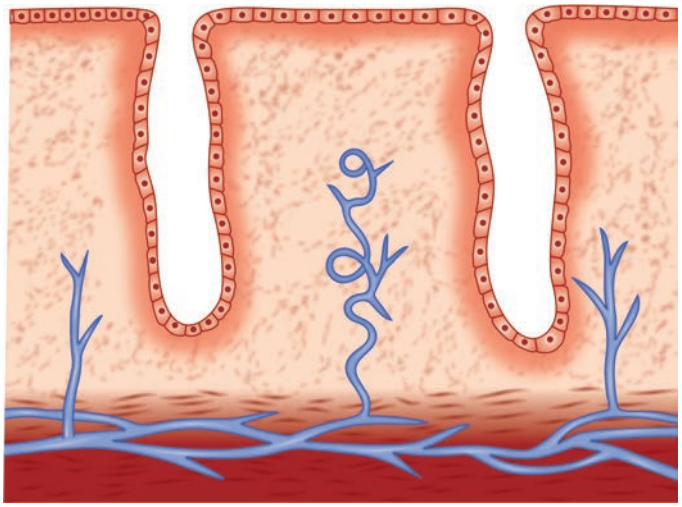

Fig. 1: Histology of human endometrium.

The culture model of human endometrium and cell sheet engineering has been tried.[8,9]

Preparation of Three-dimensional Culture System

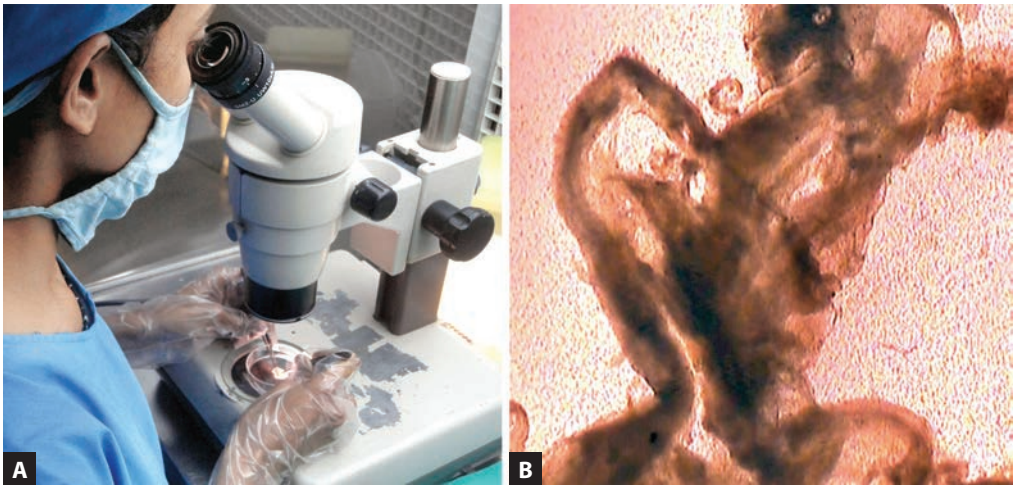
Matrigel (BD) is used as an extracellular matrix platform to culture all three components of the human endometrium. A total of 300 µL of red Matrigel is added to each well of four-well dishes, and the dish is kept in the carbon dioxide incubator for 30 minutes to solidify the gel. Such 3D culture system has the following advantages:

- It is helpful for detailed morphological studies of all three components of endometrium under phase contrast and scanning electron microscopy.
- It helps for gene and protein expression studies at each cellular component.
- It helps for the differentiation of each component with suitable sequential hormonal stimulation of estradiol followed by progesterone.
- It is easy to study the response of each endometrial component to the type of stimulus.

Preparation of the Component Cells for Seeding and Subsequent Culture

The endometrial bits are initially washed several times with PBS to remove the red blood cells. These bits are taken in a Petri dish and are minced with number 20 surgical blade and forceps. The endometrial glands can be isolated by mechanical dissection under a stereo zoom microscope **(Figs. 2A and B)**. The fine paste of the tissue is made which is then transformed into a 10 mL conical tube. 0.5 mL trypsin is added to the cell paste for 3 minutes, and vigorous mixing of cells in the enzyme is done at room temperature. To prevent the overaction of trypsin and to avoid overdigestion of the stromal cells, 1 mL of filtered human serum (patient's own) is added after 3 minutes. The human serum neutralizes the action of trypsin. The tube is then centrifuged at 2,000 RPM for 20 minutes to wash the trypsin and get the cell pellet. After centrifugation, the supernatant is removed, and 5 mL of mixture of Dulbecco's Modified Eagles Medium (DMEM) and Ham F-12 is added to the cell pellet. This cell pellet is seeded on Matrigel floor prepared in a four-well dish **(Fig. 3)**.

The dish is kept in a carbon dioxide incubator at 37°C at 5% CO_2 atmosphere. The medium is replenished every 48 hours. The stromal cells predominate in the culture plate because they form the 85% component of endometrium and look like circular, spherical cells at 0 hour **(Fig. 4)** while epithelial cells look like smaller and brighter circular cells at 0 hour **(Fig. 5)**. After 48 hours, the stromal cells start attaching the floor of the dish and look like fibroblast **(Fig. 6)** while the epithelial cells show cobblestone appearance and glandular differentiation **(Fig. 7)**.



Figs. 2A and B: Endometrial glands isolation under stereo microscope.

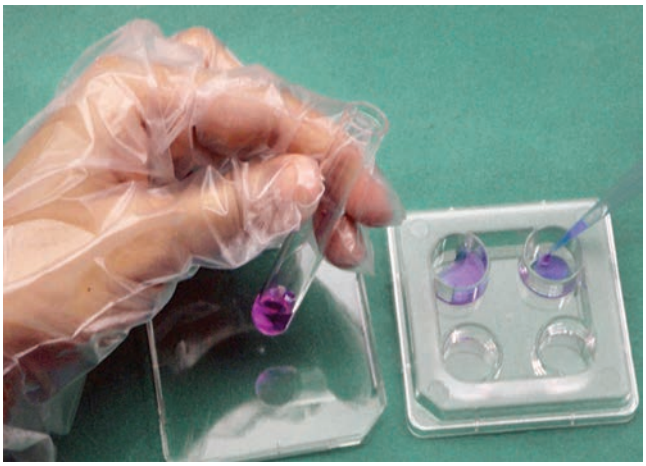


Fig. 3: Seeding of the cell pellet.

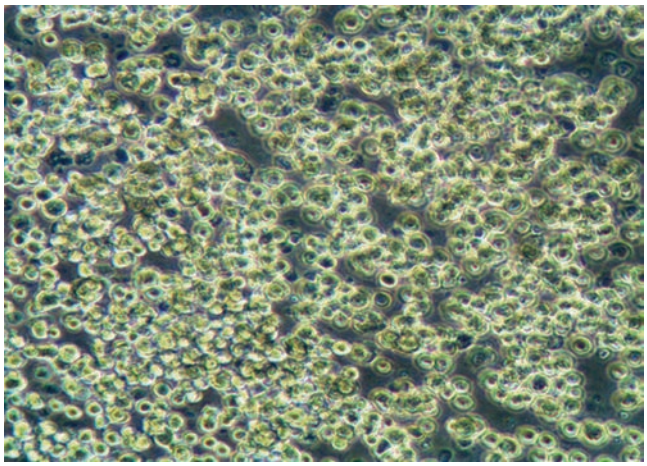

Fig. 5: Epithelial cells at 0 hour.

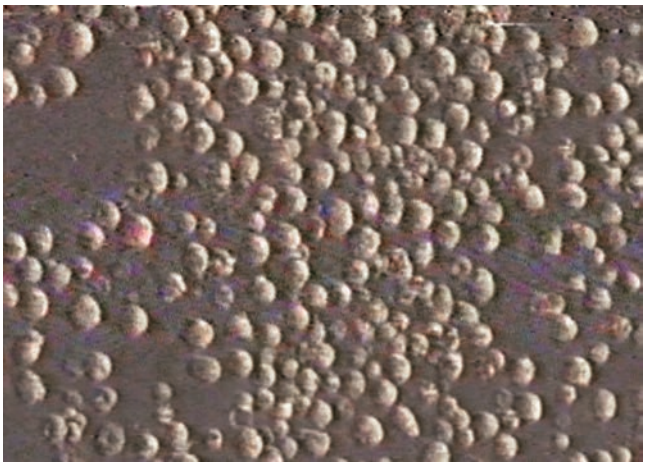

Fig. 4: Stromal cells at 0 hour.

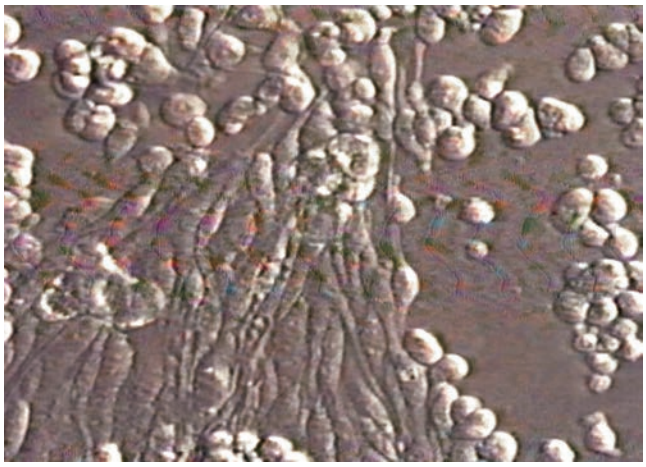

Fig. 6: Stromal cells after 48 hours.

Stimulation of the Bioengineered Endometrium with Sequential Hormonal Therapy

About 48–72 hours after the primary 3D culture of all the three endometrial components, the culture medium is supplemented with 17β-estradiol dissolved in DMEM. The epithelium, glands, and the stromal cells start rapidly proliferating under the stimulation of estradiol. The change of medium is done every 48 hours, and the supernatant containing floating dead cells is removed. Usually, by the

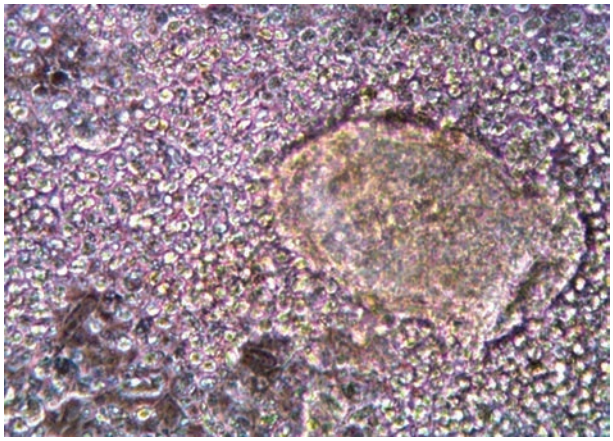

Fig. 7: Epithelial cells after 48 hours.

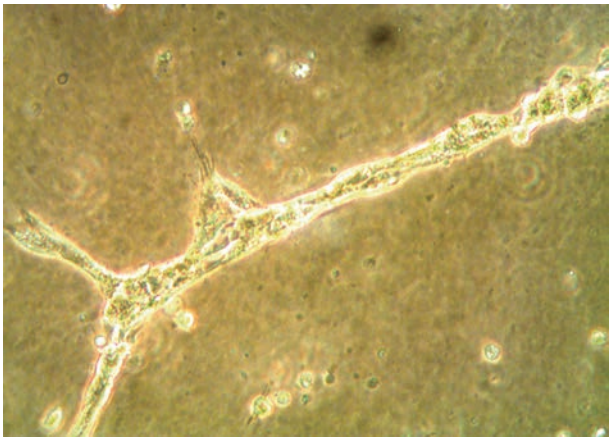

Fig. 9: Vessel formation.

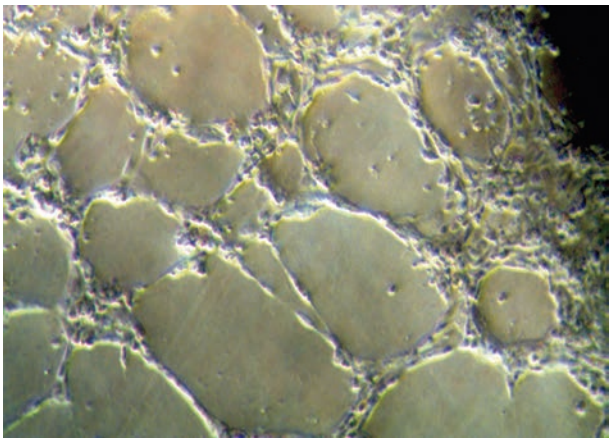

Fig. 8: Ring formation test—angiogenesis.

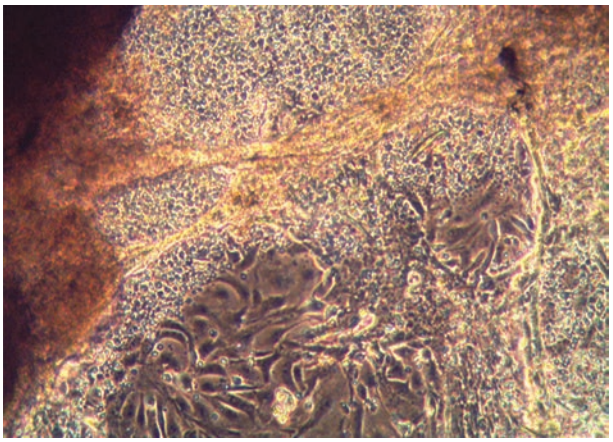

Fig. 10: Fully developed endometrium.

fourth or fifth day of estradiol supplementation, each well is fully confluent with the layered endometrium. In order to induce the process of angiogenesis, vascular endothelial growth factor (VEGF) is added to the medium in a very small quantity. Usually within 24 hours, the new vessels are seen developing from epithelial and endothelial cells which form ring-like structures **(Figs. 8 and 9)**. The aqueous progesterone is then additionally supplemented to the culture medium from day 5 of culture. This will bring about the early secretory stage.

COMPLICATIONS

As such, the procedure of culture does not have any complications. However, sometimes the contamination in the culture system can prevent cell proliferation, and on some occasions, may spoil the entire culture with the resultant degeneration of all the cells.

STUDY OF WINDOW OF IMPLANTATION ON BIOENGINEERED ENDOMETRIUM

The endometrium which is normally nonreceptive for the embryo becomes receptive for a very small period of 3–4 days, after the appearance of progesterone on the endometrium, which is adequately primed with estradiol.[10] During this period, all three components of the endometrium support the process of implantation of blastocyst through mediation by immune cells, cytokines, growth factors, and adhesion molecules.[11-13]

The bioengineered endometrium demonstrates all the sequential morphological changes during WOI. The epithelial proliferation, glandular enlargement with early secretions, stromal proliferation, and angiogenesis are the endometrial changes during WOI. All changes can be very well appreciated through a phase-contrast microscope in the bioengineered endometrium in the culture dish **(Fig. 10)**.

The most notable change in the epithelium is the appearance of "pinopode" which is believed to be involved in embryo opposition and attachment.[14,15] The pinopodes cover not only the entire surface but also cover and go deep down in the lumen of the glands also. When the culture dish of bioengineered endometrium is subjected to the scanning electron microscopy, the pinopodes can be clearly identified on the surface as well as inside the glands **(Figs. 11 and 12)**. Pinopodes are considered as a marker of endometrial receptivity.[16] The newly formed vessels can also be clearly seen under an electron microscope with their endothelial lining **(Fig. 13)**.

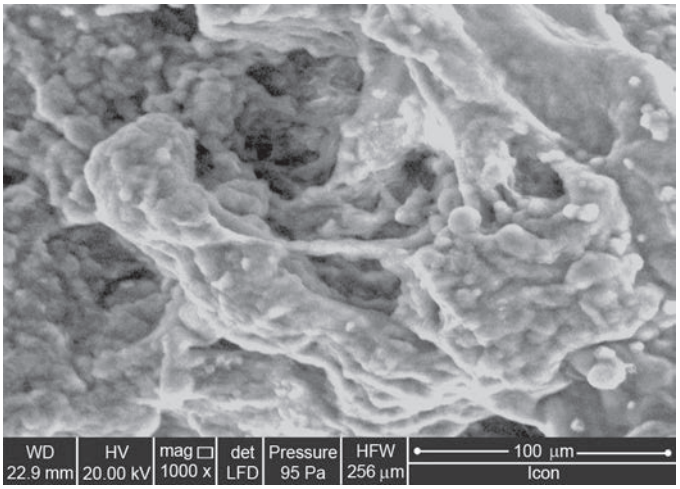

Fig. 11: Pinopodes on surface of endometrium.

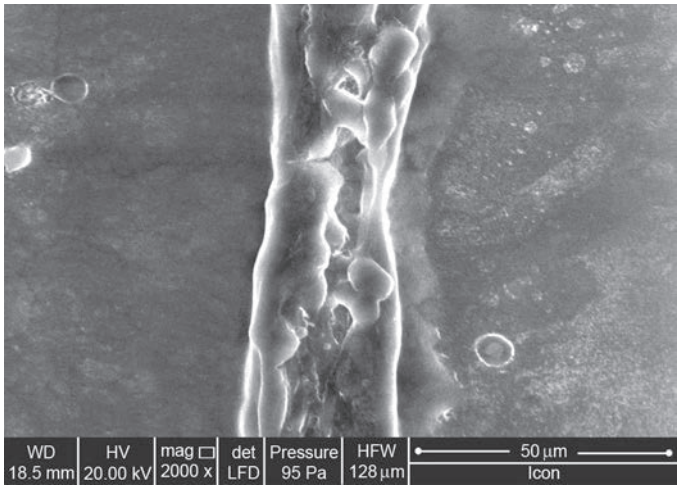

Fig. 13: New vessel observed under scanning electron microscope.

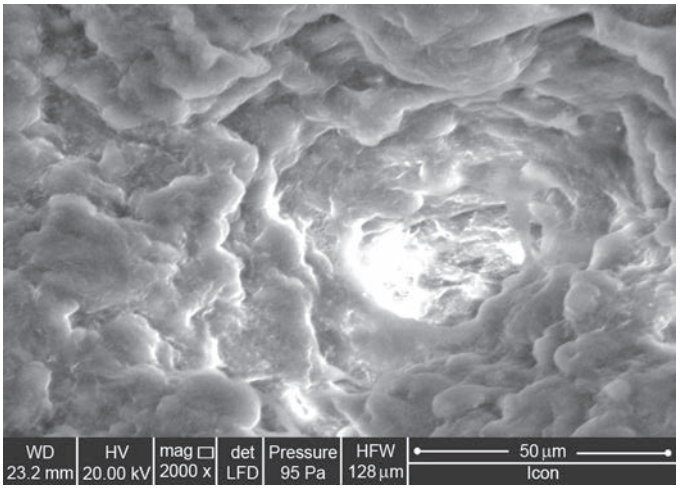

Fig. 12: Pinopodes over the glands.

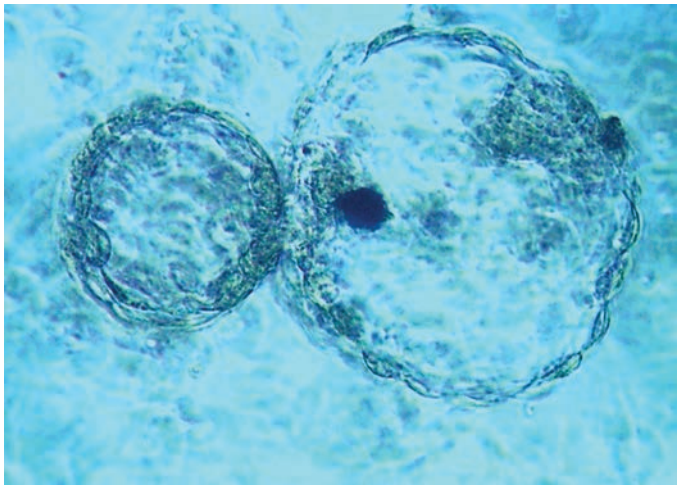

Fig. 14: In vitro hatching blastocyst on bioengineered endometrium.

Some of the genes in the endometrium are upregulated while some are downregulated making a "gene signature" during WOI.[13] Such molecular studies can be done on the cells obtained from the bioengineered endometrium.

"In vitro" Sensitization of Embryo Prior to Embryo Transfer

The embryo resulting from the procedures of ART can be cultured on such bioengineered endometrium. It is better to culture the embryo of a stage of morula as it mimics in vivo process. It is not physiological to coculture the 8–16-cell-stage embryo. Interestingly, sometimes even hatching of the blastocyst can be observed in the culture dish **(Fig. 14)**. Such sensitized embryos can then be transferred to the uterus which will have a high chance of implantation. Future research in this field can further throw light on these events.

Thus, the bioengineered endometrium is in fact a "mini uterus" in Petri dish, which can be used to study the morphological as well as molecular studies beneficial for the research not only in the field of reproduction but also in the fields of various endometrial pathologies such as hyperplasia or malignancies.

LIMITATIONS OF THE PRESENT STUDY AND FUTURE RESEARCH

The present research is the morphological evaluation of the bioengineered endometrium in culture dish, using phase contrast and scanning electron microscopy. The future research should be the molecular evaluation of the bioengineered endometrium by doing gene studies of the cultured cells. The marker studies throwing light on the various endometrial components will further widen the horizon of the research.

CONCLUSION

Bio engineered Endometrium gives opportunity to study the various components of endometrium, specially during the window of implantation. Histological, electron microscopy and molecular studies can be performed without repeated

invasive procedures of endometrial biopsy. It can be tried to sensitize the blastocysts before embryo transfer.

KEY POINTS

- Culture of the endometrial components, i.e., epithelium glands, stroma, and vessels, is possible with 3D culture techniques.
- Such bioengineered endometrium can be used as a research tool for the study of the implantation process.
- Sequential stimulation of such bioengineered endometrium with estradiol and progesterone can mimic the events which occur "in vivo" during WOI.
- The embryos can be cocultured on such bioengineered endometrium for better development "in vitro" followed by high chances of implantation after transfer.

CHAPTER 79

Recent Trends in Assisted Reproductive Technique

Arya Rajendran, Baiju Pookilath

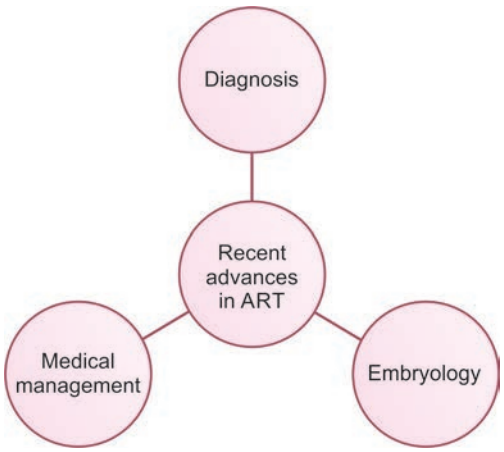
INTRODUCTION

Ever since the birth of Louise Brown in 1978, with every passing decade, there have been spectacular advances in assisted reproductive technique (ART) that have revolutionized and revamped its practice. The introduction of transvaginal scans, transvaginal oocyte retrieval, intracytoplasmic sperm injection (ICSI), preimplantation genetic screening (PGS)/ preimplantation genetic diagnosis (PGD), and time-lapse imaging are to name a few.

The current worldwide trends causing a paradigm shift include **(Flowchart 1)**:

- ART during COVID-19 pandemic
- ART and COVID-19 vaccination
- Routine blastocyst transfer instead of cleavage stage embryo transfer
- Replacement of fresh embryo transfer with embryo cryopreservation and subsequent transfer in a frozen–thawed cycle
- PGS for all
- Single embryo transfer
- Stimulation protocols—minimal stimulation protocols and progestin-primed ovarian stimulation (PPOS).

Flowchart 1: Approach to recent trends in assisted reproductive technique (ART).



ASSISTED REPRODUCTIVE TECHNIQUE DURING COVID-19 PANDEMIC

Advent of novel severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (COVID-19) as a global pandemic has changed the way humans live worldwide due to the widespread devastation caused due to death, morbidity, and economic collapse. With the first wave of COVID-19, European Society of Human Reproduction and Embryology (ESHRE) and American Society for Reproductive Medicine (ASRM) issued advice to stop all ART procedures as the risks outweighed the benefit of continuing treatment. With the pandemic well into the second year of rampage, the world has learned to adapt to the new normal and restart routine activities.

Indian Council of Medical Research (ICMR) has brought forth the following steps to be part of restarting ART clinical practice:

- *Patient information and counseling:*
  - Research on impact of COVID-19 on ART and pregnancy is still evolving.
  - Evidence so far does not indicate increased risk of congenital malformations or adverse pregnancy outcomes in association with COVID-19 disease.
  - All patients need to be educated regarding the methods of spread of COVID-19, importance of social distancing, and use of personal protection equipment—masks and hand sanitization.
  - Patients should be educated that treatment will be discontinued in case they get infected with COVID-19.
- *Consent to start treatment:*
  - Patients should be counseled regarding the risks and benefits involved in starting ART treatment during the pandemic. This decision should be individualized considering the age and severity of underlying conditions of the couple. They should be given the choice whether to start or postpone treatment to a future date; however, the virus is

likely to remain in transmission in the community for an extended period of time. After thorough discussion, the patient's choice to start treatment should be documented using the consent form given below.
- Patients with high-risk health conditions such as diabetes, cardiovascular illness, and respiratory conditions should have their present status evaluated by a specialist and fitness should be issued prior to start of ART.

- *Patient and ART clinic staff risk assessment triage:*
  - *Recommendations for patients, donors, and surrogates:*
    - ICMR risk assessment triage questionnaire must be self-answered by the patient before each visit to the clinic.
    - Following triage, patients suspected to be infected should undergo reverse transcription-polymerase chain reaction (RT-PCR) testing for COVID-19.
    - Those who have recovered from COVID-19 should be assessed by a physician and fitness to start ART should be obtained.
    - Patient and partner, all potential oocyte/sperm donors, and gestational surrogates must undergo COVID-19 RT-PCR test prior to start of treatment. Once ovarian stimulation is started, they are advised to self-isolate themselves until oocyte retrieval to prevent getting infected during the course of ovarian stimulation.
    - RT-PCR testing must be repeated on the day of human chorionic gonadotropin (hCG)-trigger and if found positive at any point during the ovarian stimulation, cycle must be canceled.
  - *Recommendations for staff working at ART clinics:*
    - ICMR risk assessment triage questionnaire must be self-answered every day.
    - Staff suspected of infection during triage must get RT-PCR testing done and self-quarantine if positive. Further, contact tracing and testing must be performed.
    - Staff should be divided into mini-teams with minimal interaction between different teams and work, so that if one gets infected, the spread can be contained.
    - Work at home must be encouraged whenever possible.
    - Reduce physical contact with patients with physical barriers and use personal protection equipment.
    - Organize virtual meetings instead of conventional ones.
- *Modification of ART clinic layout and services:*
  - Physical modifications should be brought about at the ART clinics to enable social distancing—such as separation of furniture and putting up physical barriers.
  - Thermal scanning at entrance to ART clinic
  - Scheduling outpatient (OP) visits to prevent overcrowding at the center.
  - Restrictions on number of bystanders attending the clinic along with the couple undergoing treatment, so as to prevent overcrowding.
  - Use of Arogya Setu application must be made mandatory for all staff and patients attending the clinic.
  - Friendly relationship must be maintained with a nearby ART clinic, so that in the event of breakout of COVID-19 infection at the clinic, patients can be diverted for emergency care.
- *Planning treatment specific to individual:*
  - *OP visits:*
    - Each patient's treatment plan must be individualized and properly planned so as to reduce number of visits to the center to minimum and judiciously reduce number of scan visits/blood tests.
    - Encourage home collection of semen samples with proper instructions to carry out the same.
    - Use of telemedicine to reduce the number of outpatient department (OPD) visits.
  - *OP and ART procedures:*
    - Questionnaire-based triage is adequate for attending OP, scan visits, blood tests, semen analysis, sonosalpingography (SSG), and hysterosalpingography (HSG).
    - RT-PCR testing must be undergone prior to office hysteroscopy (under paracervical block or regional analgesia).
    - Laparoscopy procedures must be categorized into emergent and elective, and planned accordingly. RT-PCR testing is mandatory prior to the procedure.
    - General anesthesia should be avoided due to risk of aerosol exposure to anesthesiologist. Regional analgesia is preferred.
    - Bipolar energy source must be preferred in comparison to ultrasonic instruments during laparoscopy to reduce transmission of virus through fumes.
  - *Embryology laboratory:*
    - Separate instruments (keyboards, pens, microscope eyepiece) should be used, as far as possible, to prevent transmission among embryologists.
    - Separate cryo-containers and closed system of vitrification must be used for embryos obtained from patients who are detected COVID-positive following oocyte retrieval and prior to embryo freezing.

- Careful disposal of follicular fluid and semen as evidence is incomplete as to whether transmission of virus is possible via these body fluids.

- *Mental health of healthcare workers and patients:*
  - Patients and health workers are at increased risk of anxiety related to treatment delays, risk of exposure to disease at the clinic, unanticipated interruptions in treatment due to infection or lockdown, etc.
  - Adequate counseling of patients regarding treatment steps and infection-preventing strategies at the ART clinic can help in mitigating undue stress to patients.
  - Prompt referral to psychological counseling sessions[1] (which can be accessed via telemedicine as well).

ASSISTED REPRODUCTIVE TECHNIQUE AND COVID-19 VACCINATION

Different types of vaccines [inactivated, messenger ribonucleic acid (mRNA), and protein subunit] are available presently in the armamentarium against COVID-19 infection during this pandemic. Information regarding the safety of vaccination against COVID-19 during pregnancy and preconceptional period is still in the emerging phase. Presently, vaccination is approved during preconceptional period, pregnancy, and lactation.

Who all should get vaccinated?

- All pregnant women are advised to get vaccinated, irrespective of the period of gestation as severity of COVID-19 disease is found to be higher during pregnancy.
- In preconceptional period, vaccination should be offered to patients at high risk of exposure to the disease (e.g., healthcare workers) or who have high-risk health conditions (diabetes, respiratory, or cardiovascular illnesses).
- Patients should not be refused ART services due to their unvaccinated status.
- *How long should couples wait to start ART treatment following vaccination?*
- ESHRE recommends completion of vaccination prior to start of ART procedures and to wait at least for a few days after vaccination, before starting ART procedures in order to provide time for immune reaction to settle down.
- In the event of allergic reaction to vaccination, ART procedures should not commence until the reaction settles down completely and physician has assessed the candidate as fit to resume treatment.
- ESHRE recommends monitoring of ART outcome in vaccinated and nonvaccinated patients to further the research on impact of vaccination on ART outcome, if any.
- Presently, there is no recommendation on the choice of which vaccine to be taken during preconceptional period.[2]

NEWER DIAGNOSTIC MODALITIES IN ASSISTED REPRODUCTIVE TECHNIQUE

Recent Trends in Ultrasonography in Reproductive Medicine

Doppler and 3D

These are the epochal recent advances in ultrasonography (USG) in reproductive medicine. Doppler studies allow evaluation of direction and magnitude of blood flow. Three-dimensional (3D) USG can provide multiplanar images, volume rendering, and surface rendering. Apart from USG, 3D dynamic magnetic resonance hysterosalpingography (dMR-HSG) and multislice computed tomography (CT) HSG are advances in tubal patency evaluation with more clarity on myometrium as well.[3,4]

Uterus

- *Endometrial blood flow:* Uterine artery resistance index (RI), pulsatility index (PI), and subendometrial RI and PI measurements as well as Applebaum's classification of endometrial blood flow have become common practice now for endometrial tracking prior to embryo transfer.
- *Myomas:* 3D USG has been seen to have diagnostic sensitivity as high as that of hysteroscopy in identifying submucosal and myometrial components of myomas, information that is critical for deciding between hysteroscopic and laparoscopic route of excision. Magnetic resonance-guided ultrasound energy has been used for thermoablation of myomas with two instances of pregnancies being achieved post-treatment.[5,6]
- *Adenomyosis:* On USG, adenomyosis appears as asymmetrical thickening of uterine walls or poorly defined heterogenous areas.
- *Müllerian anomalies:* 3D USG is a diagnostic modality of choice in detecting Müllerian anomalies.

Ovaries

- *Antral follicle count (AFC):* Sonography-based automated volume count (SonoAVC) is a volumetric analysis of follicles in ovary and is useful for careful estimation of AFC, especially in a polycystic ovarian morphology (PCOM) ovary. Receiver operating curve (ROC) analysis in a meta-analysis has shown superiority of AFC in prediction of in vitro fertilization (IVF) cycle outcome over serum follicle-stimulating hormone (FSH).[7]
- *Stromal ovarian blood flow* has lower impedance in PCOM ovaries, reflecting with lower RI and PI. These are

responsible for greater delivery of gonadotropins to such ovaries during stimulation.

- *3D evaluation of cysts* can give better delineation of cyst characteristics, especially with regard to septations, contents, etc., and to differentiate benign from malignant features.
- Measurement of *ovarian perifollicular blood flow* characteristics can be used to follow-up follicles during stimulation.

Fallopian Tubes

Three-dimensional USG is highly useful in assessment of hydrosalpinges that present as retort-shaped hypoechoic area between uterus and ovaries. Assessment of tubes to rule out hydrosalpinges is essential in pre-IVF workup since patients with hydrosalpinges have up to 50% lower implantation and pregnancy rates.

Self-operated Endovaginal Telemonitoring (SONAURA) System

This system consists of a vaginal probe connected by a USB (universal serial bus) to a small tablet. A specific website application to which the recorded data are immediately uploaded allows the operator to perform follicular and endometrial two-dimensional (2D) measurements using the video recorded by the patient. Self-operated endovaginal telemonitoring (SOET) increases patient and partner participation, decreases stress, and saves time and cost. The minor variations in folliculometry have not shown to alter treatment decisions.[8]

Smartphone USG

The transducer probe can be attached by USB cable to smartphone. After downloading the application for the scan settings, this combination of devices can be used as a portable scanning machine. Philips and MobiUS SP1 are popular brands of smartphone USG probes.

Fertiloscopy

Fertiloscopy is the performance of laparoscopy through the vagina using saline solution instead of CO_2 as working medium. It holds potential use in the evaluation of unexplained infertility as an alternative to diagnostic laparoscopy **(Fig. 1)**.

Advantages of Fertiloscopy over Laparoscopy

- Safer since neither Trendelenburg position nor CO_2 insufflation is needed.
- Evaluation of genital tract in its anatomical position
- Minimally invasive.

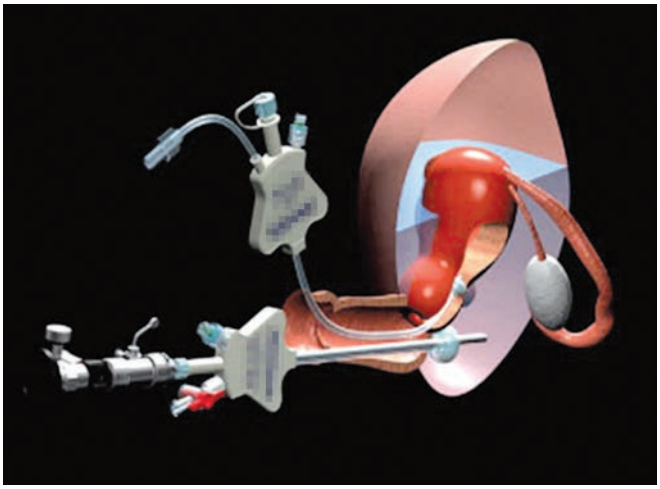


Fig. 1: Fertiloscopy.

Technique

- Careful vaginal examination is the first step to rule out contraindications for fertiloscopy such as fixed retroverted uterus [where there will be no space for penetration into pouch of Douglas (POD)] and nodules in rectovaginal septum (indicative of posterior endometriosis with close proximity to rectum and possible adherence to rectal wall).
- *Anesthesia:* (1) Local anesthesia with anesthetic swab for 10 minutes followed by a paracervical block with lignocaine; (2) Short general anesthesia is an alternative as in ovum pickup.
- *Hydropelviscopy:* Veress needle is introduced into POD 1 cm below cervix. 100–200 mL of saline should be introduced followed by removal of Veress and introduction of fertiloscope. Optic will be introduced through the scope (preferably 30° scope). Careful examination of genital structures will be carried out.
- *Hysteroscopy* is performed in collaboration to rule out intrauterine disease.

Fertiloscopy versus Laparoscopy

Fertiloscopy versus Laparoscopy (FLY) study was a multicenter randomized prospective study in which fertiloscopy and laparoscopy were performed in same patient by two surgeons randomized for the procedure. The video recording of the procedures was reviewed by two independent reviewers. Sensitivity, specificity, and concordance of both studies were evaluated. FLY study concluded that fertiloscopy should replace laparoscopy in infertile women with no obvious pathology.[9]

Endometrial Receptivity Array

Implantation of embryo requires a complex cross-talk between embryo and endometrium, which involves over

236 genes expression. The transcriptomic signature of the window of receptivity or window of implantation (WOI) of the endometrium can be identified by advances in microarray technology. Endometrial receptivity array (ERA) is a molecular diagnostic tool developed on this premise. Among women with recurrent implantation failure (RIF), use of ERA has shown that WOI is displaced in at least a quarter of them. Detecting the WOI in a woman and performing embryo transfer on a specific day is called "personalized embryo transfer (PET)" and has improved pregnancy rates making women with RIF achieve ongoing pregnancy rates at par with women without RIF (52%).[10]

How to Perform Endometrial Receptivity Array?

Endometrial receptivity array has been developed and patented by Igenomix. Endometrial biopsy is performed on luteinizing hormone (LH)+7 days (natural cycle) or on P+5 days [in hormone replacement treatment (HRT) cycle]. After obtaining a sample of endometrial tissue using a Pipelle brush, it is transferred to the vial of fixative provided with ERA kit. The sample should occupy one third of the vial. The sample is shaken well for approximately 40 seconds and then stored at 4°C for 4 hours for the cryofixation to happen. The fixed sample is then sent to the designated laboratory. The ERA test is performed with next-generation sequencing (NGS) technology. The ERA test has proven highly sensitive and accurate in detecting gene expression profiles associated with receptivity. If the report of ERA comes as "receptive", the embryo transfer should be planned on the same day of menstrual cycle as when ERA was performed. If it comes as "nonreceptive", then ERA test must be repeated on a subsequent cycle according to the predicted date given by the first test. Once the second test confirms receptive status, embryo transfer must be performed on the revised day of cycle.

Mahajan reported that 27.5% of women with RIF showed a displaced WOI. Pregnancy rates, ongoing pregnancy rates, and implantation rates improved after PET in the RIF group and became similar to non-RIF IVF cycles. Similar improvement was seen in above results for the subgroup of women with persistently thin endometrium as well.[11]

A recent prospective study assessed patients by ERA test at their first presentation for fertility treatment. They were excluded if they had RIF, recurrent pregnancy loss, stage 3–4 endometriosis, and abnormal uterine cavity or fibroids. After completion of the study, patients returned to routine clinical care as deemed appropriate by their provider. Infertility treatments and pregnancy outcomes were assessed 2 years after ERA testing. Patients who had a nonreceptive ERA were compared to those who had a receptive ERA on initial testing. The study concluded that nonreceptive ERA group had similar live birth rates as the receptive ERA group; however, majority of nonreceptive group women conceived in ovulatory cycles whereas majority of receptive group women conceived in embryo transfer cycles. Hence, a nonreceptive ERA in an HRT cycle does not seem to have prognostic value in naturally ovulating women.[12]

DNA Fragmentation Index

Sperm DNA fragmentation index (DFI) denotes the degree of damage to the genetic integrity of sperm DNA. Higher DFI rates are associated with subfertility and IVF failure. A routine semen analysis comments only on sperm concentration, motility, and morphology. Specialized tests are required to assess sperm DNA fragmentation.

Sperm Chromatin Structure Assay

Sperm chromatin structure assay (SCSA) test has been tried and tested over many years. It is technically less challenging than other tests and can be performed in minutes. It is a fluorescence cell sorter test and measures susceptibility of sperm DNA to damage after exposure to acid or heat. It measures single-stranded fragments and has high sensitivity. It simultaneously detects both DFI and the presence of immature sperm nuclei with abnormal proteins and altered protamine/histone ratios.

It has only two steps: (1) Treat the raw semen dilution with pH 1.2 buffer for 30 seconds; and (2) stain the spermatozoa with acridine orange, a dye that reveals broken DNA strands as red fluorescence and unbroken DNA strands as green fluorescence.[13]

A DFI of 30% is a widely accepted clinical threshold for significant DNA damage.

TUNEL Assay

It detects free ends of DNA by adding fluorescent stained nucleotides [labeling of the 3′-ends of single- and double-strand breaks with biotinylated deoxyuridine triphosphate (dUTP)], enabling single- and double-stranded DNA damage, either by fluorescent microscopy or by flow cytometry. The test has been further modified by adding a viability stain, thereby measuring the damage level in live sperms alone.

Sperm Chromatin Dispersion Test (Halo Test)

Halo test is "kit" form, convenient for testing for DNA without DNA damage, contrary to other tests that look for damaged sperms. It estimates the level of DNA fragmentation indirectly by quantification of the amount of nuclear dispersion or halo after sperm lysis and acid denaturation to remove excess nuclear proteins.

Comet Test

Comet test quantifies the amount of DNA damage per sperm by means of a single-cell gel electrophoretic assay. Applicable to both single- and double-stranded damage detection.

Within an agarose gel, the sperm membranes are lysed and the DNA is decondensed in a high-concentration salt solution. Disulfide bridges are broken down and then the spermatozoon is placed in an electrophoretic field where strands of charged broken DNA stream towards the cathode. As the mass of DNA fragments stream out from the "head" of unbroken DNA they resemble a "comet tail," hence the name of the assay.[14]

Higher DFI has been associated with poorer IVF outcomes (impaired fertilization and disrupted preimplantation embryo development[5]) and higher miscarriage rates[15,16] as well as birth defects in offsprings and even childhood cancers. The major limitation of testing for sperm DNA damage is that the assay renders the tested sperm unsuitable for clinical purpose. Intracytoplasmic morphologically selected sperm injection (IMSI) and hyaluronic acid selection of sperm for ICSI [physiological ICSI (PICSI)] are noninvasive methods for testing sperm DNA integrity that enable the use of normal sperms for ART.

Follicle-stimulating Hormone Receptor Polymorphism

Follicle-stimulating Hormone Receptor

The FSH and the LH are glycoprotein hormones secreted from anterior pituitary. They are heterodimers with alpha subunit being common to FSH, LH, hCG, and thyroid-stimulating hormone. Beta subunit is specific for each hormone with receptor binding specificity. FSH receptors are G protein-coupled receptors present on the plasma membrane of granulosa cells and Sertoli cells. FSH receptor gene is 192 kb in size and has 10 exons and 9 introns. Among the 10 exons, the first 9 code for N-terminal of extracellular domain of FSH receptor. The 10th exon is large and codes for C-terminal of extracellular domain, transmembrane domain as well as intracellular domain of FSH receptor.[17] The transmembrane domain has seven alpha helices and inner domain is coupled to G protein that initiates the series of events that culminate in the biological function of the receptor. FSH gene and receptor gene activity are absolutely essential for female fertility whereas in males, some degree of spermatogenesis is possible even with abnormal FSH genes.[18]

The FSH receptor gene is highly polymorphic. Single nucleotide polymorphisms (SNPs) at positions 29, 307, and 680 are extensively studied. Loss-of-function mutations in FSH receptor have been found in women with ovarian dysgenesis and primary and secondary amenorrhea. Gain-of-function mutations have been found in women with ovarian hyperstimulation syndrome (OHSS).

Single Nucleotide Polymorphisms of Follicle-stimulating Hormone Receptor Gene

There are eight SNPs in coding region and >1,300 SNPs in noncoding region of FSH receptor gene. Out of the eight SNPs in coding region, six are asymptomatic. The two polymorphisms at position p Thr^{307}Ala (rs6165) and p Asn^{680}Ser (rs 6166) are most extensively investigated.

Ser^{680} allele is clinically important in prediction of ovarian response to gonadotropin stimulation. Women with Ser/Ser and Asn/Ser genotype showed significantly higher FSH dose for ovarian stimulation when compared with Asn/Asn genotype. Peak estradiol levels, number of follicles, and oocytes were similar in all three.[19]

Women with Ala^{307}Ala genotype are significantly associated with lower dose of exogenous FSH and higher estradiol levels. 85% of women with Ala-Ala genotype developed OHSS.[20]

Asn^{680} allele is associated with a lower risk for polycystic ovary syndrome (PCOS) and Ala^{307}-Ser^{680} genotype has increased risk of developing PCOS. In a study among women with PCOS, Ser/Ser genotype at 608 showed resistance to clomiphene citrate (CC) and favorable response to exogenous FSH.[21] Asn/Thr genotype at position 307 showed higher response to FSH stimulation than both homozygous states.[22]

Homozygous Ala^{307}/Ser^{680} has been shown to be associated with higher risk of occurrence and recurrence of ovarian cancer.[23]

Alternately spliced variants of FSH receptor gene are also encountered. Alternately spliced exon 9 has been observed in normal testicular tissue.[24] Deletion of exons 6 and 9 has been seen in infertile men.[25] Among women, deletion of exon 9 has been associated with poor response and deletion of exon 6 is associated with a high response.[26]

RECENT TRENDS IN MEDICAL MANAGEMENT IN ASSISTED REPRODUCTIVE TECHNIQUE

Corifollitropin Alfa/Delta/Epsilon

Corifollitropin Alfa

Corifollitropin alfa (Elonva®) is the first hybrid FSH molecule and has sustained follicle-stimulating activity.

The beta subunit of this molecule contains the carboxy-terminal peptide of human chorionic gonadotropin. This imparts a longer half-life (approximately 69 hours), which is two times higher and slower absorption (fourfold higher time to peak serum levels) when compared with recombinant FSH (rFSH).

Pharmacodynamic properties of corifollitropin alfa are identical to rFSH as it interacts only with the FSH receptor. Corifollitropin alfa is able to sustain multiple follicular growth for a week, with a similar ovarian response and safety profile as rFSH. A single injection of corifollitropin alfa can replace seven daily injections of rFSH during the first week of ovarian stimulation in gonadotropin-releasing hormone (GnRH) antagonist protocols.

Therefore, corifollitropin alfa presents a simplified treatment protocol and reduces the burden of multiple daily injections.[27]

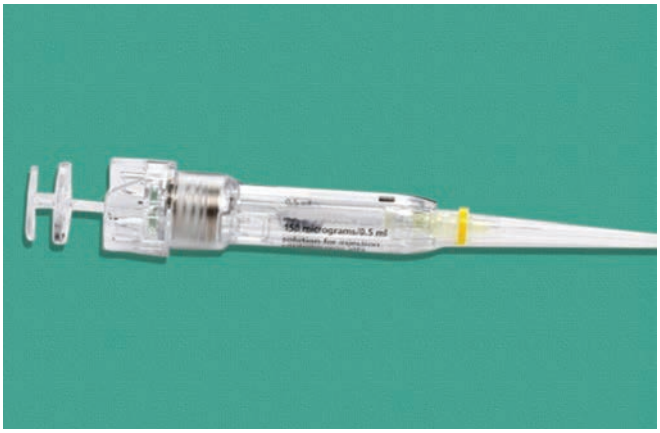

Fig. 2: Corifollitropin alfa.

Corifollitropin alfa is given as a single subcutaneous injection on menstrual day 2/3 (stimulation day 1). A GnRH antagonist can be added on stimulation day 5, depending on follicular response, to prevent a premature LH surge. Daily rFSH doses should be instituted from stimulation day 8 as required.

The optimal dose is 100 µg (<60 kg, <36 years) and 150 µg (>60 kg or >36 years) **(Fig. 2)**.[28]

Meta-analysis has shown that corifollitropin alpha is as effective as rFSH in terms of live birth rate, ongoing pregnancy rate, and clinical pregnancy rate. There is an increased number of eggs retrieved after corifollitropin; hence, a careful patient selection to screen out hyperresponders is mandatory to prevent OHSS.[29]

Corifollitropin Delta

Corifollitropin delta is the first rFSH product that has been developed from human cell line, namely PER.C6. It is unique in that dosing is optimized based on patient's body mass index (BMI) and anti-Müllerian hormone levels. Both alpha and delta have the same amino acid sequence but vary in their glycosylation and subsequently in the pharmacodynamics in humans. Steelman–Pohley bioassay done on Chinese hamster ovarian cells revealed similar pharmacodynamic curves; whereas in humans, the pharmacodynamics are different for the two. Corifollitropin delta has slower serum clearance and hence greater exposure and higher pharmacodynamic response.[30]

Corifollitropin Epsilon

Also a human cell line derived rFSH, at similar doses epsilon, has been shown to have a greater effect on follicular growth, not only on diameters but also on the follicular numbers.[75] IU corifollitropin epsilon given daily produces comparable response as that of 150 IU of rFSH (Gonal-f) and 150 IU of epsilon given on alternate days produces a greater response than 150 IU of rFSH given daily. There is a similar increase in estradiol and inhibin B levels produced while on epsilon than on rFSH or on corifollitropin delta. The drug is currently in clinical trial.[31]

Synthetic Kisspeptins

The neuropeptide kisspeptin and its receptor Kiss1R modulate the reproductive timeline of mammals by triggering puberty onset and promoting ovulation by stimulation of GnRH secretion. Kisspeptin interacts with other neuropeptides like dynorphin and neurokinin B to influence the GnRH release. Loss of kisspeptin signaling causes hypogonadotropic hypogonadism.

Kisspeptin was initially discovered as a factor that inhibits metastasis in melanoma cell lines.[32] Kisspeptin comprises a group of peptides encoded by the *Kiss1* gene. These peptides are derived from the common precursor—prepro-kisspeptin. The most abundant kisspeptin in humans is kisspeptin-54.[33]

Kisspeptin receptor belongs to rhodopsin family of G protein-coupled receptors.[33]

The short half-life of kisspeptin has been overcome by modifications that reduce proteolytic degradation and renal clearance. These modifications have increased the potency of the drug.

Different Roles of Kisspeptin

- *Regulation of gonadal steroid feedback to hypothalamus:* Kisspeptin plays a key role in mediating the positive feedback effect of estrogen via estrogen receptor alpha at the hypothalamus, which in turn causes the LH surge and ovulation. Kisspeptin gene expression is under epigenetic modulation.[34]
- *Direct action on gonads:*
  - Kisspeptin and its receptor genes are expressed in ovary and testes as well. Reduced kisspeptin gene expression in ovaries has been associated with premature ovarian failure in mice.
  - Neurotrophin signaling via NTRK2 receptor which is essential for oocyte maturation following LH surge is dependent upon kisspeptin signaling, as evident in knockout mice.[35]
  - In testes, kisspeptin potentiates the release of testosterone on hCG administration via a peripheral pathway.[36]
  - Kisspeptin and its receptor expression in spermatozoa mediate a biphasic rise in intracellular calcium release and increase sperm motility and in capacitation.[37]
- *Pregnancy and implantation:*
  - Syncytiotrophoblastic cells have the highest level of peripheral kisspeptin expression in the body. The levels increase with gestation and are more in gestational trophoblastic disease. Kisspeptin plays a role in trophoblastic cell invasion.[38]
  - Kisspeptin levels are lower in pregnancy associated with type 1 diabetes mellitus (T1DM), gestational

diabetes mellitus (GDM), hypertension, placental dysfunction, and recurrent miscarriage.[39]

- *Regulation of nutrition and fertility:* Kisspeptin plays an intermediary role between leptin and GnRH neurons. Leptin is a peptide hormone secreted by adipocytes. GnRH neurons do not have leptin receptors. Kisspeptin neurons have leptin receptors. Kisspeptin expression increases after exogenous leptin administration.[40] Deficiency of leptin results in delayed puberty and hypogonadotropic hypogonadism.

Applications of Synthetic Kisspeptins

- Manipulation of kisspeptin signaling can be made use in disorders related to decreased GnRH signaling as in hypogonadotropic hypogonadism and where the hormones need to be suppressed as in hormone-sensitive cancers.
- Kisspeptin administration in males has shown to increase plasma gonadotropin and testosterone levels.[41]
- A single bolus of kisspeptin-10 induces an immediate LH pulse, irrespective of when the previous endogenous LH pulse was, and the amplitude is higher than normal LH pulse. The next endogenous LH pulse is delayed by the normal interpulse interval; hence, it is suggestive that kisspeptin administrations reset the GnRH pulse generator.[42]
- In women with hypothalamic amenorrhea, twice daily administration of kisspeptin resulted in desensitization whereas twice weekly administration retained the response in healthy women.[43]
- Kisspeptin neurons express prolactin receptors. High prolactin levels suppress kisspeptin expression and thereby prevent the LH surge. This provides the application of synthetic kisspeptin in treatment of anovulation due to hyperprolactinemia, which is not amenable to usual medications.[44]
- Jayasena et al. investigated the effect of varying doses of kisspeptin in GnRH antagonist protocol IVF stimulation to bring about triggering of oocyte maturation. Egg maturation was achieved at 36 hours after kisspeptin administration and the mean number of mature eggs increased with increase in kisspeptin dosage. Since this involves stimulation of endogenous gonadotropin release to bring about egg maturation, the risk of OHSS is minimized.[45]

Elagolix—The Oral Gonadotropin-releasing Hormone Antagonist

Elagolix is a highly potent, short-duration, nonpeptide, orally active, competitive GnRH antagonist. Due to the entirely revised properties, it is called "second-generation GnRH antagonists." It causes rapid and dose-dependent suppression of pituitary gonadotropins, the peak effect being reached in 4–6 hours. The target dose is 150 mg/day. Phase II clinical trials have demonstrated benefit in alleviation of dysmenorrhea, chronic pelvic pain, and dyspareunia of endometriosis.

The actions of GnRH are not fully blocked throughout the day, due to shorter half-life than regular antagonists. Hence, gonadotropin and sex hormone levels are only partially suppressed. Upon discontinuation of drug, its effects are rapidly reversible. These provide an easier tolerance profile upon long-term use, especially with regard to menopausal symptoms and bone mineral density.[46]

Uterine Transplantation

The first pelvic organ transplant was that of fallopian tube, tried in animal models to develop treatment for tubal infertility. With advent of IVF, tubes were bypassed and importance came on to uterine transplantation for curing uterine factor infertility. First uterine transplantation was performed in Saudi Arabia in 2002 but it ended in graft rejection and hysterectomy at 3 months posttransplantation. Second attempt was in Turkey and resulted in pregnancies that ended in miscarriages. Successful pregnancy posttransplant came later as Baby Vincent on October 14, 2014 in Gothenburg, Sweden, among a cohort of nine patients who underwent the procedure. In her, the first menstruation happened 43 days after transplantation.

Indications

- Uterine malformations: Most common being agenesis and hypoplasia
- Posthysterectomy for neoplasms, postpartum hemorrhage, etc.
- Asherman's syndrome

Assessment of Donor Eligibility

- Proved parity with no history or evidence of any uterine disease
- To be screened for genital infections and Pap smear
- History of risk factors for infection
- Malignancy in the past 5 years
- Presence of any comorbidities
- Serology, infectious, and malignant screening
- Human leukocyte antigen (HLA) typing
- ABO and Rh typing.

Tissue Typing

The tissue typing laboratory carries out three tasks:

1. To determine the HLA type of blood for both donor and recipient by PCR.
2. Lymphocyte cross-matching to exclude circulating antibodies in recipient against HLA expressed by donor.

3. HLA antibody screening and specificity in recipient before and after transplant to guide immunosuppressive therapy.

Donor Surgery

Donor can be living or deceased. Deceased subjects were opened by midline infraumbilical incision. Uterus is heparinized and perfused with saline solution before harvesting. Use of living donors was pioneered by Mats Brännström of Sweden. Infraumbilical midline incision is used to give adequate exposure. Uterus is dissected and supportive ligaments delineated. Bilateral salpingectomy is performed. With careful dissection, uterine artery and veins should be separated from the uterus. A 10–15 mm of vaginal cuff is needed for reanastomosis. After surgical isolation, uterus is flushed bilaterally through the arterial ends with cold histidine–tryptophan–ketoglutarate solution.

The human myometrial tissue is resistant to cold ischemia for a period of 6 hours if a protective buffer is used.[47]

Recipient Surgery

Both donor and recipient surgery must be synchronized to reduce ischemia time. Internal and external iliac vessels are dissected and anastomosed to donor vessels. Vagina will be sutured and subsequent fixation of transplanted uterus is performed. Fixation of uterus to the ligaments and suturing the bladder peritoneum on the uterine graft on top of the recipient's bladder provide extra structural support. Living donor uterus requires more extensive vascular anastomosis than dead donor organ.[47]

Immunosuppression is maintained till birth of child by cesarean section and discontinued with hysterectomy soon after. The Swedish group has subjects who were maintained on immunosuppression following first childbirth for uterine preservation for a subsequent gestation.

Monitoring for Immunological Rejection

Monitoring for immunological rejection is by:

- *Ultrasound:* Endometrium and the uterus
- *Doppler:* Blood flow in the uterine arteries
- Visual inspection of cervix
- Cervical cultures
- Cervical biopsies.

Birth of healthy babies from the Swedish study has opened up hope for the subgroup of women with severe uterine factor infertility.[48] Deceased donor organ transplant has lesser success rates than living donor, probably due to preexisting conditions such as vasoactive drug use, elevated serum inflammatory markers, duration of ischemia, and type of solution used for preservation. There is a need for improvement in technology for preservation of organ in deceased donor for better posttransplant results.

Ethical Issues

Uterine transplantation is fraught with ethical issues because of following reasons—not a lifesaving organ transplant, day-to-day physiological functioning is not compromised in its absence, alternatives such as surrogacy and adoption are available, temporary in nature—removed after one or two children, and possibility of failure of IVF.

Montreal Criteria for the Ethical Feasibility of Uterine Transplantation[49]

The recipient:

- Is a genetic female of reproductive age with no medical contraindications to transplantation.
- Has documented congenital or acquired uterine factor infertility, which has failed all current gold standard and conservative therapy.
- (1) has a personal or legal contraindication to surrogacy and adoption measures, or (2) seeks the uterus transplantation (Utx) solely as a measure to experience gestation, with an understanding of the limitations provided by the Utx in this respect.
- Has not had her decision to undergo Utx deemed as irrational by expert psychological evaluation.
- Does not exhibit frank unsuitability for motherhood, and
- Is responsible enough to consent, informed enough to make a responsible decision, and not under coercion.

The donor:

- Is a female of reproductive age with no medical contraindications to donation.
- (1) has repeatedly attested to her conclusion of parity, or (2) has signed an advanced directive for postmortem organ donation.
- Has no history of uterine damage or disease, and
- Is responsible enough to consent, informed enough to make a responsible decision, and not under coercion.

The healthcare team:

- Is part of an institution that meets Moore's third criteria as it pertains to institutional stability.
- Has provided adequate informed consent to both parties regarding risks, potential sequelae, and chances of success and failure.
- Has no conflict of interest independently or with either party, and
- Has the duty to preserve anonymity if donor or recipient does not explicitly waive this right.

First ICMR-approved uterine transplantation program in India is currently underway at our center, in collaboration with Mats Brännström (Sweden).

Bioengineered Uterus

Absolute uterine factor infertility (AUFI) is caused by congenital [absent uterus as in Mayer–Rokitansky–Küster–Hauser

(MRKH) syndrome, uterine malformations] or acquired uterine conditions (severe intrauterine adhesions, following hysterectomy) that preclude the possibility of pregnancy. Brännström of the Stockholm group pioneered uterine transplantation as a cure to AUFI. Among the nine women who underwent uterine transplantation, the indication was MRKH for eight of them and posthysterectomy for early-stage cervical cancer for one candidate. Among the nine, seven candidates had graft survival at 1-year postsurgery and were able to go ahead with embryo transfers and so far, five live births have been achieved of the lot.[47]

But uterine transplantation comes with its accompaniment of perils. A 10-hour long surgery for the recipient, long-term immunosuppressant use, and risks and health effects of tissue rejection reaction are to name a few. Long-term effects of immunosuppression include chronic conditions as well such as diabetes, hypertension, and accelerated arteriosclerosis.[50] Also there is a mismatch between demand and supply of matched donors to recipients. This has led to development of bioengineered uterus.

Bioengineering of organs is based on using a synthetic or biologically derived scaffold to provide structural support for pluripotent cell proliferation and differentiation.[51] A biological scaffold is produced by decellularization of an organ. Decellularization is the process of removal of immunologically active cells from a normal organ, leaving behind a framework of extracellular matrix.[52] Decellularization is carried out by exposure to detergents or to physical forces (freeze–thaw or pressure) or enzymatic activity. Embryonic and mesenchymal stem cells are the most used cell source for repopulation.[53] The vascular conduits in biological tissue-derived scaffolds are used to cannulate and connect to perfusion bioreactors during recellularization.[54] For whole uterus construction, larger scaffolds and vascular conduits will be necessary and is still in the stage of experimentation at level of rat uterus. Encouraging results have been obtained for strategies for partial uterine reconstruction with tissue-engineered uterine patch for use to cover partial uterine defects such as following resection of placental tumors, myomectomy, etc.[55]

Ectogenesis

- Artificial uterus (or artificial womb) is a hypothetical device that would allow for extracorporeal pregnancy or extrauterine fetal incubation by growing embryo or fetus outside of body of an organism that would normally internally carry the embryo or fetus to term.
- Extreme prematurity is the leading cause of neonatal morbidity and mortality. In particular, respiration is affected by bronchopulmonary dysplasia, which is the arrest in lung development secondary to premature transition from liquid to gas ventilation. There is circulatory failure as well due to imbalance between preload and afterload in artificial support circuits. Thirdly, there is a high chance for sepsis due to exposure to open fluid incubators. Lambs at 100–115 days of gestation are biologically equivalent to 22–24 weeks of premature human infant. An experimental team has successfully maintained preterm lambs in this artificial womb circuit and opens avenues of possibility in treatment of preterm human babies.
- Ectogenesis aims to overcome these three main obstacles by a system with following three components:
  1. *Pumpless arteriovenous circuit:* Blood flow is driven by the fetal heart and oxygenated by a low-resistance oxygenator.
  2. *Closed fluid environment with continuous fluid exchange:* A biobag, closed system, single-use design was used. Watertight ports were included for cannula access, suction, and temperature probes.
  3. Umbilical vascular access

A major concern in this artificial setup was anticoagulation, which has the risk of intracranial hemorrhage in preterm infants. Artificial womb has low effective surface area and hence the dose of anticoagulant is low and comparable to that used in extracorporeal membrane oxygenation **(Fig. 3)**.

Lambs grown in this external womb had no structural or ischemic defects. Myelination of nerves was also comparable to term offsprings. The target population for this therapy is 23–25 weeks extreme preterms.[56]

INVO Procedure (In Vivo Fertilization/ Vaginal Incubation)

Intravaginal culture of oocytes (INVO) procedure is an ART that makes use of a specially designed vaginal incubation device for oocyte fertilization and early embryogenesis **(Fig. 4)**. INVOcell™ intravaginal culture system has three parts:

1. *INVOcell culture device:* It consists of an inner vessel surrounded by an outer rigid shell. The inner vessel holds culture medium, eggs and sperm, or ICSI fertilized embryos. The inner vessel is placed into the outer rigid shell, which provides additional resistance to contamination. Made of polystyrene and silicone ring and medical grade synthetic rubber, all of which are nonembryotoxic.
2. *INVOcell retention device:* Helps in retention of the culture device within the vagina during the incubation period of 72 hours.
3. *INVOcell holding block:* For temperature maintenance during loading and collection procedures.

The sperm concentration is limited to 30,000/mL and not more than seven eggs are placed in the culture device. At the end of 72-hour incubation period, the device is collected and the contents are examined for viable embryos. Since its Food and Drug Administration (FDA) approval in November 2015, several hundred babies have been born in the United States by this technique.

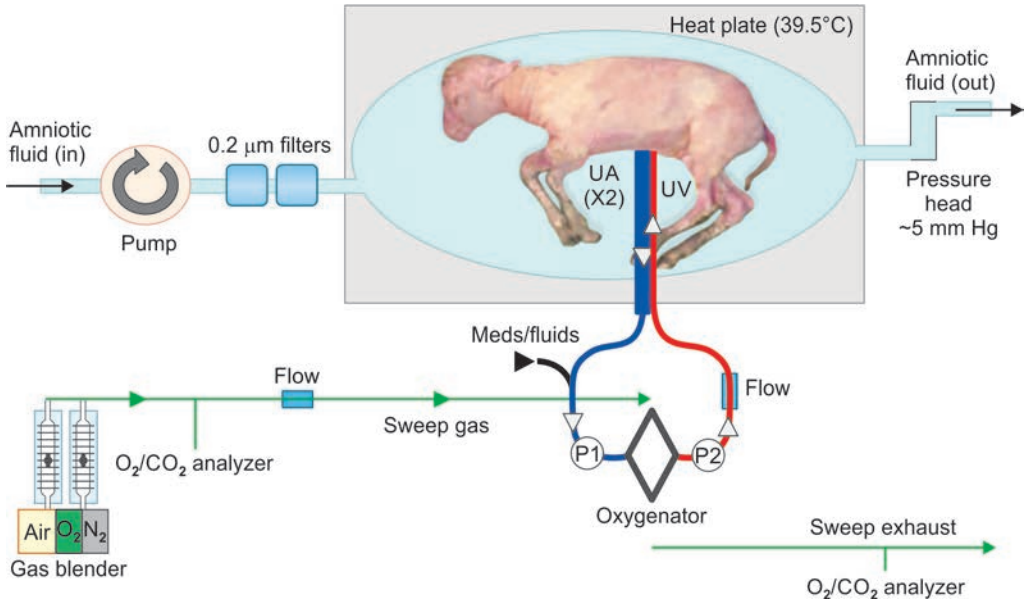

Fig. 3: Ectogenesis.

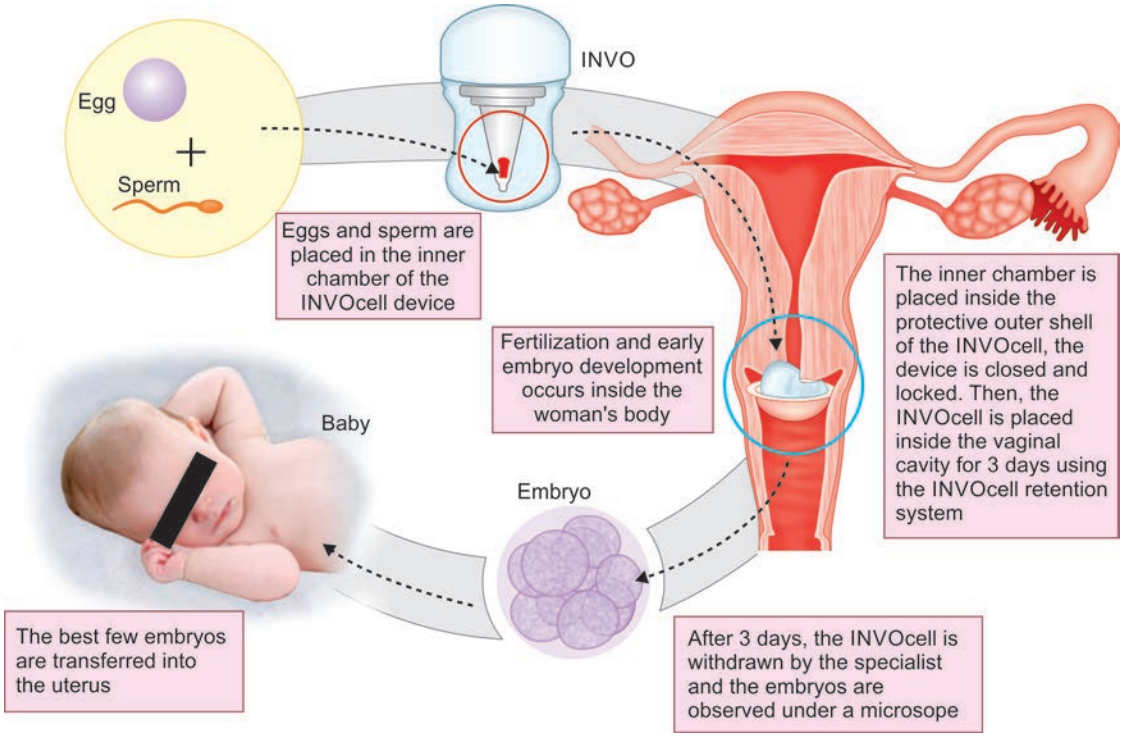

Fig. 4: In vivo procedure.

Benefits

Benefits of this procedure are:

- Greater patient involvement is a source of comfort to the couple
- Natural and stable culture environment
- Rules out the possibility of wrong embryo transfer
- Reduction in cost of IVF procedure.[57]

Embryonic Stem Cells

Embryonic stem cells are derived from cells of inner cell mass, which are removed and cultured under appropriate conditions. These cells have the ability to proliferate and develop into any cell type in the body **(Fig. 5)**.

Even though mouse embryonic stem cells were reported as early as 1981, the first reports of human embryonic stem

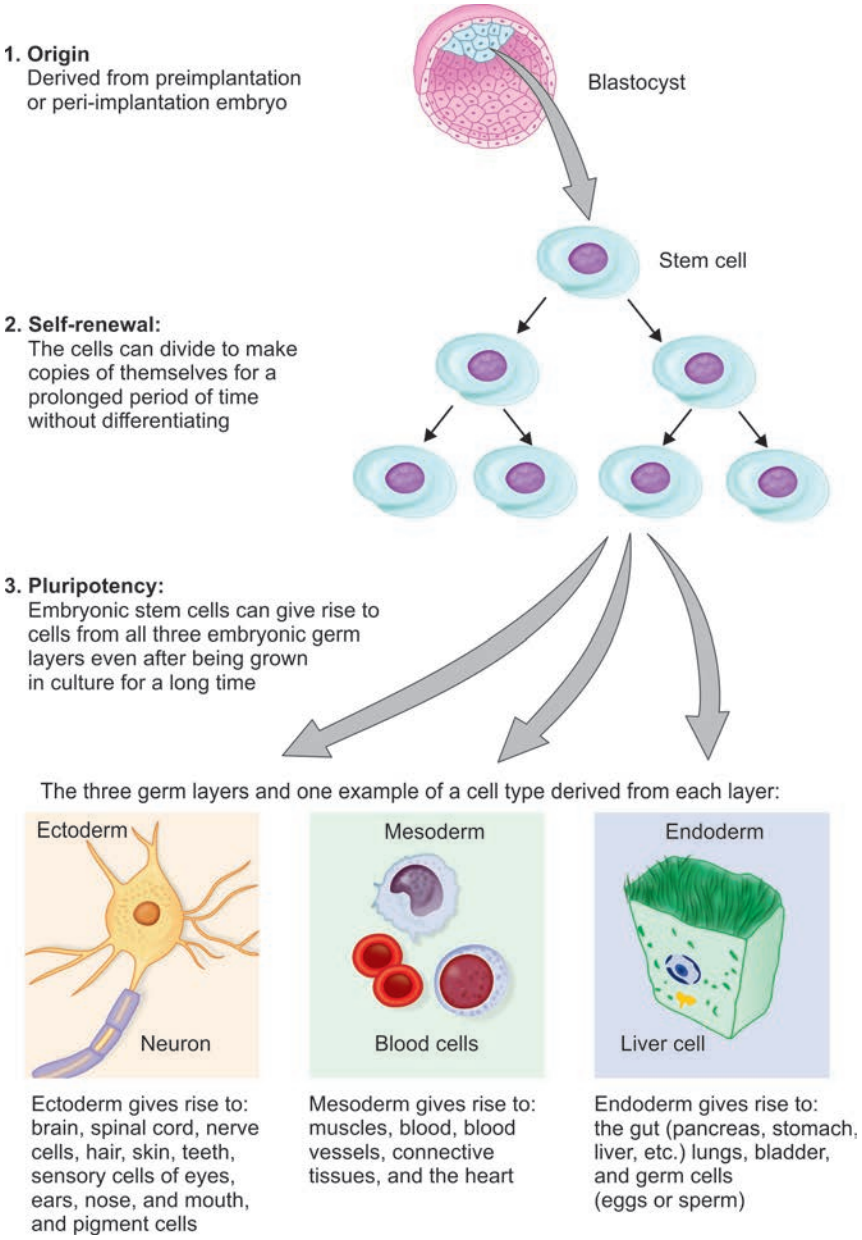

Fig. 5: Characteristics of embryonic stem cells.

cells came only in 1998.[58] The delay was due to scarcity of human embryos as a source for these cell lines. With advent of IVF, spare embryos became possible, which were no longer required by the commissioning couple. These became the source for extracting inner cell mass cells.

There are challenges in the culture of human stem cells:

- The cloning efficiency of human stem cells is low when compared to mouse cells.
- Initially, mouse fibroblasts were used for coculture of human embryonic stem cells. This provides a chance for introduction of pathogens as well as introduction of mouse cell strain impurities. Newer culture systems are being developed to avoid the use of mouse fibroblasts for coculture.[59]
- Another challenge is the possibility of accumulation of genetic and epigenetic changes over a period of stem cell culture.[60] The behavior of imprinted genes is also a matter of intrigue.[61]

Applications

- *Therapeutic drug research:* Access to unique stem cell lines can provide a platform for drug testing. This can prevent toxic drugs from reaching the level of clinical trials and harming participants.
- *Transplantation medicine:* Stem cells can provide a source for specific cells for substitution in diseased states, such as the use of insulin-producing cells in diabetes or dopaminergic neurons in Parkinson's disease.

- Human embryonic stem cells derived from samples taken for PGD can provide in vitro models to study the effect of these mutations on cell proliferation and differentiation and hence lead to a better understanding of the pathophysiology of these diseases.[62]

In Vitro Gametogenesis

The creation of human gametes in vitro [in vitro gametogenesis (IVG)] is an area of interest, related to embryonic stem cell research. IVG has been successfully completed in mice and has resulted in live birth.[63] Gametes were derived from embryonic stem cells obtained from inner cell mass of mice blastocyst. Similarly, gametes have been derived from human embryonic stem cells as well. Even primordial sperm cells have been formed from female human embryonic stem cells.[64] Even more outstanding achievement has been the creation of embryonic stem cell-like cells, which are pluripotent in nature, by the process of dedifferentiation of somatic cells and subsequent differentiation into spermatogenic cells and egg-like cells.[65]

Applications of In Vitro Gametogenesis

- To obtain gametes for IVF in patients with paucity of normal gametes such as poor ovarian reserve (POR), postmenopausal, and azoospermia. This obviates the need for gamete donors and allows them the possibility of their own genetic progeny.
- *Solo-IVG:* The concept of a single individual becoming a parent. Stem cells derived from epidermal cells can be used to create gamete of the opposite gender. This gamete and the normal self-gamete are fertilized to obtain an embryo.[66] There are greater technical challenges and genetic errors in this procedure because the entire genome is derived from a single individual.[67]
- Same-sex couple—can have their own child by using stem cell-derived gamete of one spouse and naturally derived gamete of the second spouse.
- *For PGD:* Greater number of embryos available can benefit PGD to select a disease-free embryo in individuals with multiple genetic defects.[68]
- *Multiplex parenting:* When four people want to have a genetic child together, embryos are formed from each couple respectively by conventional IVF, the inner cell mass is extracted from the embryos and cultured to differentiate into gametes. The fusion of these gametes will give rise to a second-generation embryo with 25% genetic contribution from each of the four individuals.[66]

Mitochondrial Replacement Therapy

Mitochondrial DNA constitutes <0.1% of total DNA content of a cell. Yet, defects in mitochondrial genes can lead to several debilitating diseases such as Duchenne muscular dystrophy, ragged-red fiber disease—mitochondrial myopathies, and Leber's hereditary optic neuropathy. The inheritance of mitochondrial defects will vary depending on the number of defective DNA copies per cell, ranging from asymptomatic to life-threatening.[69] At the time of fertilization and formation of zygote, the entire cytoplasm is derived from the mother and consequently, mitochondria are exclusively maternally inherited.[70]

Mitochondrial replacement therapy (MRT) aims at avoiding inheritance of defective mitochondrial genes in women with known mitochondrial disorders. There are two ways to achieve MRT:

1. *Maternal spindle transfer:* An oocyte sourced from a healthy donor is enucleated and the nucleus isolated from the genetic mother (who has the mitochondrial disease) is transferred into the enucleated donor oocyte. This is followed by ICSI and fertilization. The embryo is followed up for development for 5 days. The embryos are checked for mitochondrial heteroplasmy by quantitative PCR to confirm the absence of mitochondrial disease.[71]
2. *Pronuclear transfer:* One donor oocyte and a self-oocyte are sourced from the donor and the intended parent, respectively. Both the oocytes are fertilized with the male parent's sperm. Once fertilization is at the two-pronuclei stage, the female pronucleus derived from the genetic mother is isolated. The female pronucleus derived from the egg donor is removed. The genetic mother-derived female pronucleus is inserted into the donor-derived embryo, whose female pronucleus has been removed.[72]

Ethical Concerns

- Concerns that alterations in germ cells may produce heritable changes have been quenched by the explanation that mitochondrial DNA constitutes <0.1% of total DNA content and also that external characteristics of humans are not coded by these genes.
- *Designer babies:* Since MRT aims at removal of disease-causing mitochondrial genes and not at enhancing normal embryos, it does not come under the purview of "designer babies".
- There is a concern that there is a possibility of interaction between mitochondrial DNA derived from the donor and nuclear DNA derived from the genetic mother. The ramifications of such an interaction are yet unknown.
- Safer options such as egg donation, PGD, and prenatal screening for fetal diseases have been proposed. Egg donation takes away the mother's right to have her own genetic child. Whereas PGD and prenatal testing are neither well-established nor are they totally accurate, with regard to mitochondrial diseases.
- Widespread use of MRT might fuel the need for more donor oocytes and possibly can lead to exploitation of egg donors.[73]

Mitochondrial Replacement Therapy Today

The United States FDA has not approved of human clinical trials to establish the efficacy of MRT as a clinical modality. However, MRT-derived embryos and stem cell lines have been cultured in research setting in New York.[71] In the UK, HFE (Human Fertilisation and Embryology) Act has been amended in October 2015 to allow the use of MRT.

Gene Editing

Gene editing is a biotechnological advancement that enables us to produce permanent and heritable changes in genome. Earlier, advances in this regard were thwarted by poor targeting efficiency of techniques. This has been recently overcome by obtaining double-strand breaks adjacent to integration sites.[74] This has led to the development of sequence-specific nucleases (SSNs) such as CRISPR (clustered regularly interspaced short palindromic repeats).

The CRISPR/Cas9 are endonucleases that can cleave DNA and store short sequences in the genome. These can be expressed as RNA molecules that search for complementary DNA sequences and can produce double-strand breaks at specific sites.[75]

Applications

- *Preimplantation embryos:* The endonuclease is injected into the zygote and embryos are screened for selection of embryos with correct genome.[76]
  A challenge in this selection process is brought about by mosaic nature of corrected embryos that precludes the use of PGD as a selection tool.
- *Germ cells:* Errors can be corrected in sperm cell or oocytes to prevent their transmission to embryo. Spermatogonial cells are technically easier target than oocytes.
- *Pluripotent cells:* Corrected pluripotent stem cells can be differentiated into sperm or oocyte and can be used for ART.[76]

Uses

- *Correction of mutations* is responsible for monogenic disorders such as cystic fibrosis and sickle cell disease. Affected genomes as well as carrier state can be prevented henceforth. Robertsonian translocations such as trisomy 21 can also be edited and restored to normalcy.[77]
- *Enhancement of phenotype:* Traits such as poor eyesight, short stature can be attempted, to be resolved using this technology. Even though, the polygenic nature and influence of environment are facts that make the likelihood of such a possibility dimmer.

Newer Strategies in Management of Thin Endometrium

Persistent thin endometrium is a frequently encountered problem in ART. Endometrial thickness of 7 mm is commonly accepted as the lower limit to define thin endometrium, even though pregnancies have been reported with endometrium as low as 5 mm.[78] Estrogen supplementation, low-dose aspirin, vitamin E, sildenafil, pentoxifylline, and acupuncture are the various modalities in practice to tackle thin endometrium. Newer strategies have been envisaged for thin endometrium but are associated with controversial evidence as to their benefits.

Human Chorionic Gonadotropin Injections

Endometrial cells express hCG receptors and produce hCG during the secretory phase. hCG has local paracrine and immune-modulating effects that enhance endometrial receptivity.

On the eighth day of estradiol administration, hCG 150 IU subcutaneous injections were started for 7 days and endometrial thickness was monitored in a study. There was >10% increase in endometrial thickness in 52.9% of patients and >20% increase in 35.3%. Forty-one percent had live birth. This study showed improvement in both endometrial thickness and clinical outcome.[79] However, at higher doses, the benefits are lost.[80]

Granulocyte Colony-stimulating Factor

Granulocyte colony-stimulating factor (GCSF) is a glycoprotein that has proliferative and decidualizing influence on endometrium. GCSF supplementation on endometrial cell cultures showed that GCSF modulates gene pathways involved in endometrial vascularity and remodeling.[81] But a well-powered randomized controlled trial (RCT) in this regard has showed no difference in either endometrial thickness or in clinical pregnancy rates.[82]

Platelet-rich Plasma

Platelet-rich plasma (PRP) is a source of vascular endothelial growth factor, platelet-derived growth factor, epidermal growth factor, and transforming growth factor. Combined, these enhance the cellular migration and proliferation as well as laying down of extracellular matrix in the endometrium.[83] Marked improvement has been noted in endometrial thickness with the use of intrauterine PRP instillation.[84]

Since it is an autologous product, there is limited risk of infection and autoimmunity.

Preparation of Platelet-rich Plasma

About 15 mL of venous blood of patient is collected in a syringe with 5 mL of acid citrate dextrose (ACD)—an anticoagulant solution. This is centrifuged at 200 g for 10 minutes. There is formation of three layers in the tube—topmost is plasma, buffy coat in middle, and red cells in bottom. The upper two layers are removed into a second tube and recentrifuged at 500 g for 10 minutes. The pellet

obtained at the bottom of this tube is resuspended with 0.5 mL of supernatant. This 0.5 mL solution contains platelets at a concentration 4–5 times that of blood. This is loaded into an intrauterine catheter and instilled into the uterus on the 10th day of cycle and can be repeated on the day of the start of progesterone.[83]

Gonadotropin-releasing Hormone Analogs

Qublan et al. conducted an RCT that administered 0.1 mg triptorelin subcutaneous injections on the day of ovum pickup, the day of embryo transfer, and one dose 3 days later. The control arm was given conventional luteal support. Significant improvement in pregnancy rates was noted.[85] But further studies have not come up in this regard to support this use.

Stem Cell Therapy

Stem cells can be sourced from bone marrow or from embryonic stem cells and instilled in uterus where they can differentiate into epithelial and stromal cell lines within the endometrium. Among patients who have received bone marrow transplantation, 1–10% of them have been documented to have donor-derived cells in their endometrium.[86] Nagori et al. have reported a case of live birth following instillation of autologous bone marrow stem cells extracted from iliac crest in a patient with Asherman's syndrome.[87]

Role of Endometrial Receptivity Array in Thin Endometrium

A thin endometrium is not always a nonreceptive one. ERA can be used to assess the displacement of WOI, and PET can aid in overcoming the change in WOI. A study performed on women with endometrium ≤6 mm found ERA to be nonreceptive in 23% and receptive in 77%.[11]

NEWER TRENDS IN CONTROLLED OVARIAN STIMULATION

Minimal Stimulation Protocols

The concept of minimal stimulation protocols was envisaged by Edwards et al. in 1996 as a means to provide ovarian stimulation with minimal treatment risks and to be more patient friendly.[88]

Endocrine Basis for Minimal Stimulation

In a normal ovarian cycle, the increased estrogen output by granulosa cells of the dominant follicle will cause negative feedback effect on pituitary secretion of FSH. Thus, the lower FSH blood levels become inadequate to sustain the growth of smaller preantral and antral follicles, leading to their atresia.

Controlled ovarian stimulation (COS) is based on exogenous gonadotropin supplementation, which lengthens the FSH window wherein more antral follicles continue to grow and become multiple dominant follicles.

Studies have shown that even mild interference in the FSH reduction in midfollicular phase is enough to sustain the growth of more dominant follicles.[89] This is the crux of minimal stimulation protocol wherein a normal intercycle rise of FSH is utilized to initiate follicular recruitment and smaller gonadotropin doses in combination with oral ovulogens are used to lengthen the FSH window.

Oral Ovulogens Combined with Gonadotropins

Use of CC in early follicular phase and further supplemented with gonadotropins produces synergistic beneficial effects and remove the adverse effects of CC on endometrium.

Aromatase inhibitors, by inhibiting conversion of androgens to estrogens in granulosa cells, increase intraovarian androgen milieu and help in recruitment of more antral follicles, possibly reducing the dose of gonadotropins require subsequently.[90]

Benefits of Minimal Stimulation[91]

- Less duration of treatment
- Lesser dose and expenditure of gonadotropins
- Lesser risk of hyperstimulation
- Less incidence of multiple pregnancies
- Improved embryo quality since high dose gonadotropin stimulation and supraphysiological E2 levels affect chromosomal segregation and impair embryo quality.
- Better endometrial receptivity due to absence of high E2 level mediated endometrial advancement and embryo–endometrial asynchrony.
- Cumulative live birth in a year is same as that of conventional stimulation
- Proven to have less psychological burden on couples receiving treatment, in comparison to conventional protocols.

Demerits of Minimal Stimulation

- Fewer embryos for transfer produced per oocyte retrieval cycle
- Higher cycle cancellation rates due to mono or bifollicular responses when gonadotropins are started on day 5 of the cycle.
- If more cycles are required to bring about a live birth, a greater number of oocyte retrievals will be necessary, which is the most invasive step in IVF. This can contribute to anxiety and emotional stress.

Role of Growth Hormone in Poor Responders

Growth hormone (GH) is a peptide hormone secreted by lactotrophic cells of anterior pituitary gland and exerts its action through insulin-like growth factor-1 (IGF-1)

generated in the liver. IGF-1 receptors are present on oocytes, granulosa cells, and theca cells. IGF-1 facilitates the action of FSH during follicular growth. Use of GH during COS has been shown to increase the receptor density of GH, LH, FSH, and bone morphogenic protein (BMP-1B). Use of GH in COS has crossed 25 years; however, its role is still debatable and newer evidence is emerging.

Use of GH in COS has shown to reduce the duration of COS, reduce the total dose of gonadotropins used, increase the peak estradiol level, and increase the number of oocytes retrieved and embryos generated. However, there is no improvement in live birth rate. It is unclear as to whether the absence of benefit in live birth rate is absolute or whether the studies are underpowered to discern the benefit.

Australian multicenter study, "LIGHT" trial, randomized women with previous poor response to IVF stimulation to those who received 12 IU of GH from the start of stimulation and those who received gonadotropin alone. About 98.5% of women in intervention arm achieved an oocyte retrieval as compared to 78% in placebo group, and the number of oocytes retrieved was greater by 1 in the study arm. However, there was no difference in the number of women who reached embryo transfer neither in the quality of embryos formed.

It is put forth that use of GH may benefit a subgroup of poor responders who have poor oocyte/embryo quality, the so-called suboptimal responder. Recent evidence is also emerging on usefulness of GH in women with refractory thin endometrium. Both of these concepts warrant further validation.[92,93]

Long Antagonist Protocol

A novel protocol using a single-dose long-acting GnRH antagonist injection, degarelix, on day 24 of menstrual cycle preceding the COS cycle was introduced as a proof of concept study by Papanicolao et al. in 2018. No LH rise was noted in any of the 10 oocyte donors on whom the study was conducted. The same oocyte donors underwent a conventional antagonist protocol stimulation 6 months later and served as their own control arm. There was no significant difference in ART outcome parameters including oocytes retrieved, embryo output, and clinical pregnancy rates. The advantage of this protocol is that it issues greater flexibility to the programming of IVF cycles as COS can be started as late as 10 days into the follicular phase of menstrual cycle. Secondly, agonist triggering is possible, avoiding the perils of OHSS.

Degarelix is available in the Indian market, being used in the treatment of carcinoma prostate.[94]

Double Stimulation Protocols

Double stimulation protocols involve COS during follicular and luteal phase of same menstrual cycle. This is based on the fact that follicular recruitment occurs in multiple waves spread across the menstrual cycle. Performing consecutive stimulations and oocyte retrievals within the same menstrual cycle aids in reducing time to collect more oocytes, which is useful among women with rapidly declining ovarian reserve such as age >40 years and also in oncofertility.

Different protocols have evolved with double stimulation as its crux.

Shanghai protocol uses letrozole/CC and human menopausal gonadotropin (hMG) for COS in follicular phase, GnRH antagonist for prevention of LH surge, and GnRH agonist for triggering of oocyte maturation. DuoStim protocol (Ubaldi et al.) uses rFSH and hMG for COS and after 5 days of oocyte retrieval, second COS is started. According to Ubaldi et al., the number of euploid embryos increased from 41.9% (among oocytes obtained from follicular phase stimulation alone) to 69.8% (among oocytes pooled from both follicular and luteal phase stimulation). This increase in the number of euploid embryos is of paramount importance in the subgroup of women with poor ovarian reserve. This was further substantiated by a case series done in 2020 by Vaiarelli et al. Obtaining euploid blastocyst increased from 14% to 31% with luteal stimulation and cumulative live birth rate increased from 7% to 15%. Reducing the duration of time needed to create more embryos reduces the emotional burden on couple undergoing treatment and reduces the treatment dropout rate.[95,96]

ADVANCES IN EMBRYOLOGY LABORATORY TECHNIQUES

Newer Sperm Selection Techniques

Intracytoplasmic Morphologically Selected Sperm Injection/Physiological Intracytoplasmic Sperm Injection

Intracytoplasmic morphologically selected sperm injection involves the injection of sperm into oocyte after the selection of sperm with good morphology under a magnification of 6,300.

Intracytoplasmic sperm injection, performed under a magnification of 200–400, excludes spermatozoa with major morphological defects. Whereas IMSI can look for subtle nuclear defects. MSOME (Motile Sperm Organelle Morphology Examination) criteria for normal nucleus include smooth, symmetrical, and oval nucleus with homogenous chromatin material with not more than one vacuole occupying <4% of nucleus.[97]

Use of IMSI to rule out subtle nuclear defects has a definite role in improving pregnancy outcome.[98] The fertilization rate with IMSI is significantly greater than that with ICSI, especially among oligoasthenospermic males.[99] Blastocyst conversion rate is also higher post-IMSI.[100]

Physiological ICSI identifies and uses mature hyaluronan-binding sperm for injection into oocyte.

Immaturity of sperm is known to cause aneuploidies.[101] Live birth rates with PICSI are higher than in ICSI,[102] especially in male factor infertility. Some studies have also documented improved embryo quality and implantation rates with PICSI.[103]

Electrophoretic Sperm Separation

Electrophoretic sperm separation is a membrane-based electrophoretic separation that can separate sperms with maturity and least DNA damage. It works on the premise that sperm cells with least DNA damage and more maturity will carry a greater negative charge. This allows their separation from leukocytes and immature germ cells.[104] Spermatozoa are highly susceptible to oxidative stress due to the high content of unsaturated fatty acids. Leukocytes generate reactive oxygen species that create oxidative stress. Hence the separation of sperms from leukocytes is imperative.[105] Negative charge on mature spermatozoa is acquired by sialic acid residues on CD52 molecules on sperm surface.

CD52 molecules are acquired during epididymal transit and reflect on the maturity of sperms.[106]

Electrophoretic sperm separation works with a cassette that has two separate chambers of 400 μL each, separated by a filter and sealed by polyacrylamide gel, which allows permeation of buffer. Semen is put into one cabin, 75 mA of current is applied, and a filtered sperm suspension is obtained in adjacent cabin.[104]

Magnetic-assisted Cell Sorting

Magnetic-assisted cell sorting (MACS) is an efficient way to identify and separate functional sperms. Apoptotic sperms show loss of membrane integrity and phosphatidyl serine is exposed. Annexin V conjugated with magnetic microspheres and exposed to a magnetic field can segregate the apoptotic sperms from the nonapoptotic sperms.[107]

By removal of apoptotic sperms, there is improvement in embryo quality and pregnancy rates but there is no difference in the miscarriage rates. Density gradient centrifugation combined with MACS is a preferred method for sperm selection.[108]

Polscope and Rescue Intracytoplasmic Sperm Injection

Oocyte morphology has always been a focus of interest, primarily to choose the best oocytes for IVF or ICSI with the probability of development of good quality embryos. Assessment of cumulus, zona, and cytoplasm for granulation, vacuoles, and polar body configuration has been a widespread practice.

With the advent of orientation-independent polarizing microscope "polscope," meiotic spindle examination of living and unstained oocytes has become a reality.

When two orthogonally polarized light rays pass through an orderly arrangement of filamentous structures such as the microtubules constituting the meiotic spindle, the light rays get slowed down or retarded. The retardance is in direct proportion to the density of the structure that they pass through. This is the principle underlying the phenomenon of birefringence.[109]

In this manner, meiotic spindle of oocytes can be assessed as part of morphological assessment of oocytes. Disorganized meiotic spindles result in segregation errors and aneuploid embryos.[110] Meiotic spindle can be damaged by temperature fluctuations and also inadvertently by the ICSI procedure itself.[111] To prevent damage to spindle, ICSI needle is always positioned at 90° to polar body.

Mature (MII) oocytes with a single meiotic spindle show the highest fertilization rates.[112]

Clinical Application: Rescue Intracytoplasmic Sperm Injection

Intracytoplasmic sperm injection performed on day 1 of unfertilized matures oocytes (at 18–21 hours postoocyte retrieval) is called as rescue ICSI. Examination of meiotic spindle helps in selection of oocytes for ICSI. By seeing a single meiotic spindle and single polar body, it can be confirmed that there has been no fertilization so far and hence prevent three pronuclei (3PN) state following ICSI of such an oocyte. Presence of MII oocytes with two spindles indicates sperm penetration of oocyte followed by oocyte activation failure. Such oocytes are ineligible for rescue ICSI. Rescue ICSI can yield good quality embryos and often need cryopreservation of embryos to achieve better embryo–endometrial synchrony. This can come as a big relief to patients who were otherwise destined for total fertilization failure and cycle cancellation.[113]

Assisted Oocyte Activation

Total fertilization failure happens in 2–3% of ICSI cases. Oocyte activation following fertilization is mediated by a biphasic rise of intracellular calcium.

Step 1—Trigger: The trigger originates from the oocyte cortex, following interaction of oocyte membrane with sperm.

Step 2—Oscillator: Around 30 minutes following trigger, there are sustained short-duration and high-amplitude pulses of calcium release. A soluble factor from sperm is postulated to bring about the oscillator.[114]

Total fertilization failure ensues when the calcium release fails or is suboptimal. This might be due to inherent defects in sperm (severe teratospermia and globozoospermia) or in oocyte. To discriminate between sperm and oocyte

defect, heterologous ICSI with mouse oocyte is performed [mouse oocyte activation test (MOAT)]. If fertilized also, developmental defects such as cleavage arrest are seen with suboptimal calcium rise.

In ICSI, the injection process by itself triggers calcium rise. In failed fertilization, use of calcium ionophores is known to restore the calcium release and aid in fertilization in majority of cases. Assisted oocyte activation (AOA) is brought about by exposure to $CaCl_2$ followed by calcium ionophores.

Other less effective means of AOA are use of electrical pulses, mechanical, and vigorous cytoplasmic aspiration.[115]

Globozoospermia

Globozoospermia is a rare form of teratospermia that accounts for 0.1% of male infertility. It is characterized by absent acrosome and rounded nucleus in majority of sperms. It causes fertilization failure due to inability of sperm to bind to zona pellucida in the absence of an acrosome reaction. Even with ICSI, fertilization rates are poor due to absence of oocyte activation factor, phospholipase C zeta. Calcium ionophore activation is especially useful in these patients to bring about successful fertilization.[116]

Elongated Spermatid Injection

In patients with nonobstructive azoospermia, surgically retrieved spermatids (haploid in nature) can be used for ICSI. Round spermatids have lesser fertilization rate compared to elongated spermatids. Due to absence of phospholipase C zeta, calcium ionophores are required to bring about oocyte activation when elongated spermatids are used for ICSI.[117]

Time-lapse Monitoring of Embryos

- Time-lapse monitoring (TLM) of embryos is the most significant advancement in ART of this decade. It enables the continuous monitoring of embryos, to observe the cleavage pattern, morphological changes, and growth dynamics without having to take the embryos out of their ideal culture conditions.
- Built-in digital inverted microscope within the incubator takes photographs at distinct time intervals and the data are automatically compiled into a video sequence by software.
- Presently available TLM technologies are Primo Vision (Vitrolife), EmbryoScope (FertiliTech), and Eeva (Early Embryonic Viability Assessment, Auxogyn).
- Embryos whose cleavage times occupy the two middle quartiles have the maximum implantation potential. Also, adherence to time pattern of development showed greater correlation with euploidy. Thus, the best embryo of the lot can be selectively transferred, aiding in the practice of single embryo transfer.[118]

CONCLUSION

- The major change that has come in the world of ART recently is the advent of COVID-19 pandemic that necessitated changes in functioning of ART centers. The change encompasses modifications in patient counselling, treatment recommendations for couples, donors and surrogates, recommendations for staff working at ART centers, modifications in ART center layout and functionality.
- Vaccination against Covid-19 has been made mandatory at a national level.
- Newer diagnostic modalities in ART include Self operated endovaginal telemonitoring, Smartphone USG, Fertiloscopy, Endometrial receptivity array (ERA), Sperm DNA fragmentation index (DFI).
- Recent trends in ART medicines include newer gonadotropin preparations such as Corifolitropin Alpha/delta/epsilon, synthetic kisspeptins. Uterine transplantation has emerged as a ground-breaking treatment modality in absolute uterine factor infertility with its arrival in India. Bio-engineered uterus, ectogenesis, in-vitro vaginal incubation of embryos, embryonic stem cell technology, in-vitro gametogenesis, mitochondrial replacement therapy, gene editing are some of the cutting edge research happening in the field of ART.
- Thin endometrium has always been a tough and enigmatic challenge for clinicians of ART. Newer strategies in the arsenal against thin endometrium include intrauterine HCG, intrauterine platelet rich plasma infusion (PRP), intrauterine granulocyte colony stimulating factor (gCSF) and stem cell therapy.
- Newer trend in ovarian stimulation protocols is Minimal stimulation IVF,use of growth hormone as adjuvant in ovarian stimulation, long antagonist protocol and double stimulation protocols.
- Advances in embryology lab procedures include newer sperm selection techniques such as IMSI/PICSI/Electrophoretic sperm sorting/Magnetic assisted cell sorting.
- Newer embryology lab techniques include rescue ICSI, assisted oocyte activation and Polscope and Time-Lapse imaging (Embryoscope).

CHAPTER 80

Uterine Transplantation: Research, Techniques, and Results

Mats Brännström, Jana EJ Pittman

INTRODUCTION

Prior to the successful evolvement of uterus transplantation (UTx), as a treatment option for women with absolute uterine factor infertility (AUFI), these women were considered unconditionally infertile. Women with AUFI have either a congenital/surgical uterine absence or a uterine abnormality (anatomic/functional) that impedes embryo implantation or further pregnancy.[1] It is estimated that the prevalence of AUFI is around 20,000 women of fertile age, in a total population of 100 million.[2] Gestational surrogacy can provide genetic and, after adoption from the gestational carrier, also legal motherhood. However, in most countries, gestational surrogacy is either prohibited or highly restricted due to ethical, religious, and/or legal reasons. For a woman with AUFI who desire motherhood, UTx allows the ability to be both a gestational and genetic mother.

A uterine allograft is unique from all other organ transplants. It is a type of vascularized composite allograft (VCA) transplantation, like the hand and face. However, the donor can be either a live donor (LD) or a deceased donor (DD), in the case of UTx, but for other VCAs, only the DD alternative is available. Furthermore, the uterus graft is an ephemeral organ, as the allograft will be removed when the woman has achieved the desired number of children or after a specified time to reduce the risk of side effects associated with immunosuppression (IS). Unlike other solid organ transplants, the blood flow of the graft will be shared by mother and fetus. While surgical success (SS) of a UTx procedure can be determined soon after transplantation by the three findings of normal blood flow, cervical biopsies with no signs of necrosis, and menstruations, the determination of overall success is prolonged until a live birth occurs. Consequently, it will typically take at least 1.5 years after the Utx procedure until it can be concluded that the transplantation was successful.

The world's first human UTx case was an LD UTx case performed in Saudi Arabia in 2000, but this pioneering surgical procedure was not successful and ended in removal of a necrotic graft 99 days after transplantation.[3] This first case of human UTx sheds light on the issue that animal-based research is needed before a possible reintroduction in humans and stimulated several centers around the world to start research activities within the field. The evolution of UTx, from basic animal studies toward clinical application, has then followed both Moore criteria[4] and IDEAL recommendations[5] for the introduction of major surgical innovations.

ANIMAL RESEARCH IN UTERUS TRANSPLANTATION

Animal UTx research, performed during the last two decades, has paved the way for clinical UTx trials. The research has involved all classical experimental animals and followed a well-established sequential approach in each animal species, testing and improving multiple factors of importance for the development of a safe and effective UTx procedure for human use. The central aspects of surgery and fertility outcomes in the important UTx models are discussed below.

Surgery in Animal Models

Surgery of UTx has to be accustomed to the size of the vasculature and the opportunity to accomplish vascular connections. In the rodent models (mouse, rat), DD UTx models were developed since central parts of the vascular tree (aorta, caval vein, common iliac vessels) had to be harvested alongside the uterine graft, in order to gain large enough vessels to undertake the vascular anastomoses. The mouse UTx model was with the uterine graft transplanted into a heterotopic position in the upper abdomen, with end-to-side caval–caval and aortic–aortic vascular anastomoses.[6] In the rat, with considerably larger sizes of blood vessels and uterus, a model was developed to place the uterus orthotopically and perform end-to-side anastomoses between the common iliacs of the graft and the recipient.[7]

The sheep has been the most commonly used large-domestic species in animal UTx research. This model

was originally explored as an autologous UTx model with anastomoses of the anterior branch of the internal iliac artery and the complete utero-ovarian vein of the graft end-to-side to the external iliac vessels.[8] To allow for fertility studies in this autologous model, with the inclusion of undisturbed blood flow to the utero-tubal-ovarian unit, surgery was later modified to also include the ovarian artery, which, by a patch, was anastomosed to the aorta.[9] In an allogeneic LD ovine UTx model, end-to-end anastomosis of the uterine vessels was performed, but this model necessitated simultaneous hysterectomy surgery in the recipient, in order to have pedicles of uterine vessels of the recipient to carry out the anastomoses of the uterine vessels.[10] The latter model was tested as an LD UTx concept, with the uterus switched within pairs of sheep. The DD sheep UTx model involves anastomosis with a caval-aortal macrovascular patch technique.[11]

Uterus transplantation models have also been developed in nonhuman primate species. The importance of that is the near-human anatomy and physiology of these species. The initial nonhuman primate UTx model was the autologous baboon model with surgery involving a side-to-side fusion of the internal iliac arteries and the ovarian veins of the graft on the back table and then unilateral end-to-side anastomosis to the external iliac vessels.[12] By adapting minor modifications, the functionality, in terms of menstruation, increased threefold in this auto-UTx model.[13] In the LD allogeneic baboon model,[14] vessel anastomosis was end-to-side to the external iliac vessels as described above. The baboon DD UTx model, to carry out allogeneic UTx, utilized a macrovascular aortic-caval patch technique which was anastomosed on the subrenal aorta and vena cava of the recipient.[15] The cynomolgus macaque is the nonhuman primate species which has been most widely used in UTx research. The anatomy of this species is similar to the baboon and the human, but since the body size is only around a third of the baboon, surgery is more challenging. Initially, an autologous UTx model was developed in the cynomolgus macaque, with the uterus retrieved together with bilateral uterine arteries and the deep uterine veins and anastomoses on the external iliacs.[16] The dissection of deep uterine veins was complex, and the technique was modified to use the ovarian veins as outflow vessels, resulting in a considerably shorter surgical time.[17] Furthermore, surgery of DD UTx was performed in the cynomolgus macaque and in this allogeneic setting, a comparison was made with models including retrievals of either the common iliacs or parts of the aorta/vena cava.[18] Anastomoses were performed on the corresponding vessels.

Fertility in Animal Models

Fertility is the important endpoint of UTx, and thus it is essential to evaluate this component in UTx, which may be autologous, syngeneic, or allogeneic transplantation. In the animal models that have been explored, the autologous and syngeneic models have initially been tested for fertility and those experiments, in nonrejection settings, have then been followed by allogeneic transplantation models. Allogeneic transplantations would need IS treatment to prevent rejection. Several UTx-specific factors may affect the fertility potential such as changed uterine position, denervation, altered blood flow and outlet, and naturally negative side effects of IS.

The first demonstration of pregnancy in a UTx model was in a syngeneic transplantation model between inbred mice, with no need for IS, since the donor and recipients had full histocompatibility.[19] In this initial study, with the uterus in a heterotopic position and the cervix positioned intra-abdominally, only occasional early pregnancies were seen after transmyometrial embryo transfer (ET). The reason for a low pregnancy rate was most likely damaging effects on the endometrium, secondary to accumulation of cervical mucus within the uterine cavity.[19] The mouse UTx model was then modified with a cervical cutaneous stroma, which allowed proper drainage of mucus.[6] In that syngeneic model, the pregnancy rate per uterus was equal in the transplanted uteri as compared to the native control uteri and also in comparison to the uteri of nontransplanted animals with sham operations.[6] The pregnancies went to term. Weights of offspring and growth trajectory up to adulthood were normal. No studies on fertility after allogeneic UTx in the mouse have been performed.

In the rat UTx model, fertility was first tested in a syngeneic setting between inbred rats, with no need for IS.[20] In this syngeneic model, the pregnancy rate and the number of pups per pregnancy were similar in transplanted animals as in sham-operated control animals. Furthermore, the growth trajectory of offspring was similar in offspring from the UTx group and the control group. Fertility after allogeneic UTx was first reported in a rat model, with discordances between two major histocompatibility sites.[21] Tacrolimus IS was given via mini-osmotic pumps. The pregnancy rates, assed around pregnancy date 13, were comparable in the UTx group and in the control group.[21] In a follow-up study, with another allogeneic combination of rats and tacrolimus as IS, the pregnancies went to term.[22] The pregnancy rate was somewhat lower in the UTx group as compared to the two sham-operated control groups. However, birth weights of UTx offspring and growth trajectory of the pups until postnatal week 16 were unaffected in comparison to controls.[22]

The first large-animal UTx model to be tested for fertility was the sheep, and initial experiments were performed in an autologous UTx model. This autologous UTx model was with uterine-tubal-ovarian transplantation and end-to-side vascular anastomoses of the uterine artery, utero-ovarian vein, and ovarian artery, including an aortic patch, to the

external iliacs.[9] The reason for transplanting the uterine-tubal-ovarian en bloc was to allow for natural mating and conception. Conception occurred spontaneously and offspring of normal sizes were delivered by cesarean section, around 2 weeks before term.[9] The allogeneic sheep UTx model involved surgery, where the uteri were switched between two animals and with cyclosporine as IS.[23] After ET in five ewes, pregnancies were seen in three animals. A live birth occurred via cesarean section at day 138 of pregnancy. This was the first birth after allogeneic UTx in a large animal.[23]

Concerning fertility in UTx models of nonhuman primates, experiments have only been conducted in the cynomolgus macaque. In the first study on fertility after auto-UTx, two animals underwent UTx with unilateral preservation of the oviduct and the ovary and anastomoses between the uterine arteries and the external iliac arteries bilaterally, with venous outflows of deep uterine vein and ovarian vein ipsilaterally.[24] Menstruation resumed spontaneously and pregnancy occurred post three menstruations and after spontaneous mating. Prematurely, around 3 weeks before expected delivery, a cesarean section was performed due to bleeding and partial placental abruption. A live offspring was delivered but with fetal respiratory distress.[24] No attempts were done to secure further survival of the fetus. This birth, which was reported already in 2012, was very important for the field of UTx and the coming human clinical trials (see below), since it was a proof-of-concept of live birth after UTx in a primate. The same Japanese team published in 2020[25] the first live birth in a nonhuman primate species after allogeneic UTx. Although this was a great accomplishment, the importance for the UTx field was less than the live birth after auto-UTx in macaque from 2012,[24] since human UTx had already been proven successful, with five live births reported already in the interval from 2014 to 2016 within the first human UTx trial,[26,27] as further discussed in a section below. Allogeneic UTx was performed between major histocompatibility complex (MHC)-defined cynomolgus macaques, which were haploidentical, thus providing a semi-allogenic transplantation setting.[25] Anastomoses were end-to-side aortal–aortal and caval–caval at an infrarenal site, with transplantations carried out in six animals. The IS was induction with both antithymocyte globulin and rituximab and then triple maintenance IS. Although donor-specific antibodies, posttransplantation lymphoproliferative disease, and two spontaneous abortions after ET occurred in one specific animal, this animal became successfully pregnant around 2 years after UTx. A cesarean section was performed at full-term and the offspring was healthy. This birth represents the first and the only birth after UTx in an allogeneic nonhuman primate model.

SURGICAL TECHNIQUES IN HUMAN UTERUS TRANSPLANTATION

A number of clinical UTx trials have been initiated, involving either LD UTx procedures or DD UTx procedures and in some comparative trials, inclusion of both LD UTx and DD UTx. This first section provides an overview of the different surgical techniques in LDs, DDs, and recipients, where it has been an evolution from classical laparotomy, toward the introduction of minimal invasive surgery (MIS). The results of the trials are summarized in sections further below.

Laparotomic Uterus Procurement in Live Donor

The classical approach of organ retrieval in LD UTx is by laparotomy. The technique has been described in detail[26] and a briefer description is given below. The laparotomic uterus retrieval in LD UTx starts with a subumbilical, midline abdominal incision. To ensure long ligaments on the graft, for later fixation in the recipient, the round ligaments are divided laterally and tagged. Subsequently, using monopolar diathermy, a large bladder flap, nearly to the bladder dome, is dissected. This peritoneal sheet is created to cover the vesicouterine fossa and for fixation in the recipient, by suturing the sheet on top of the bladder at transplantation. The surgery then moves toward the pelvic sidewalls. The initial focus is to isolate and dissect the ureters. Complete ureterolysis, from around 2 cm below the iliac crossing until the inlet into the bladder, should be performed, which also includes dissection of the ureteric tunnel. At dissection of the ureteric tunnel, care must be taken not to cause any injury to the uterine artery, passing over the ureter, and handle the thinned-wall deep uterine veins, which often ride under the ureter, in a delicate fashion. Several venous plexuses are firmly attached to the ureters and must be gently dissected off the ureter. The surgery should advance equally on both sides. Once the ureters are free, the focus moves to the arterial supply of the graft. In most cases, only one major arterial segment remains with the graft on each side and that segment is mostly made up of the complete major trunk of the anterior portion of the internal iliac artery. All other branches from the anterior iliac artery are ligated and transected, and these distinct branches include the iliolumbar artery and pudendal artery. Importantly, to ensure uncompromised blood flow to the gluteal muscles, the gluteal artery, which commonly is the first major posterior branch of the internal iliac artery, should be preserved in the donor. Subsequently, venous dissection begins, which is challenging and time-consuming. Venous anatomy differs substantially between each donor, and there may be one or two large deep uterine veins bilaterally and they will reach the internal iliac veins on the pelvic side wall just above the pelvic floor. The venous vascular pedicles should include segments of the

internal iliac veins, which ensure wider vessel diameters for anastomoses in the recipient and thereby decrease the risk of venous thrombosis over the anastomosis line. The dissection approach of the distal part of the deep uterine veins is preferably from the pelvic sidewalls toward the graft. Lastly, the rectovaginal space is opened to separate the upper, posterior parts of the vagina from the rectum, and the remaining ligaments, including the sacrouterine ligaments, are divided. The small vaginal arteries are also divided in the paravaginal tissue and the vagina is then transected by scissors and bipolar diathermy. To ensure an uncomplicated vaginal–vaginal end-to-end anastomosis during recipient surgery, at least 20 mm of a vaginal rim should be included in the graft. The large vessels are then clamped and divided, starting with the internal iliac arteries and then the veins. The graft, with long vascular pedicles, is then taken to the back table for chilling and flushing.

Robotic-assisted Uterus Procurement in Live Donor

The robotic donor surgery approach has become more widely used in LD hysterectomy. The methodology has recently been described in detail and with illustrative material.[28] A brief description of donor hysterectomy by robotics is given below. It is recommended that two experienced robotic surgeons, preferably one gynecologist and one transplantation surgeon, should work in collaboration in dual consoles by a four-arm setup. The robotic instruments which are recommended include Maryland bipolar forceps, monopolar curved scissors, a large needle driver, a clip applier for medium and large clips, ProGrasp forceps, and a vessel sealer. In most cases, additional laparoscopic ports are also used to enable a laparoscopic surgeon to assist to apply clips on vessels and for retraction of tissue. Before docking, the donor is placed in a steep Trendelenburg (up to 28°) position and then 45° side-docking, toward the hip of the donor, is performed to provide access to the vaginal route for alternate uterine positioning during surgery. This is performed by an assisting surgeon, using a hand-held, atraumatic vaginal probe, which does not cause any damage to the cervical canal. Initially, the surgery involves isolating the large bladder peritoneal flap for subsequent fixation in the recipient, followed by divisions of the round ligaments. Differing from laparotomy, it is recommended to concentrate dissection on one side of the graft at a time and to continue on one side until the ureter and the vessels are fully dissected. The unilateral dissection will start with the identification and gross dissection of the uterine arteries, anterior portions of internal iliac arteries, and umbilical arteries. Subsequently to this, complex ureteric isolation is performed, requiring delicate dissection in the ureteric tunnel and also separating the ureter from its attachments, caudally of the crossing of the uterine artery. Bipolar diathermy and scissors should be used with dissection at a fair distance from the ureter, in order to avoid thermal ureteric injury. There exist venous irregularities and uterine veins and their branches are well hidden within the tissue. A ureteric stent may aid in the dissection and fluorescent dye could help to identify the vessels that are hidden in the tissue. Once the ureter is fully isolated, the surgery focuses on the dissection of the internal iliac vein in the region of the inlet of the deep uterine vein(s). Following full mobilization of the ureter, the finer dissection of the uterine artery should be performed, with prolongation to include the anterior portion of the internal iliac artery. All branches of the internal iliac artery are dissected and transected after securing blood flow. Hemoclips, with a securing suture, or titanium clips are placed on either side of the transections, depending on the size of the vessels. Then the deep uterine vein is dissected free from the paravaginal tissue, so it is fully mobilized until the inlet into the deep uterine vein. All steps are then repeated on the contralateral side. On completion of both pelvic sidewalls, dissection of proximal parts of the utero-ovarian vein from the corner of the uterus up until the ovarian branch of the utero-ovarian vein is performed to secure additional venous outflow. The pouch of Douglas is then dissected, with separation of the rectum from the posterior vagina and including division of the sacrouterine ligaments. By alternate use of bipolar diathermy and scissors, the vagina is transected, leaving a cuff on the graft of around 2 cm for attachment to the recipient vaginal tissue. Finally, as with the laparotomy, the six vascular pedicles are clamped (often with a laparoscopic staple instrument) and transected. The graft is then placed in a sterile laparoscopic specimen bag and extracted through the vagina. The vaginal cuff is closed by a V-lock suture and the large vessels are secured. All instruments and ports are then extracted and the port sites on the skin are sutured accordingly.

Uterus Procurement in Deceased Donor

For obvious reasons, only laparotomic uterus procurement for the DD is performed. The recovery of the uterus graft from a DD is often part of a multiorgan donor retrieval process. The donor hysterectomy in DD has been described in detail[29] and is briefly outlined below. A large midline incision is usually performed from the xiphisternum to the pubic symphysis and for greater access to the pelvis, the incision can include bilateral inguinal extensions. The ureters are ligated, transected, and tagged (to mark the uterine artery location). Following this, the round ligaments are also ligated, transected, and tagged. The bladder flap is then extensively dissected, taking care not to damage the uterine veins which may curve upward close to the lateral aspects of the bladder. At the level of the distal common iliac vessels, the internal iliac artery and vein dissections begin, taking the vessels caudally. The gluteal, obturator,

and inferior rectal branches of the internal iliac artery are all ligated. After vessel dissection, the rectovaginal space is opened, and good lengths of the uterosacral ligaments are preserved for use as fixation points in the recipient. The external iliac arteries should be exposed for catheterization to enable separate flushing of the uterus, while the other organs are flushed through the aorta. After procurement of thoracic and abdominal organs, with the uterus being flushed and cooled during this procedure via the femoral artery catheters, uterus procurement can begin. The vagina is transected, and the internal iliac vessels are clamped and ligated before removing the graft to the back table.

Uterus Transplantation by Laparotomy

Recipient surgery is typically done by laparotomy. In laparotomic transplantation into the recipient,[26] a subumbilical midline incision is performed and the external iliac vessels are dissected with veins and arteries separated. In patients with the Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome, further dissection of the pelvic sidewall structures, including the round ligament, may be required due to presence of rudimentary uterine-tissue buds, typically positioned between the round ligament and the external iliac vein. In the MRKH patient, which so far has been the typical UTx patient, the vaginal vault is prepared, often with the use of a vaginal probe which is pushed in the direction of the umbilicus. This is necessary to expose the vaginal vault, which typically is hidden under a midline, uterine rudiment as well as the overfolding bladder. The midline rudiment is cleaved down to the fascia, which is overlaying the vault and the rectum is then separated from the posterior of the vagina. An area of the vaginal vault of about 50 mm longitudinally and 40 mm transversely should be freed from the bladder and rectum for subsequent vaginal–vaginal anastomosis. The chilled graft is then positioned inside the pelvis, and end-to-side vascular anastomoses are performed between the internal iliac segments of the graft and the external iliacs of the recipient, starting with the vein and then moving onto the artery on one side at a time. The vagina is then opened by monopolar diathermy in the midline and the vaginal vault of the recipient is secured to the vaginal rim of the graft by end-to-end fashion. Uterine fixation is then performed to the round ligaments, cleaved midline rudiments, and sacrouterine ligaments. Noteworthy, in patients post subtotal hysterectomy, the cervical stump should be removed or in women who have a normal-sized but nonfunctional uterus, such as a patient with Asherman's syndrome, a total hysterectomy will need to be performed as part of the preparatory surgery of the recipient. In both these cases, it is important that the vagina is closed temporarily to avoid transcending infection.

Uterus Transplantation by Robotic-assisted Laparoscopy

Fully robotic-assisted transplantation of the uterus in the recipient was introduced by the Swedish team in 2021. For this robotic implantation procedure, a similar setup is used as per the donor hysterectomy (four-arm robot, dual consoles, similar instruments, two robotic surgeons, and a laparoscopist). Additionally, one extra assisting surgeon is required to maneuver the vaginal probe during vault preparation. The surgical procedure starts with the preparation of the recipient vessels for the anastomosis. The surgery is then directed toward the vaginal vault, where anatomical variations exist depending on the cause for uterine infertility, as outlined in the paragraph above. The rectum and bladder are then gently separated from the vagina and the chilled graft is brought into the abdomen through a small supraumbilical midline incision, which is covered by a GelPort. One significant difference in the robotic transplantation, as compared to the laparotomic implantation of the uterus, is the recommendation for only two venous and two arterial end-to-side anastomoses in robotics, since anastomosis surgery will be prolonged in the robot and rewarming ischemia should not be extended. Anastomoses are by two continuous sutures on each anastomosis using Gore-Tex, CV-6. On each side, the deeper-positioned vein is the first site for anastomosis. End-to-end vaginal anastomosis is then performed by V-lock sutures after a sagittal opening of the vaginal has been accomplished. Fixation is by suturing the end of the round ligaments to the remnants of the round ligament, and the bladder flap is sutured to the top of the recipient bladder rather than via several ligamentous fixation points as in laparotomic implantation.

RESULTS OF THE ONLY COMPLETED HUMAN UTERUS TRANSPLANTATION TRIAL

The first registered UTx clinical trial was initiated in Sweden in 2012, including nine LD UTx procedures, with recipient age range of 27–38 years.[26] This is so far the only trial with completed reproduction,[27] after hysterectomies of the grafts[30]) within the time frame of up to 6.5 years after UTx. One recipient had acquired AUFI after a radical hysterectomy for cervical cancer and the remaining eight had MRKH syndrome. This is a congenital syndrome, with uterine and upper vaginal aplasia in a female with normal karyotype and normal secondary sex characteristics.[31] The LDs were either genetically related (mother, sister, maternal aunt) or close family friend (mother-in-law, friend). The donors were 37–62 years old and five of the nine donors were postmenopausal.[26] Comprehensive medical and psychological investigations were completed in all recipients, partners, and donors.[26,32] Uterus recovery by laparotomy was lengthy and had durations of 10.5–13 hours.[26] The

deep uterine veins and uterine arteries on the graft were procured with segments of the internal iliac arteries and in a few procedures, portions of the utero-ovarian veins, between the uterus and ovary, were harvested. Pre- and postoperative outcomes of LDs were favorable, but with one case of a ureteric-vaginal fistula which necessitated ureteric reimplantation surgery repaired 3 months postuterus donation.[26] All donors were in good psychological and medical health at follow-up 1 year after surgery.[33] The duration of recipient surgery was 4–5 hours, including dissection of the external iliacs and preparation of the vaginal vault. SS, defined as a viable graft 1 month after transplant, was evident in seven out of nine grafts.[26] Graft failures because of immediate vascular thrombosis in one case and hypoperfusion with secondary infection occurred in two cases within the first months.[26,30] The psychosocial health of the recipient and their partners were in general fine during the first posttransplantation year, although initial worries concerning rejection were seen during this time frame.[34] Single ETs were to be performed from around 12 months after UTx in the seven patients with successful UTx procedures. Further follow-up of psychological health of donors during years two and three showed that they were relatively stable regarding health-related quality of life, mood, and marital relationship, but slight negative deviations existed in some patients, with possible associations with older age and continued nonpregnancy results from their donations.[35] Concerning the psychological health of recipients and their partners during the interval from 1 year after transplantation to 3 years after transplantation, it was evident that graft failure and failure to achieve parenthood pose psychological strains on couples during this time period after transplantation.[36]

The world's first human live birth after UTx was reported from the Swedish trial in September 2014, when a boy was born in gestational week 31+6, after a pregnancy that was complicated by preeclampsia.[37] The Swedish trial, with surgeries in 2012–2013, is the first UTx trial to present full data of reproductive and obstetrical outcomes.[27] The complete dataset is from the seven women with surgically successful graft after UTx and with initiated ETs from 12 months after transplantation. Six of the seven women had in total nine live births, with three women giving birth twice. Five out of nine live births were after the transfer of day 5 (D5) embryos and the same number of live births were from in vitro fertilization (IVF) treatments after UTx. One patient, a woman who never achieved a live birth, underwent 16 ETs, which resulted in six miscarriages, some as late as gestational week 15. The overall clinical pregnancy rate (CPR) per ET was 32.6% and the live birth rate (LBR) per ET was 19.6% in the seven women undergoing ETs. The total LBR is lower than in a usual IVF population, with possible explanations being that one out of seven women had a very high number of implantation failures or miscarriages and that as many as 76% ETs were with day 2 (D2) embryos. A subgroup analysis of ETs of D2 and D5 embryos showed that LBRs per ET were 8.6% for D2 and 45.4% for D5 in the seven women undergoing ET and 12.5% for D2 and 83.3% for D5 in the six women who gave birth. The cumulative LBR for the seven women with viable grafts was 85.7%.[27] The nine children were all delivered by cesarean section and deliveries were either per protocol (n = 5; range 35+0 to 38+0) or due to obstetric complication (n = 4; range 31+6 to 35+3). The obstetric complications which caused acute delivery were preeclampsia in three women and intrahepatic cholestasis of pregnancy in one woman. The weight deviations [median (range)] were –1% (–13 to +23%) and Apgar scores (1 and 5 minutes) were 9 (3–9) and 10 (8–10). Four of nine neonates developed mild respiratory distress syndrome and they were all born in the interval 31+6 to 35+0. The growth trajectories and health follow-up for the first 2 years were normal for all children. Longer follow-up studies of UTx children have not yet been published.

RESULTS OF UNCOMPLETED STUDIES AND SINGLE CASES OF UTERUS TRANSPLANTATION

There exist a number of UTx studies that have been initiated worldwide, with some presenting interim results of as many as 20 procedures and some that have only published results of single cases. The number of published UTx studies/cases, where information of SS can be extracted, is so far 67 procedures **(Table 1)**. SS is defined as a graft with uncompromised blood flow during the initial months after UTx and with resumed menstruations, as signs of functionality. Two menstruations should be seen so, typically, it will be at least 2–4 months after UTx until success or no success can be decided. Concerning reproductive and obstetrical outcomes, it is not meaningful to look at these parameters until a study is completed, by graft removal, in all patients of the study cohort. Thus, interim results concerning reproduction and obstetrics are not further discussed in the section below, which focus on reported cases, SS, and postoperative complications in LDs and recipients.

One case report warrants special attention and this is the first published live birth after DD donor UTx, with the birth taking place in Brazil in late 2017.[38] A 32-year-old woman with MRKH received a uterus from a 45-year-old DD, with brain death due to subarachnoid bleeding. Pregnancy occurred at the second single ET, which was 7 months post-UTx. The pregnancy was uneventful and delivery was by cesarean section in gestational week 35+3. The neonate was healthy. The uterus was removed in the same surgical procedure as the delivery.

As shown in **Table 1**, LD UTx procedures have involved donor hysterectomy by laparotomy (n = 33), robotic-assisted laparoscopy (n = 17), and traditional laparoscopy

TABLE 1: Summary of published (n = 67) cases of uterus transplantation (UTx). Data on surgical success (SS), rate of major (≥Clavien–Dindo class 3) postoperative live donor complications (DC), and rate of major (≥Clavien–Dindo class 3) surgery-related postoperative complications in recipients with successful grafts (RC).

(DD: deceased donor; LD: live donor)

(n = 4). Thirteen DD UTx procedures have been reported **(Table 1)**. The 31 LD UTx procedures by laparotomy have been reported from trials/cases in Saudi Arabia,[3] Sweden,[26] Germany,[39] Czech Republic,[40] Lebanon,[41] and USA.[42] The 17 LD UTx procedures by robotic-assisted laparoscopy have been reported from trials/cases in China,[43] Sweden,[28,44] USA,[42] Spain,[45] France,[46] and Brazil.[47] The four LD UTx procedures by traditional laparoscopy have been reported from one trial in India.[48,49] The 13 DD UTx procedures have been performed in Turkey,[50] Czech Republic,[40] USA,[42,51-53] and Brazil.[38]

Table 1 summarizes SS, defined as a graft with uncompromised blood flow during the initial 3–4 months after UTx and with resumed menstruations. **Table 1** also provides information on the rate of major surgery-related postoperative complications in LDs and recipients. The distinction of a major postoperative complication is based on the Clavien–Dindo (CD) score system,[54] where we have chosen to classify complications higher than CD 2 as major **(Table 1)**. Grade 3 includes complications requiring radiological, endoscopic, or surgical intervention. Grade 4 includes complications involving single-organ dysfunction or multiorgan dysfunction.

Concerning SS, the overall success rate was 79%, which has to be considered acceptable in this new type of transplantation, which involves complex surgery both in the LD and the recipient. There are too few cases published yet to determine if the SS is higher in any type of Utx, and it has to be taken into consideration that there is a learning curve in this type of surgery. Major postsurgical complications in recipients occurred in 9% of the surgically successful procedures. The complications were mostly related to occurrence of vaginal stenosis over the anastomosis line between the vaginal vault of the recipient and the vaginal rim of the graft. This complication was seen in recipients of both LD UTx and DD UTx procedures. Vaginal stenosis is corrected by dilatation or vaginal surgery, or a combination of these.

Rejection episodes occur in a majority of the UTx procedures and they are commonly subclinical and diagnosed on histology of cervical biopsies.[55] The rejection episodes are reversed by corticosteroid treatment or by an increased dose of maintenance IS.

The rate of major postoperative complications in LDs was 15% and they were distributed equally between procedures by laparotomy and robotics. A majority of these postoperative complications in LDs have been related to the ureters, with ureteric laceration, ureteric–vaginal fistula, and hydronephrosis reported.

TABLE 2: Reported pregnancies with live births ($n = 35$) after uterus transplantation.

	Week of live birth	*Pregnancy complication*	*Indication for delivery*	*Apgar (1/5 minutes)*	*Neonatal complication*

LIVE BIRTHS AFTER UTERUS TRANSPLANTATION

Up until today 35 live births after UTx have been published **(Table 2)**. The great majority (27/35) of the live births have been after LD UTx and most of the births have occurred in Europe[27] and USA.[56] There is a wide variation in gestational length of the births, ranging from gestational week 28+0 until 38+0. As shown in **Table 2**, maternal pregnancy complications and respiratory distress syndrome of the neonate were common events. It is predicted that this rate will decrease in the future since per protocol delivery has been adjusted from 35 weeks until 37–38 weeks in many centers.

CONCLUSION

Uterus transplantation is the first and only treatment for the hundreds of thousands of women around the world with AUFI. The UTx procedure is still in the phases for development and evaluation and should therefore be considered as an experimental procedure within the field of infertility treatments.

CHAPTER 81

Ovarian Transplant

Pravin Mhatre, Jyoti Mhatre

HISTORY OF OVARIAN TRANSPLANT

Man has always been fascinated with the idea of longevity and eternity. However, the main desire was youth forever. This eternal youth desire leads to the idea of gonadal transplantation. Browsing through the history, there are many examples in the world literature. Almost all religions are replicated with such stories. The famous example of king Yayāti taking the youth from his son Pururava is well known in Hindu mythology **(Fig. 1A)**.

Not only mythological events but well-documented events in Christian literature also exist. Emperor Caligula used to have decoction prepared with testicular extracts to achieve eternal youth, while Pope Pius II used what was described as a fountain of youth **(Fig. 1B)**, where he drank the juice prepared from semen and blood of young boys.

The story of a famous Chinese general in the 18th century is very fascinating. He was a *eunuch* and carried his castrated gonads around his waist and believed to draw energy for all his great achievements from them **(Figs. 2A and B)**. He was the most powerful general and had traveled half the world in his naval fleet.

Although the discovery of hormones and their role in imparting the youth made these practices unworthy, the continuation of such treatment in the modern era is extremely shocking. The famous examples of Sophia Lauren and Charlie Chaplin using these modalities to achieve eternal youth are well documented.

Charles-Édouard Brown-Séquard, well known for his work in physiology, neurology, and anatomy, declared the use of such treatment on himself and in achieving the youth **(Figs. 3A to G)**. This work was presented at a world conference held in Paris. His famous quote was

"Everything I have done badly due to advancing age, I am able to perform most admirably today".

The most surprising fact is that such clinics are running even today and boasting of their elite *clientele* **(Figs. 3A to G)**.

Christiaan Barnard, noted for his first heart transplant after 1980, started such a clinic in Switzerland and is still operating, having done 65,000 treatments till 1990.

The gonadal or testicular transplant was carried out in a big way in USA. These were more testicular implants than transplants. Frank Lydston from Chicago first reported these testicular implants in 1916 to achieve rejuvenation. In 1919, the largest series of more than 1,000 patients were carried out unethically in San Quentin prison. Surprisingly, these experiments were continued unofficially till 1960. Brinkley from Kansas performed 16,000 such cases of testicular

implants in 1930 alone **(Figs. 4 and 5)**. With the increasing demand resulting in dwindling supply, some researchers started to use monkey or goat glands for rejuvenation.

The real scientific transplantation began in India 600 years before Christ, and the sage Sushruta is credited for the first nose transplant. Sushruta is credited to be the

Figs. 5A to C: Frank Lydston and testicular implants.

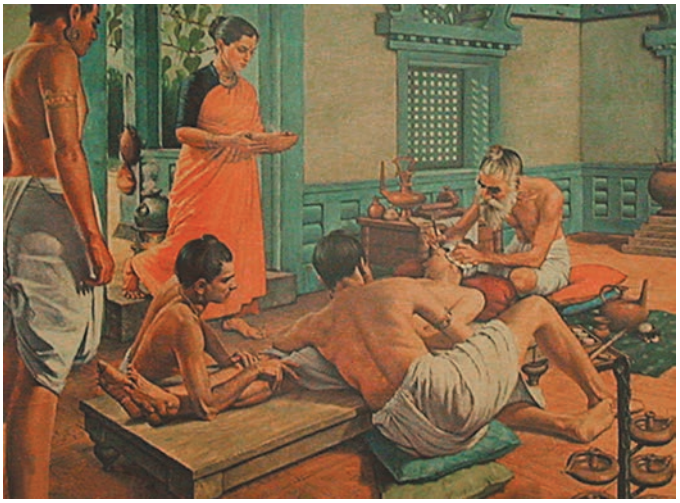

Fig. 6: Sushruta 600 BC.

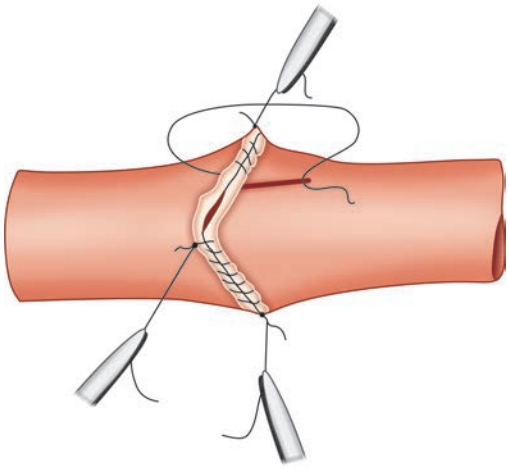

Fig. 7: Alexis Carrel and technique of vascular anastomosis.

father of transplantation **(Fig. 6)**. However, Alexis Carrel in 1900 developed the technique of vascular anastomosis leading to a revolution in organ transplant and hence should be called the father of modern transplant history **(Fig. 7)**. He was the first surgeon to receive the noble prize although he was barred from medical practice. His contribution opened a plethora of organ transplants till 1930, but the lack of knowledge of immunology resulted in failures and was followed with a period of lull till 1950.

The work of Medawar on understanding immunology gave an impetus to organ transplantation, resulting in true success. The first successful renal transplant was performed in 1954, paving a wave of organ transplants. The actual credit goes to Yu Yu Voronoy from Russia, who performed the first renal transplant in 1933 and a successful one in 1950 from a cadaveric donor **(Fig. 8)**. The authorities who were dissatisfied asked him to repeat the procedure and gave him a person who was dead for 8 days, thus resulting in failure, and denounced his experiment, which is a classical case of rivalry and jealousy.

Many workers have worked scientifically on ovarian transplant.

ANIMAL EXPERIMENTS

Foa in 1900 showed that neonatal ovarian tissue in rabbits survives against the adult one in ovarian homografts.

Harris and Eakin in 1949 showed that ovarian homografts in rats survived better only after removing the recipient ovaries. They showed that the recipient oophorectomy improved success by reducing the lymphatic response.

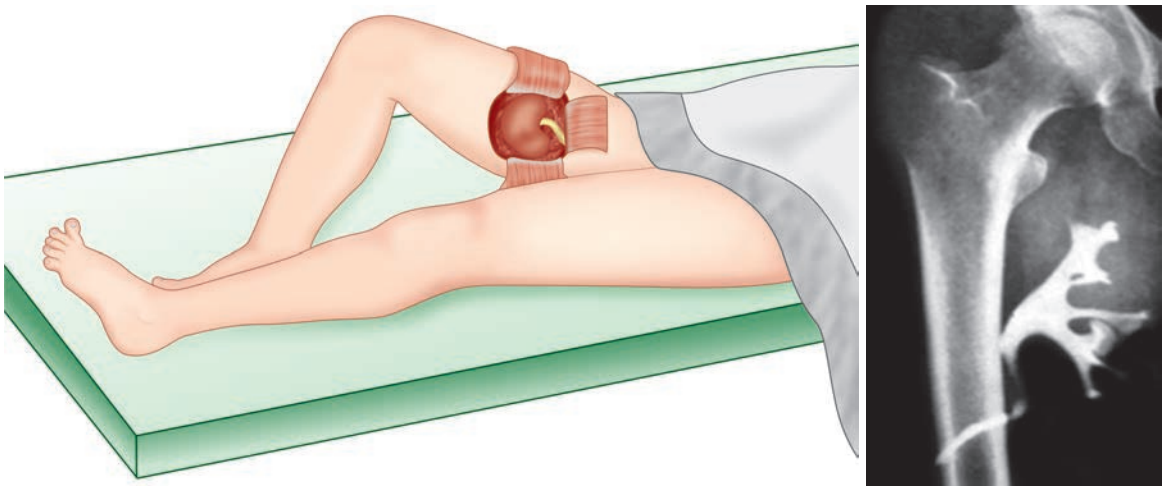

Fig. 8: Yu Yu Voronoy from Russia who performed the first renal transplant.

Deanesly in 1956 described the histological appearance and function of long-term subcutaneous homografts in rats, some of which were frozen prior to grafting.

In 1955, Krohn noted that homotransplantations in mice had improved results by using cortisone. Estrogen and gonadotropins were also beneficial in the improvement.

Hicken and Krohn were the first to show the role of histocompatibility genes.

HUMAN EXPERIMENTS

Sturgis and Castellanos in 1958 demonstrated the survival of human ovarian homograft in the Millipore chamber of six patients of Turner syndrome.

Desaire transplanted the ovary in spleen in the patient having generalized cancer and was castrated. Holmer transplanted the ovarian tissue in gonadal agenetic patients. None of these attempts in humans was successful.

INDICATIONS FOR OVARIAN TRANSPLANT

Theoretically, there are many indications for ovarian transplant; however, ethical considerations are more important in the decision-making. Unlike other solid organ transplants where they are more of lifesaving, ovarian transplant is for improving the quality of life. The indications are as follows:

- Dysgenetic gonads—as in Turner syndrome—is the most important indication
- Ovarian agenesis
- Bilateral oophorectomy or post onco- or radiotherapy
- Fertility restoration
- Treatment of menopause.

Whatever may be the indication, it must be a long-term therapeutic and not a one-time procedural gain as to achieve pregnancy.

PROBLEMS ASSOCIATED WITH OVARIAN TRANSPLANT

- It is vital to understand that ovarian transplant, unlike other solid organ transplant, is not lifesaving but only improves the quality of life.
- The second major issue is that as of today, ovarian transplant is from a live donor only. The cadaveric ovarian transplant is not possible as the primordial follicles are extremely susceptible to oxygen concentration and are lost almost immediately following death. The safety time zone between the time of death and organ retrieval is practically absent. The ovarian function of hormone production is maintained for a long time, even in low oxygen concentration. The follicles are extremely susceptible to low oxygen, and there is a significant loss of primordial follicles due to hypoxia **(Table 1)**.
- Cryopreservation of ovarian grafts and tissue is now standardized and has a fair success rate; however, the entire ovarian cryopreservation is not yet successful.
- One of the major problems is immunological rejection. On the scale of immunogenicity, tissues such as cornea, cartilage, and cardiac muscles are at the bottom due to the paucity of cell nucleus, and there is great evidence to believe that the ovary also has less immunogenicity. It was believed for a long time that the ovary is privileged for transplant; however, our experience in human ovarian transplantation paints a different picture. It has been found that the ovary has one dominant system of transplantation antigen and probably 30 or more so-called weaker systems. An incompatible dominant system results into a marked graft rejection within 8–10 days, while when the weaker systems are involved, rejection occurs after a considerable length of time. Thus, it was found that the ovaries are resistant to graft rejection across minor histocompatibility barriers and are highly resistant to homograft reactivity.

TABLE 1: Oxygen uptake of endocrine tissues.

Tissue	*QO_2 (μM/g tissue/h)*
Liver	35
Adrenal	26
Thyroid	17
Placenta	11
Ovary	9
Parathyroid	7

- Special position on transplantability scale: Less human leukocyte antigen (HLA) antigens.
- Master organ in terms of cell potential so more acceptability.
- O_2 requirements for growth and function are less.
- Ability to be fragmented and transplanted and take new blood supply is good.
- Endocrine function of the transplanted ovary is achieved easily. Blood supply and nutrition are of greater importance for ovulation.
- Ovary transplanted from immature to a functional environment develops more rapidly than it would ordinarily be expected to do so (Foa 1900).

The *immunological rejection* can be prevented by three different ways:

1. *Central inhibition:* This is achieved by thymectomy and splenectomy in which the aim is to reduce the lymphoid tissue. The other way is general or selective radiation. None of these methods are practicable.
2. *Efferent inhibition:* The most important part of immunosuppression is brought about by pharmacological therapy. Two types of drugs mainly used are steroids and cytotoxic drugs. The basic drug is prednisolone and the most important cytotoxic drugs are azathioprine and cyclosporine. The second principle of immunosuppression is the removal of or destruction of circulating immunized lymphocytes. This can be achieved by prolonged irradiation of extracorporeally shunted blood. Recently, antilymphocytic globulins have also been introduced for the similar effect.
3. *Local inhibition:* The third principle of immunosuppression is to protect the allograft from immunological attack. This can be achieved by local infusion of steroids into the allograft artery.

The most important problem is ovarian vasculature. The orthotopic placement of the ovary poses the real challenge in achieving the transplant. Various attempts were done in graft placement in heterotopic sites.

OVARIAN VASCULATURE

The ovary has a low metabolic activity as compared to other vital organs; however, it receives the arterial blood supply directly from the heart at substantial high pressure. To circumvent this discrepancy in anatomical supply and the physiological need, the ovarian vasculature undergoes unique changes **(Fig. 9)**.

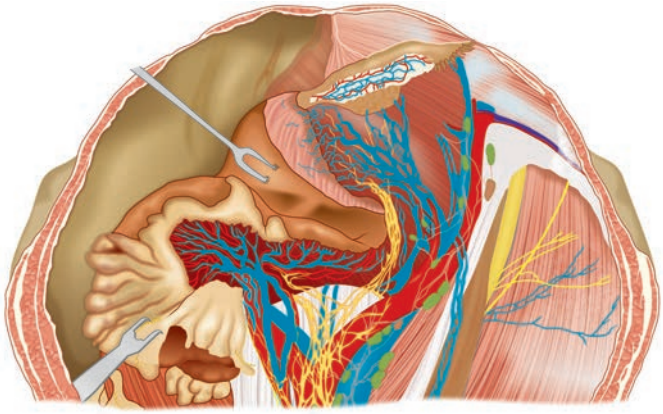

Fig. 9: Pelvic vasculature.

The ovarian artery after arising from the aorta runs a straight course and before it enters the ovary, it has distinct convolutions. There are three sets of convolutions in the ovarian artery course—upper, middle, and lower **(Figs. 10A to C)**. With the help of these anatomic convolutions, the ovary achieves reduction in the arterial force to match its physiological needs.

This is an extremely unique anatomical arrangement probably not seen in any other organ.

Ovary being a pelvic organ also has its unique nature of venous drainage system. As the ovarian veins drain directly into the vena cava, a high-flow drainage system, it requires to change its anatomical structure. The ovarian vein no more remains a single large drainage system but gets replaced by a multitude of small drainage vessels forming a confluence. These ovarian vessels form a mesh around the ovarian artery.

By far these unique anatomical changes occurring in the ovarian vasculature pose the greatest challenge in the ovarian transplant and form a major stumbling block in achieving its success **(Figs. 11 and 12)**.

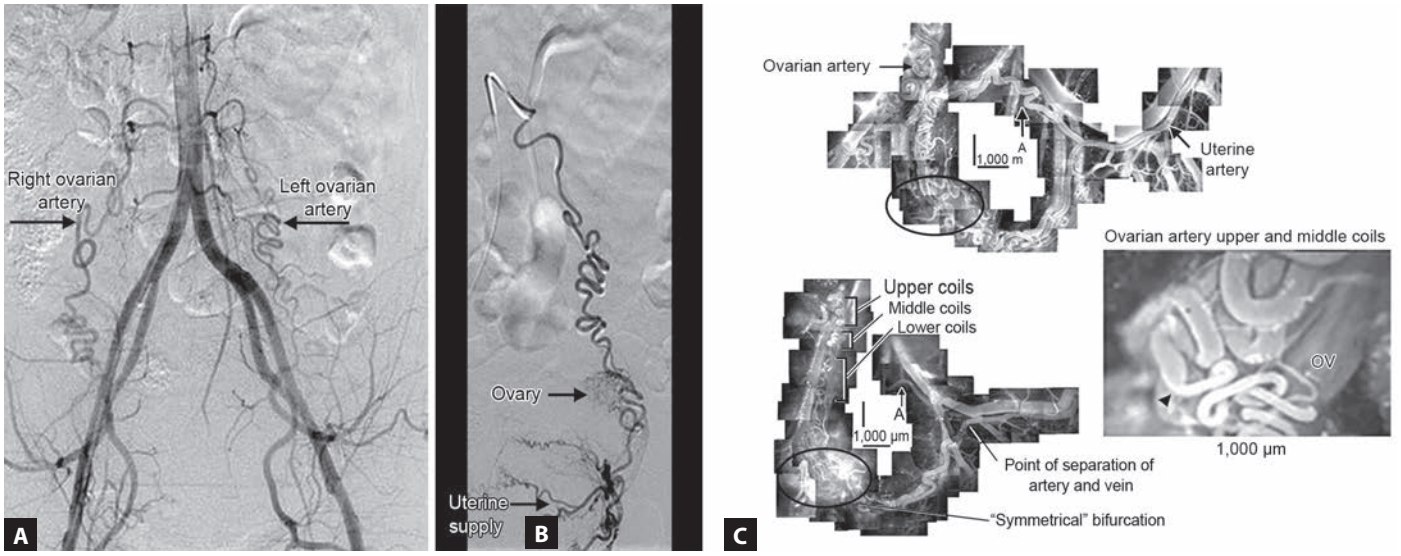
The larger vessel diameter for anastomosis and the availability of a large single drainage vein are the hallmarks of success in the solid organ transplant.

SITE OF OVARIAN TRANSPLANTATION

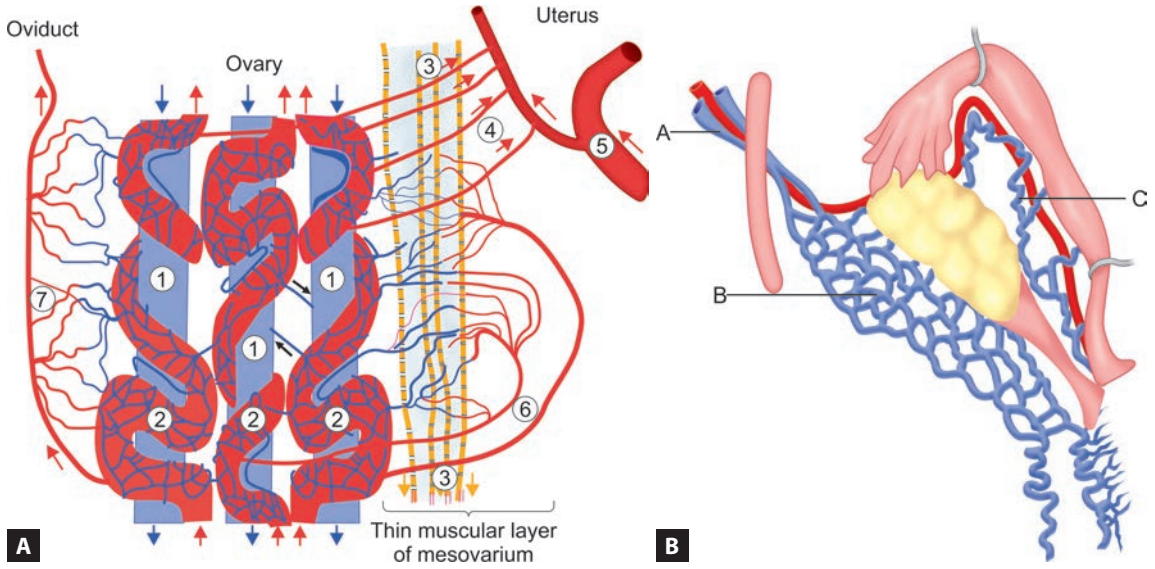
Orthotopic Transplant

To achieve both the reproductive and the hormonal function, it is paramount to transplant the ovary in its orthotopic site. Although the most ideal, the following factors affected its success:

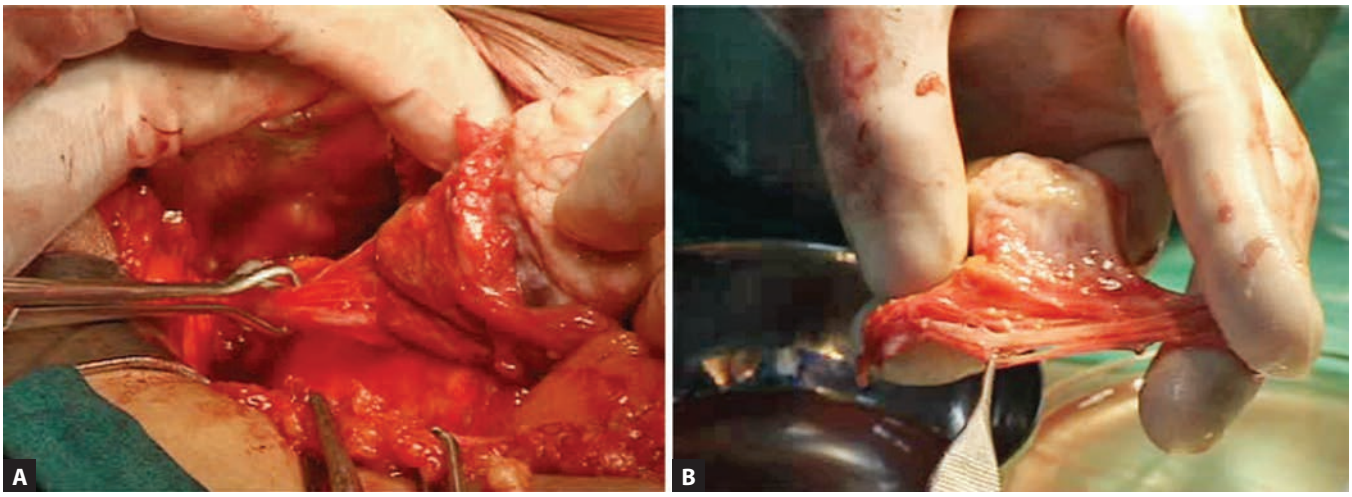
- Unique vasculature
- Difficult anatomical position
- Nonavailability of matching vessels in the pelvis
- Need of its proximity to the fallopian tube for fertility.



Figs. 10A to C: Ovarian artery and its convolutions.



Figs. 11A and B: Ovarian vasculature. (A) Relation of ovarian vasculature with oviduct and uterus; (B) Mesoovarian vasculature; (C) Tubo ovarian vasculature. (1) Ovarian vein; (2) Ovarian artery; (3) Lymphatics; (4) Utero-ovarian connections; (5) Uterine artery; (6) Arteriovenous shunts.



Figs. 12A and B: Ovarian vasculature.

Subcutaneous or Intramuscular Ovarian Grafts

Many workers have shown the subcutaneous survival of the ovarian tissue in both animals and humans. However, the graft did survive for a short time span. These ovarian tissues underwent neoangiogenesis and developed their blood supply from the surrounding tissues but eventually underwent atrophy.

Anterior Chamber of the Eye

This is an extremely common site for the transplant of endocrine tissues in the animals as it allows direct visualization of the graft. Over a period of time, the graft undergoes vascularization in the eye chamber and the rejection of the ovarian graft occurs. Interesting work from Woodruff needs a special mention. The thyroid tissue when transplanted initially in the eye chamber and later placed in the subcutaneous tissue survives. This probably shows the principle of adaptation.

Uterine Fundus and Uterine Cornu

Robert Tuttle Morris did a pioneering work when he implanted the ovaries in the uterine fundus. The Estes operation is well known where ovaries are stitched to the cornu of the uterus. This operation was devised for the irreversible tubal pathology rather than ovarian transplant.

The Spleen

The spleen has been a popular site of ovarian transplant in the animals and early human transplants. The rich vascularity of the spleen was a major factor of consideration in the survival of the graft.

THE SOLUTIONS

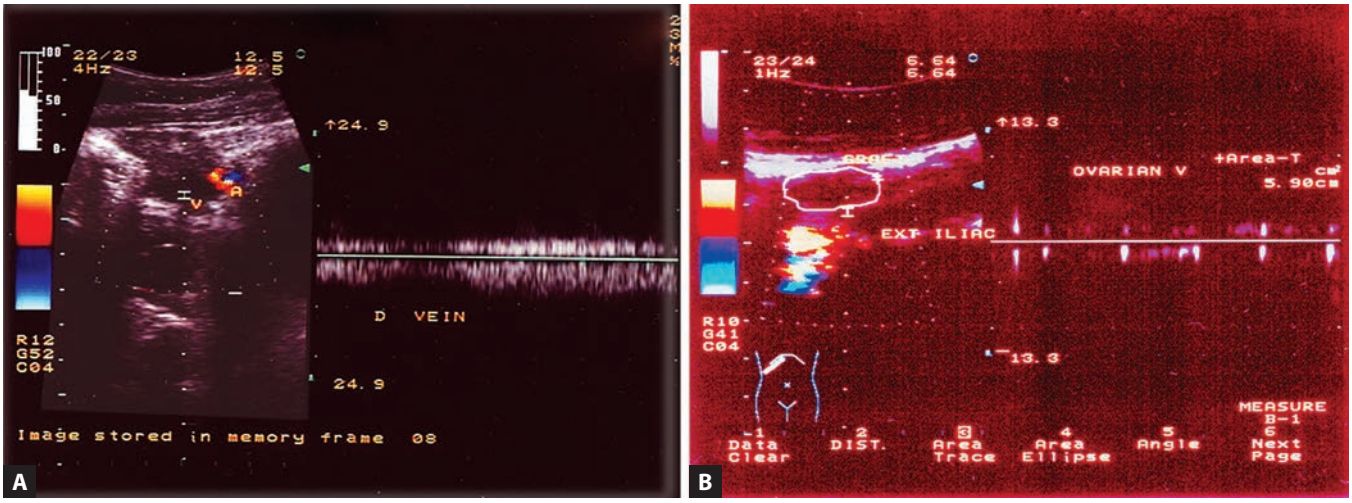
- The main problem for ovarian transplant is the unique nature of ovarian vessels. In an effort to maintain the arterial coiling, we dissected the ovarian vessels at a high level. This was done by extraperitoneal dissection of the infundibulopelvic ligament. The ovarian artery was taken much above the pelvic brim maintaining the arterial coils. This dissection at a higher point also allowed selecting a large diameter vein for anastomosis.
- Nonavailability of matching size vessel is the second major issue in ovarian transplantation. This problem was the main stumbling block in achieving success.

After many cadaveric dissections, the solution was identified.

- *Arterial anastomosis:* The ovarian artery has a diameter of 1–1.5 mm. The various arteries available for the anastomoses are native ovarian artery, uterine artery, internal iliac artery, and inferior epigastric artery. The native ovarian vessels usually are not developed or have undergone atrophy. The uterine vessel (4–5 mm) is too large and cannot be used due to its disproportionate size. The internal iliac artery is also too large (10 mm). The only matching diameter is of the inferior epigastric artery. The inferior epigastric artery is in the anterior abdominal wall and after dissecting, it is brought into the extraperitoneal space to be anastomosed to the donor ovarian artery.
- *Venous anastomosis:* As discussed before, the ovarian vein is not a single large vein but a confluence and a mesh. There are no matching size veins in the pelvis. The native ovarian veins are practically atrophied; the uterine veins are also a confluence of veins not suitable for anastomosis. The only large vein available is the external iliac vein. After a lot of deliberation and many cadaver dissections, it was decided to use the external iliac vein. The greatest problem is that the external iliac vein has a high flow velocity unsuitable for the low drainage of ovarian venous flow. However, with no other better choice available, the external iliac vein drainage was used. The postoperative findings of the transplanted ovary showed a dramatic adaptation of the venous flow pattern over a period of time, showing a change from high to low drainage system (unpublished data).

Venous flow after 1 month and 6 months posttransplant **(Figs. 13A and B)**: The greatest breakthrough was the selection of the appropriate vessels for anastomosis and the technique of using the extraperitoneal dissection for the surgery. These two factors were most important for the success of achieving the first successful orthotopic, vascular, and whole ovarian transplant by the author in March 2002.

- Unlike other solid organ transplants, ovarian vasculature cannot be studied prior to transplant. Therefore, the exact nature of this vasculature remains an enigma and prior planning is not possible. The decision-making happens only on table, keeping the surprise element. Contrary to this, renal, hepatic, cardiac, pulmonary, or small bowel vasculature can be documented prior to surgery and the surgeon is well prepared for the same.
- Although there are many factors against the success of the ovarian transplant, an important factor favors its success. What makes ovarian transplant different? It is the process of vasculogenesis and angiogenesis. The ovary is the only organ having vasculogenesis and angiogenesis as a normal physiological event. Its ability to be fragmented and transplanted and take new blood supply is good; hence, ovarian grafting succeeds even in the absence of vascular anastomosis.
- Ovarian follicles and corpora lutea have been shown to contain and produce angiogenic factors.
- These angiogenic factors appear to be heparin-binding and belong to the fibroblast growth factor (FGF) and vascular endothelial growth factor (VEGF) families of



Figs. 13A and B: Ovarian vein Doppler blood flow 1 month and 6 months post operation.

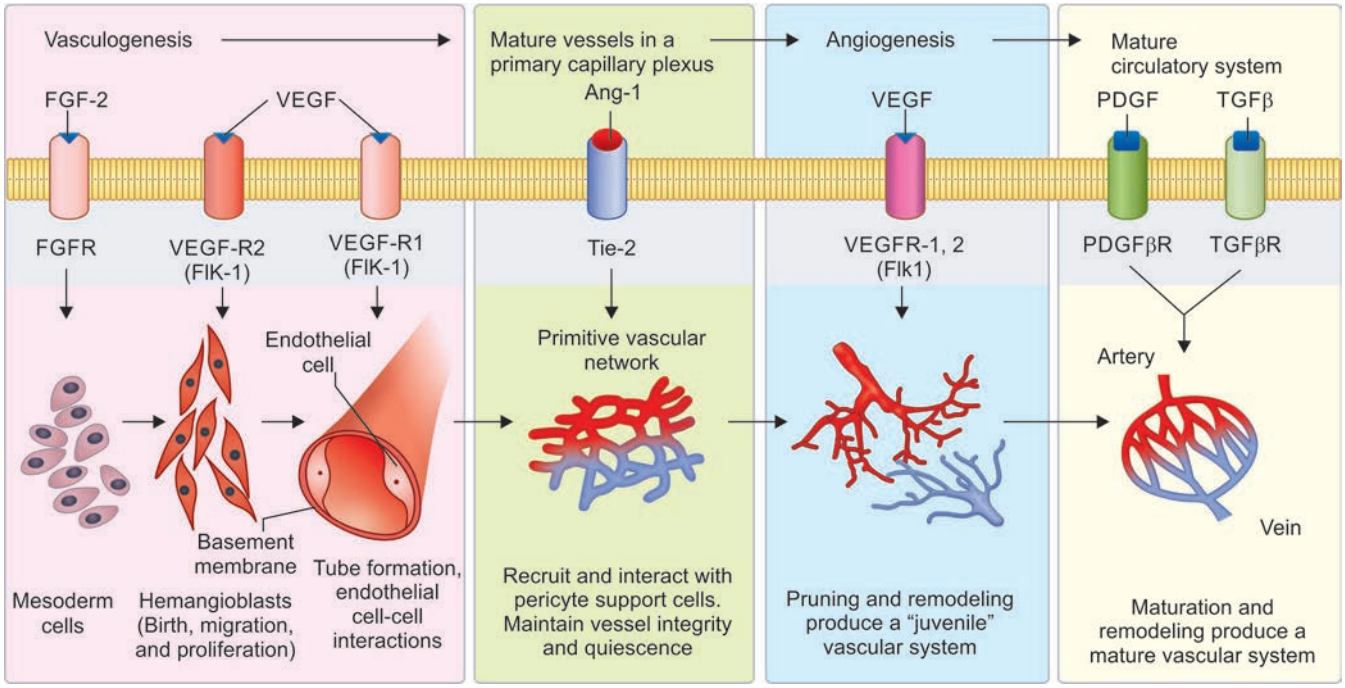


Fig. 14: Vasculogenesis and angiogenesis. (Ang-1: angiopoietin-1; FGF-2: fibroblast growth factor 2; FGFR: fibroblast growth factor receptor; PDGF: platelet-derived growth factor; PDGFβR: platelet-derived growth factor beta receptor; TGFβ: transforming growth factor beta; TGFβR: transforming growth factor beta receptor; VEGF: vascular endothelial growth factor; VEGF-R1: vascular endothelial growth factor-receptor 1; VEGF-R2: vascular endothelial growth factor-receptor 2)

proteins. In addition, factors regulating gap junctional communication may play a critical role in coordinating the interactions between luteal vascular and nonvascular tissues.

- Further elucidation of the specific physiological roles of these factors in follicular and luteal growth, development, and function will ultimately lead to improved methods for regulating fertility in mammals. Immune cells are active players in luteal angiogenesis.
  - Neutrophils stimulate the formation of luteal endothelial cells and capillary-like structures.
  - Macrophages play a crucial role in maintaining vascular integrity.
  - Bone marrow-derived vascular progenitor cells and macrophages contribute to neovascularization during corpus luteum (CL) formation.
  - The role of macrophages is potentially the most important since these cells can be differentiated into the "tissue remodeling" M2 phenotype by the luteal microenvironment. M2 macrophages then produce various proangiogenic factors including VEGFA, VEGFC, and FGF2 to promote angiogenesis.
- The vasculogenesis and angiogenesis are two separate entities, and one must understand the difference between them **(Fig. 14)**.

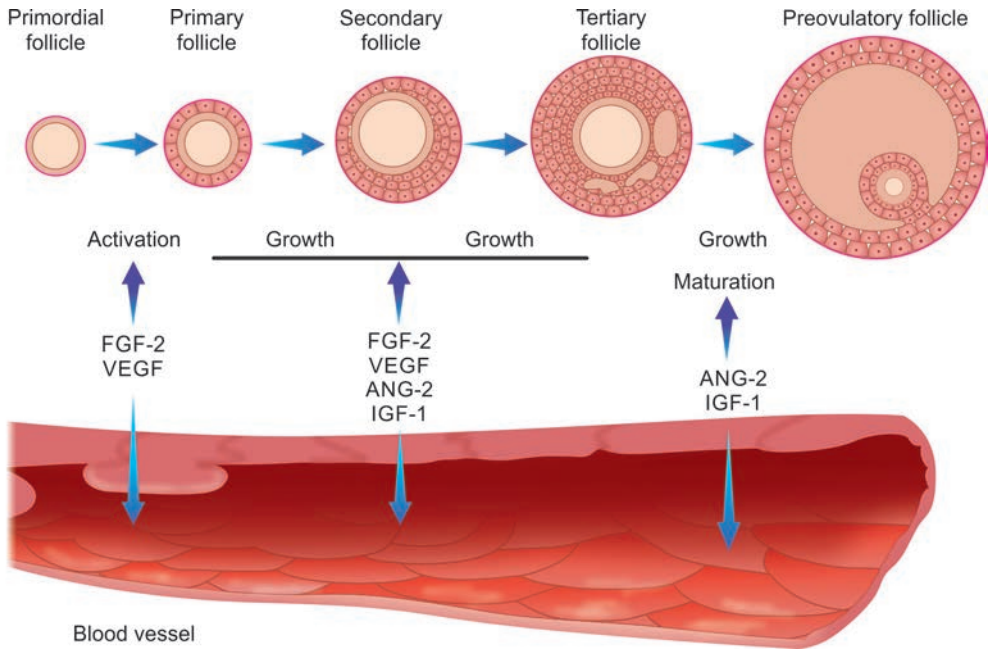

Fig. 15: Angiogenesis factors. (ANG-2: angiopoietin-2; FGF-2: fibroblast growth factor 2; IGF-1: insulin-like growth factor 1; VEGF: vascular endothelial growth factor)

The vasculogenesis has a primary role in the early development of gonads and in the formation of ovarian development. However, in testicular development, angiogenesis plays an important role. Angiogenesis has a role in the follicular development and in formation of CL. The factors governing these are different.

- In a transplanted ovary, the donor ovary has its own set of vasculogenesis factors, while the angiogenetic factors come from the recipient **(Fig. 15)**. This may be an important cause of ovarian rejection. This remains still an ill-understood topic.

JOURNEY TO THE FIRST TRANSPLANT[1-3]

The author achieved the first ever successful ovarian transplant on March 29, 2002. This was a whole ovary, vascular, and orthotopic transplant achieved from a live-related donor to her sister. The success story was long spanned over a period of 20 years of research spanning from conceiving the idea to a fruitful culmination.

- *Animal experiments:* These were carried out with the help of the National Institute for Research in Reproductive Health (NIRRH). These experiments were done primarily on rats to find about the subcutaneous grating of ovarian tissues and their fate over a period of time interval.
  The dog sterilization units from the municipal corporation were chosen to learn the testicular vasculature and the anastomosis techniques. Similar exercises were done on animals from the abattoir.
- *Cadaver dissections:* Permission was obtained to perform the cadaveric dissection to understand the ovarian and pelvic vasculature. It is extremely important to understand that the pelvic vasculature not only differs from individual to individual but also from right to left side. More than 20 cadaveric dissections were carried out for understanding the vasculature. The experience during extraperitoneal dissections of oncological surgical procedures was also helpful.
- *Immunology:* The immunological matching was based on the knowledge from other solid organ transplants. It was decided to do the matching by both major and minor HLA systems as well as to do lymphocytic crossmatch.
- *Renal transplant:* Observer ship—I was fortunate to be an observer in many renal transplant units to understand the entire process—surgical, medical, and social aspects of the transplants.
- *Microvascular surgery:* It is extremely important to have sound knowledge of vascular surgery and it challenges both intra- and postoperative and the management of the complications.

GOVERNMENT PERMISSION

- As per the transplant law, I first obtained the necessary skills for becoming a gynecological transplant surgeon.
- A transplant center was formed as per the law and was certified.
- Necessary permission was obtained from the transplant coordinating committee for conducting the first ovarian transplant.
- On March 29, 2002, an ovarian transplant was performed on a 17-year-old recipient suffering from Turner's syndrome. The donor was her 26-year-old sister, with two living children. The donor and recipient were immunologically

matched by major and minor HLA matching and lymphocytic crossmatch. This happened to be the first successful ovarian transplant (published data).

CONCLUSION

- The history of transplantation actually started with gonadal transplant. The primary goal being achieving immortality with permanent youth by gonadal transplant. This is evident by many mythological stories, as well as recent past experiments conducted almost till 1990.
- The other solid organ transplants flourished exponentially over the last 60 years, however the ovarian transplant has not grown in numbers even after 20 years since we described the first successful vascular orthotopic whole ovarian transplant.
- Many factors are responsible for this shortcomings, namely it being live related transplant with age and fertility bar for the donor. Immunological factors are responsible for failure to ovulatory function. The recent studies have indicated incompetence in vasculogenic and angiogenesis factors which comes from recipient and donor respectively.
- The heart and liver donations can never come from live donors but the ovarian donation such as the renal ones can come plentiful from live consenting donors.
- As the technique of cryopreservation of the entire ovary becomes possible, cadaveric donation and ovarian banking of whole ovary are not a distant dream.

KEY POINTS

- The ovary, unlike kidney, liver, or heart, is not a vital organ required for life sustenance and therefore not lifesaving in true sense of words, but it definitely improves the quality of life and is life producing for the recipient.
- The heart and liver donations can never come from live donors but the ovarian donation such as the renal ones can come plentiful from live consenting donors.
- As the technique of cryopreservation of the entire ovary becomes possible, cadaveric donation and ovarian banking of whole ovary are not a distant dream.

CHAPTER 82

Novel Ways of Creating Vagina

Pravin Mhatre, Jyoti Mhatre

INTRODUCTION

Almost 200 years have passed since Peter Muller described the Müllerian ducts. However, we are still groping in the dark to understand the nuances. The development of the Müllerian duct is one of the most ill-understood topics in gynecology and remains an enigma. Surprisingly, it is impossible to find the total absence or aplasia of the Müllerian structure, but it always presents as a partial absence or hypoplasia. Its correlation with anti-Müllerian hormone (AMH) is still unclear.

DEVELOPMENT OF MÜLLERIAN DUCT

- The Müllerian duct appears close to the region of primitive gonads at about the 7th week of pregnancy.
- The caudal tip of this Müllerian duct is comprised of a solid band of cells, which continues to grow from cephalic end to caudal end.
- As they grow caudally after some distance, they turn medially across the mesonephric duct and lie in close proximity to each other.
- Partial fusion occurs in the Müllerian duct and they continue to grow caudally.
- The lower end of the fused Müllerian ducts projects into the urogenital sinus as a Müllerian tubercle.
- The upper part of Müllerian duct develops into the fallopian tubes, the fused part into the uterus, and the upper three-fourths of the vagina. While the lower one-fourth develops from sinovaginal bulbs. The hymen is developed from the junction of sinovaginal bulbs and the urogenital sinus.
- The uterus develops by the end of 3rd month. During the 5th month of intrauterine life, the septum disappears and a single uterus results. The muscle wall also starts developing, and a circular muscle layer is identified by the 5th month. The longitudinal muscle layer develops during 7th month of pregnancy.
- In summary, Müllerian ducts appear at 6 weeks of gestation:
  - By 10 weeks, they fuse to form the uterus.
  - By 22 weeks, the lining is formed.
  - By 32 weeks, it become an adult uterus ready to bleed, as witnessed by witch menstruation.

The fusion of the two Müllerian ducts with subsequent canalization and hypertrophy leads to the development of the adult female genital tract. The total absence of Müllerian development will lead to aplasia, while the partial development, which is a common occurrence, leads to tubal and partial uterine development and complete absence of upper three-fourths of vagina. It is commonly observed that absence of Müllerian tubercle in urogenital sinus leads to absence of lower one-fourth of vagina. In some rare cases, the lower one-fourth of the vagina may develop in absence of Müllerian counterpart. Failure of canalization in the sinovaginal bulb may lead to an imperforate hymen to complete the absence of lower one-fourth of the vagina.

CLINICAL PRESENTATION

- In most of the cases of upper vaginal absence, the uterus is usually duplicated, hypoplastic, or rudimentary. The ovaries are normal but are placed on lateral pelvic wall along with the uterus. Classically, this is described as the "Mayer–Rokitansky–Küster–Hauser" (MRKH) syndrome. Probably, it has autosomal recessive genetic transmission. These patients have normal secondary sexual development.
- The other presentation is rather rare in the form of lower one-fourth of vaginal atresia with normal Müllerian counterpart. These girls may present early in age as cases of hydrocolpos or hydrometrocolpos, where there is a collection of watery fluid in the vagina and uterus, causing distention and an abdominal mass. These girls, at the time of puberty, develop hematocolpos or hematometrocolpos, causing acute distention

and abdominal mass. Very often, but not always these girls may be operated upon with a wrong diagnosis of duplication cyst or ovarian tumor.

- Another common presentation is in the form of testicular feminization syndrome or androgen insensitivity syndrome, where the patient is 46, XY but phenotypic female having a short, blind lower one-fourth of vagina and absent pubic and axillary hair.
- The classical clinical presentation of imperforate hymen is cryptomenorrhea, cyclical abdominal pain from pubertal age to the development of hematocolpos, hematometra, etc.

  All these types of presentations are as a result of developmental errors; the etiology remains unexplained. Contrary to this, the group of patients with intersexuality also presents with absent vaginal or fusion defects, where the etiological factors are known.

  As a dictum, when the vagina is absent, the uterus is absent too. However, there are many minor differences noted and must be given importance while planning the treatment. Suffice to say, there cannot be a single method of vaginoplasty for all the conditions, but the patient needs to be catered to according to their individual merits.
- Almost all the Müllerian malformations must be suspected of having concomitant urinary developmental defects unless proved otherwise. As a result, all the patients must be subjected to ultrasound sonography (USG), intravenous pyelography, and in some selective cases, magnetic resonance imaging (MRI).
- It is commonly associated with single kidney, horseshoe-shape kidney, and pelvic kidney. Ureteric developmental defects in the form of duplication and absence are also found.
- Laparoscopy, till recently, was considered as an unnecessary investigation. However, according to the authors' study, it forms a very important diagnostic tool, not only to assess the defect in detail but also confirms the utricle and gonadal size and position, rules out or details the pelvic kidney. The size of utricles can help in deciding future uterine implantation.

USE OF PERITONEUM IN NEOVAGINAL LINING

Many surgical techniques such as use of colon, intestine, and skin have been described for the creation of neovagina; however, none of them are successful in developing a normal vagina (**Figs. 1A to C**). Almost all of them are surgically challenging, multistage involving gross technique and resulting in cosmetic disfigurement.

The use of peritoneum in vaginoplasty was first described in Russian literature. This method was popularized by Davydov **(Figs. 2A and B)**. The peritoneal use procedure was done by the open laparotomy method. Semm first described the creation of neovagina using a laparoscope. He used dura mater cerebri grafts (Semm 1983). His procedure was time-consuming, required extra instrumentation, and was associated with complications. The more recently reported technique describes laparoscopic application to modify the original Davydov procedure.

Dr Mhatre's Modifications

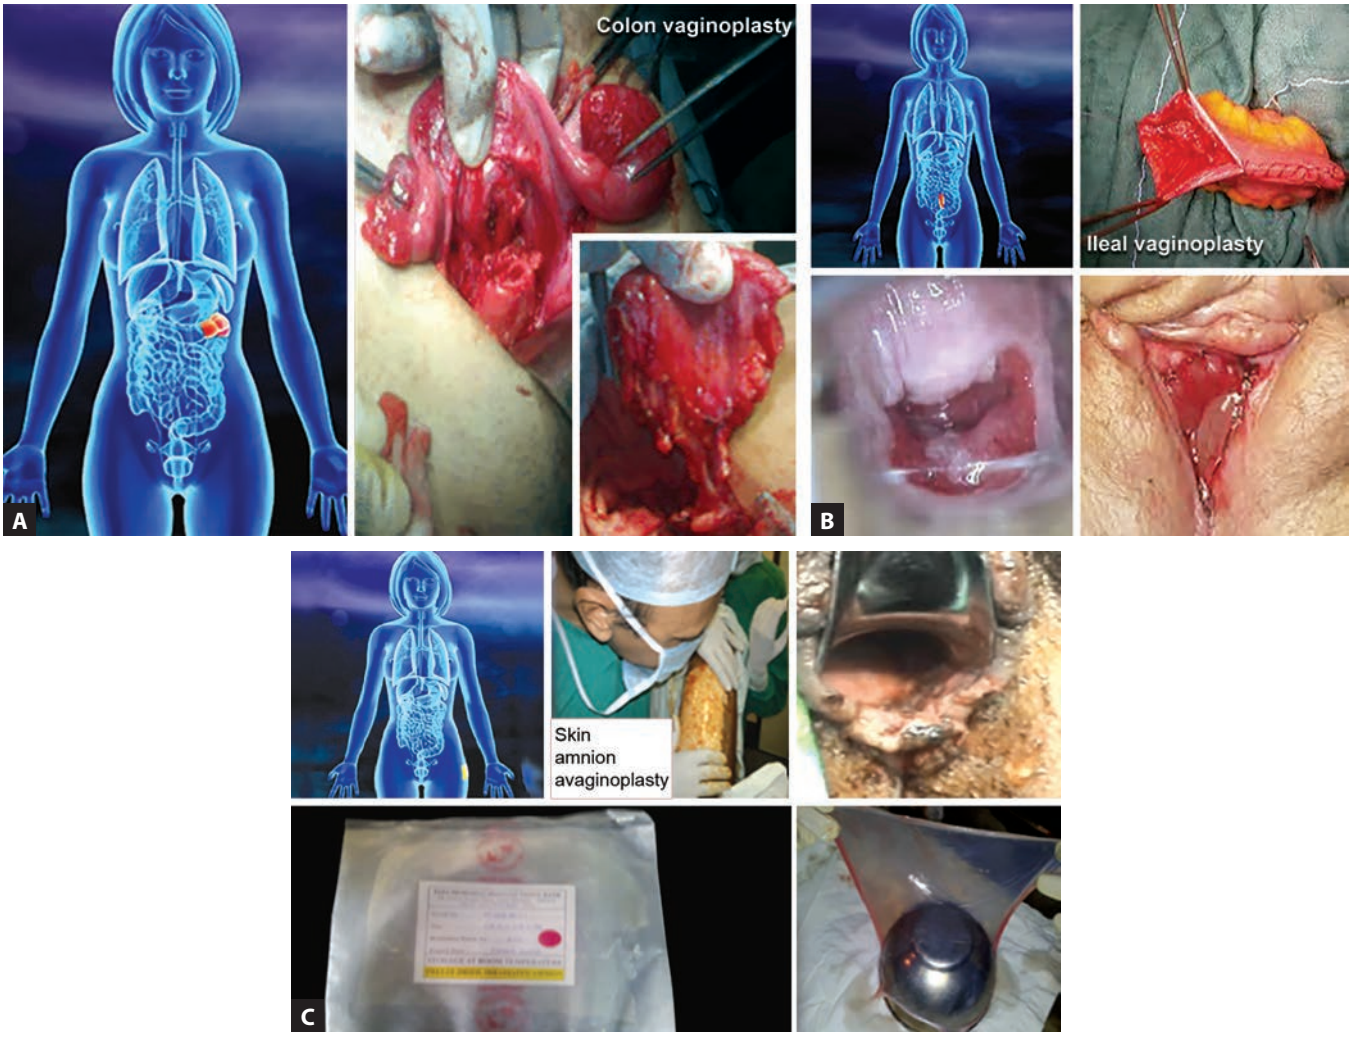
The author has described three different techniques of peritoneal vaginoplasty:

1. Use of thin peritoneal graft
2. Use of thick peritoneal graft with substratum
3. Combined use of peritoneum with amnion grafts in cases of MRKH syndrome along with pelvic kidney, where retrieval of peritoneum is difficult and is associated with complications.

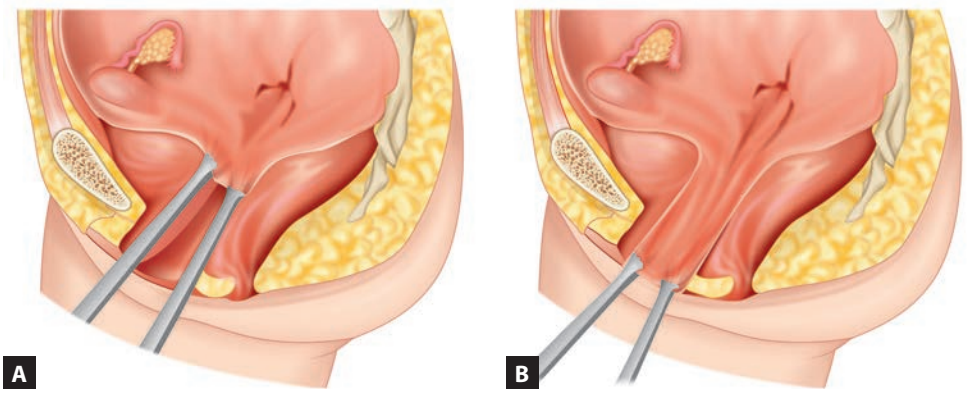
Apart from routine preoperative work-up, a diagnostic laparoscopy was performed to determine mobilization and feasibility of creating anterior and posterior flaps for peritoneal pull through and to see the size and position of the utricles on lateral pelvic walls to determine the possibility of uterine implantation in the neovagina.

PROCEDURE (FIGS. 3 TO 6)

- The neovaginal space is created by making a horizontal incision below the urethral orifice, taking care not to damage the urethra. The further dissection is carried out by blunt dissection, creating an adequate length.
- With the help of operative laparoscope, anterior and posterior thin peritoneal flaps are created.
- The attachment of these peritoneal flaps to the parent peritoneum is maintained.
- In some cases, thick peritoneal flaps along with substratum were obtained. Care must be exercised to achieve hemostasis in cases of thick peritoneal grafts. Hemostasis may be achieved with the use of bipolar cautery or the use of harmonics.
- These peritoneal flaps are brought down in the neovaginal space and sutured to the introital mucosal edges.
- The vault is closed either vaginally or laparoscopically maintaining adequate vaginal length.
- The peritoneal flaps are kept in continuation with the parent site through the attachment, thus ensuring continuation of blood supply.
- In select cases, the utricles were implanted either as a single or after unification to the neovagina as a separate second stage procedure.
- In patients who underwent peritoneal pull-through surgery, vaginal mold was not required. The peritoneal lining prevents vaginal shrinkage and adhesions.
- During follow-up, the neovaginal space can be dilated gradually to maintain the desired length till sexual activity



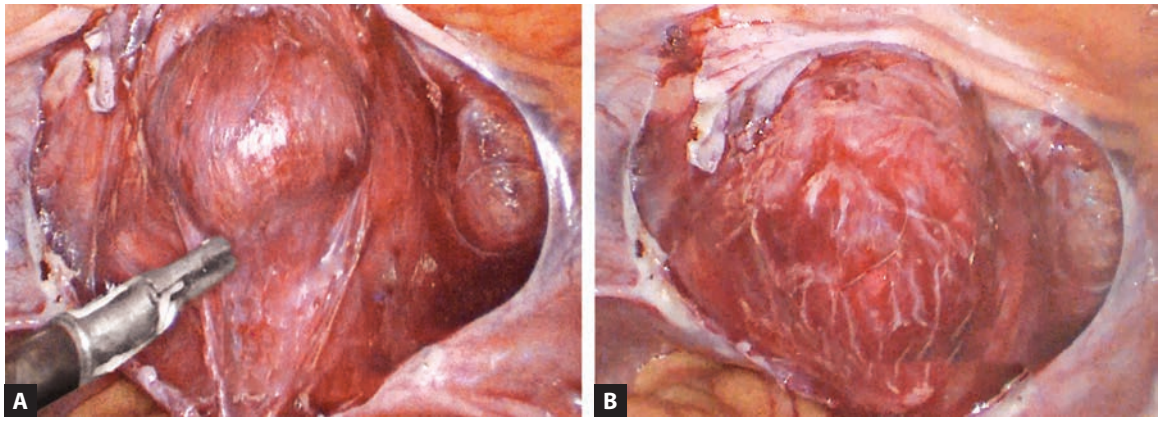
Figs. 1A to C: Surgical techniques for creation of neovagina with the use of (A) Colon; (B) Ileum; and (C) Skin.



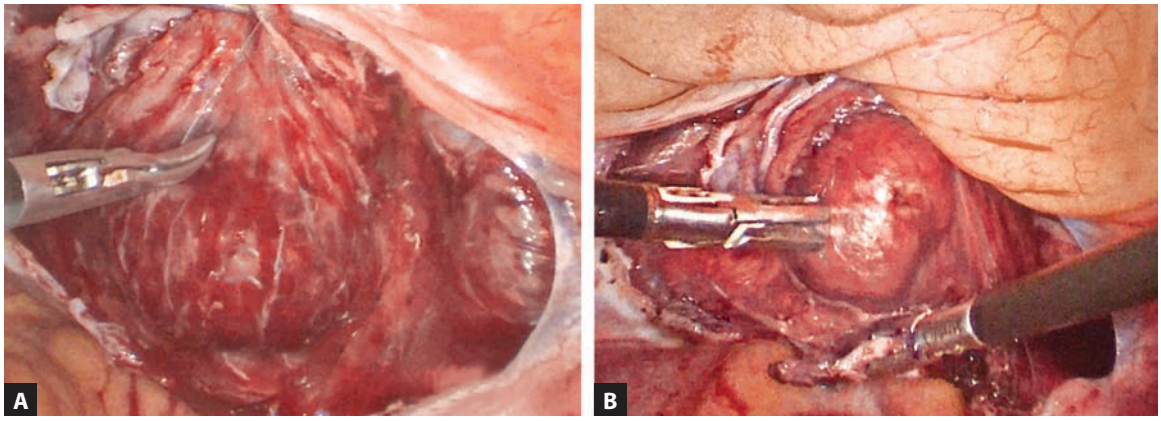
Figs. 2A and B: Application of laparoscopy for the creation of neovagina.

is resumed. Dilatation using glass dilator increases the length and diameter of neovagina and also changes the axis to one which is ideal for intercourse. The neovagina is in correct anatomical axis. The pelvic peritoneum lining the neovagina is responsive to estrogen. It is imperative to remember that the vascular anatomy differs drastically from patient-to-patient and even in the same patient from either side. It is very important to identify uterine artery and vesical arterial disposition during the dissection.

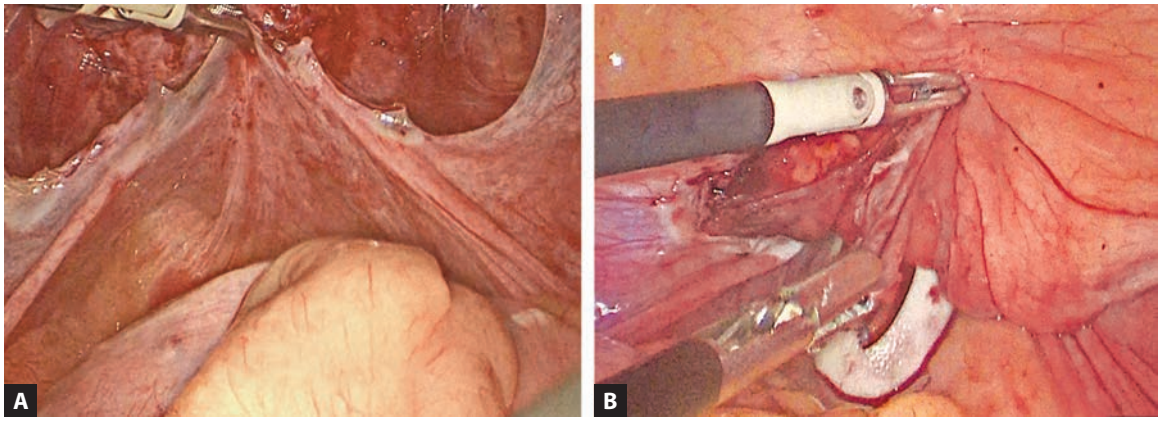
- These patients with Müllerian agenesis have different anatomical presentations, and many of them have associated renal anomalies making this dissection



Figs. 3A and B: Dissection of anterior and posterior peritoneal flaps.



Figs. 4A and B: Dissection of bladder and rectum, and opening of vault of neovagina.



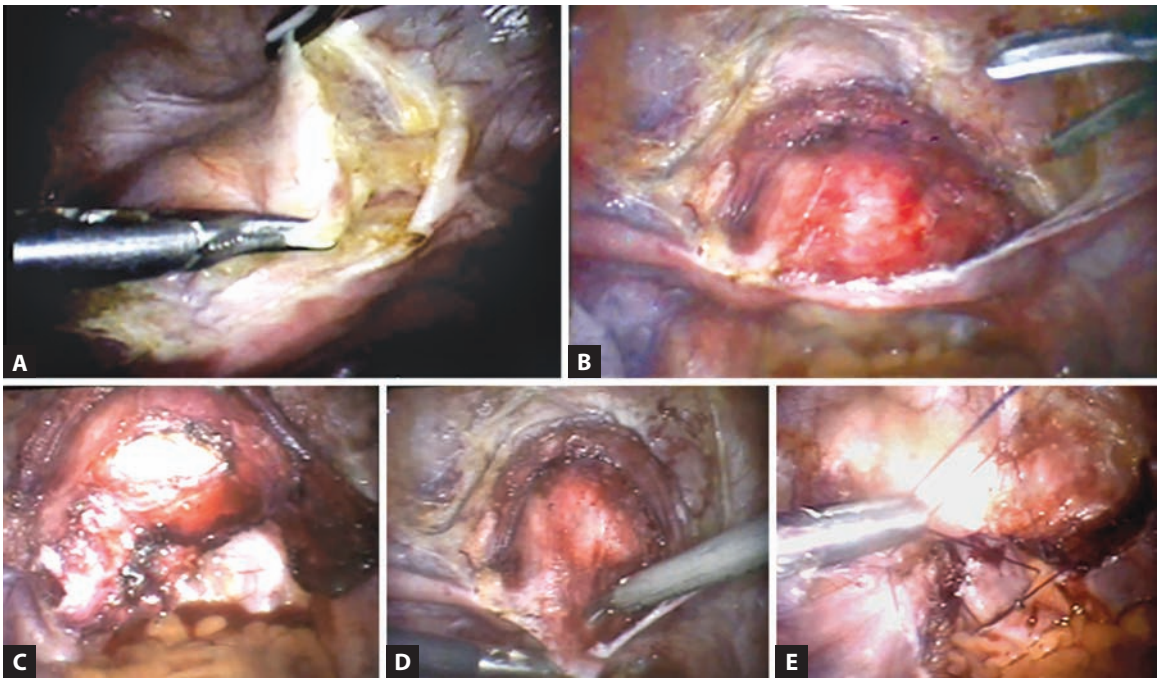
Figs. 5A and B: Mobilization of peritoneal flaps in the neovaginal space.

surgically challenging. Classically single kidney, malrotated kidney, pelvic kidney, and anomalies of ureter such as double ureter pose great surgical challenges **(Fig. 7)**.

- Modification of the peritoneal flaps may be done depending on the availability of free peritoneum. In number of cases, posteriorly the rectum is in close apposition and for fear of rectal damage; it is advisable not to take a posterior peritoneal graft. In such an event, both the flaps may be designed from the anterolateral pelvic peritoneum.
- In such cases, fashioning of peritoneal grafts may be difficult and may be combined with freeze-dried or fresh amnion grafts.

RESEARCH HYPOTHESIS

The ability of the peritoneum to undergo metaplasia is a well-documented fact. It can transform itself into a variety of tissues such as endometrium, cartilage, intestinal epithelium, etc. This knowledge has helped us to understand the genesis of endometriosis and a variety of ovarian neoplasms.



Figs. 6A to E: Technique of using thick peritoneal grafts.

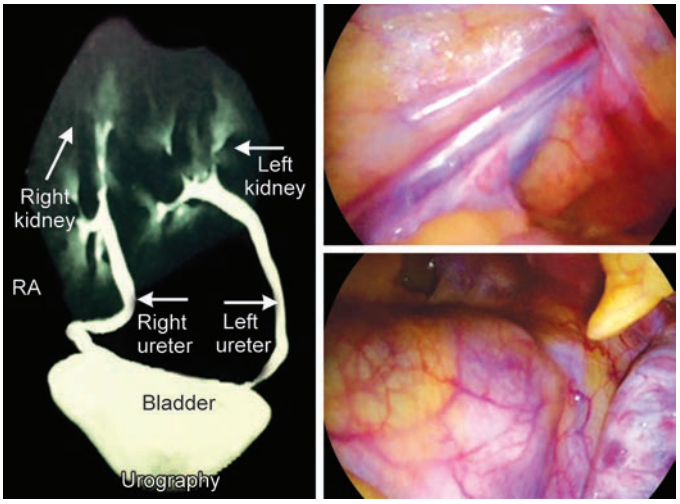


Fig. 7: Single pelvic kidney, fused pelvic kidney with two ureters, and single kidney with double ureter.

The peritoneum and the Müllerian ducts have the same parentage. Both develop from celomic epithelium. The Müllerian ducts develop as invagination of the celomic epithelium finally leading to fusion and canalization. This knowledge prompted us to carry out research in peritoneal vaginoplasty, to find out how the peritoneal metaplastic conversion occurs in the vaginal epithelium.

The peritoneum, when displaced in the vaginal space, undergoes metaplastic stimulation. The nature of the stimulus is still unknown; however, we wish to put forward some hypothetical considerations.

- Anatomically when exposed to the exterior environment, the metaplastic stimulus starts to play its role.
- The dilatation and the friction by the glass dilator provide a mechanical stimulus responsible for the metaplastic conversion.

  The peritoneal metaplasia is not from simple multiplication of low-cuboidal epithelium but a complex phenomenon passing through activation followed by suppression of mesothelial progenitor cells.

  The research was directed toward documenting exactly the stages of these metaplastic conversions. This was achieved by studying the neovaginal biopsies done at regular interval documenting the histological events. These changes were documented at three levels:
  1. Epithelial changes
  2. Stromal changes
  3. Neoangiogenesis.
- All the biopsies performed of the neovagina showed stratified squamous epithelium. The keratinization occurred after 3–5 months of surgery. Serial transformation was demonstrated by biopsies taken at weekly intervals **(Figs. 8 and 9)**.

Day 7 of Neovagina

Day 7 of neovagina shows single layer epithelium with loose adventitial layer below it. Vaginoscopy of neovagina at day 7 showed pink-color lining with healthy look **(Fig. 10)**.

Day 14 of Neovagina

Day 14 of neovagina shows polymorph and mononuclear infiltrate along with vascular endothelium. Adventitial layer is dense as compared to day 7. The vaginoscopy shows pale neovaginal mucosa **(Fig. 11)**.

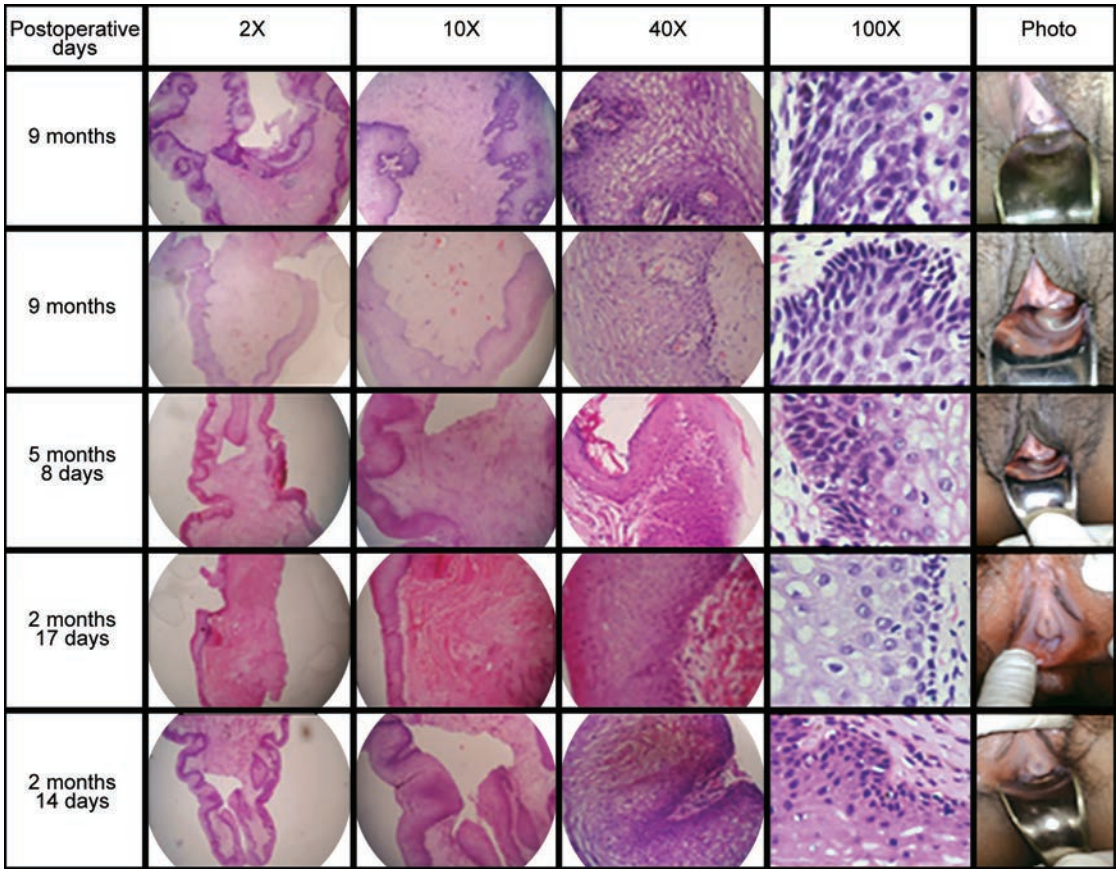

Fig. 8: Vaginal biopsies and vaginoscopic pictures of neovagina.

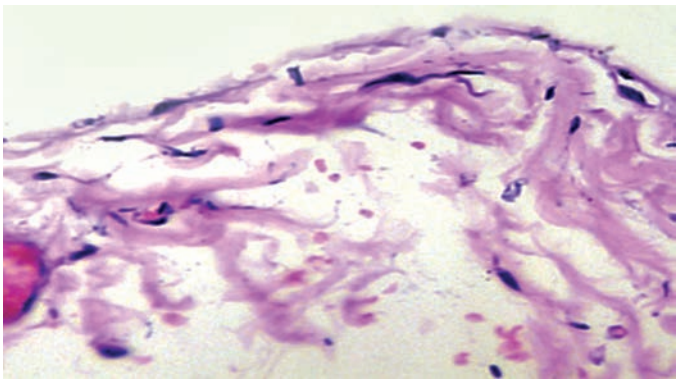

Fig. 9: Normal peritoneal epithelium and loose adventitial layer.

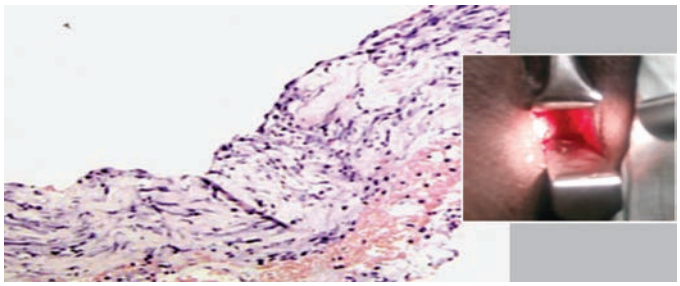

Fig. 10: Day 7 of neovagina with single layer epithelium and loose adventitial layer.

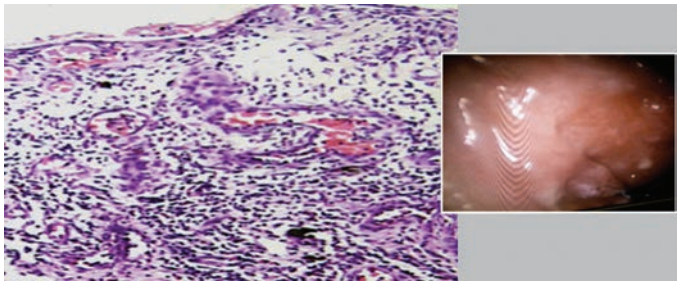

Fig. 11: Day 14 of neovagina with—multilayer, polymorph, and mononuclear infiltrate with vascular endothelium and dense adventitial layer.

Day 21 of Neovagina

Day 21 of neovagina shows increased polymorph and mononuclear infiltrate with angiogenesis. Adventitial layer is dense and compact as compared to day 14. The vaginoscopy shows metaplastic white areas with normal looking pink posterior wall **(Fig. 12)**.

Day 28 of Neovagina

Day 28 of neovagina shows increased polymorph and mononuclear infiltrate with well-organized capillaries and edematous adventitial layer. Vaginoscopy shows white lesions on the vaginal wall representing metaplastic activity **(Fig. 13)**.

Having confirmed this histological conversion, the research was directed toward identification of specific progenitor cell in the peritoneum responsible for this metaplasia.[1]

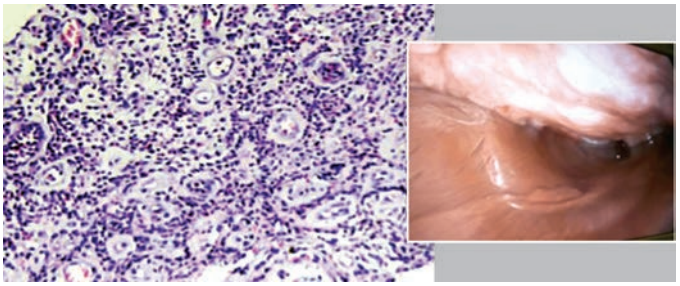

Fig. 12: Day 21 of neovagina with—increased polymorph and mononuclear infiltrate with angiogenesis and dense adventitial layer.

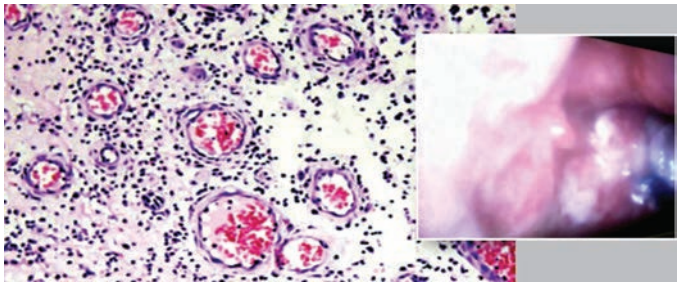

Fig. 13: Day 28 of neovagina with—increased polymorph and mononuclear infiltrate with well-organized capillaries and edematous adventitial layer.

IMMUNOHISTOCHEMISTRY

Neovagina sections of 5 mm thickness were deparaffinized and rehydrated using descending grades of methanol. Endogenous peroxidase activity was quenched by incubating the sections in 0.3% hydrogen peroxide for 30 minutes. This was followed by microwave treatment of the sections for 10 minutes in an antigen unmasking solution (Vector Laboratories, Burlingame, CA, USA). Sections were blocked with 2% goat serum (for the section to be incubated with polyclonal antibodies against all antigens) in phosphate-buffered solution for 1 hour at room temperature. Sections were then incubated with the respective primary antibodies for 16 hours at 4–8°C. The negative control sections were incubated with rabbit or mouse immunoglobulin G in place of primary antibodies. This was followed by incubations of the sections with fluorescent-labeled secondary antibodies raised in goat (Vector Laboratories, Burlingame, CA, USA) for 1 hour at 37°C. Sections were then counterstained with hematoxylin and gradually dehydrated, cleared in xylene, and mounted. The staining intensities for immunoreactive antigens were determined using confocal microscope (Zeiss, Germany). At least 10 areas from each section were randomly selected for measuring the integrated optical density (IOD). The IOD values of the respective negative control (without primary antibody) were subtracted from the IOD values for the sections stained with primary antibody.

Immunohistochemistry tests (IHC) were performed on peritoneal biopsy samples and the presence of progenitor cells was demonstrated by octamer-binding transcription factor 4 (OCT4) and SRY-Box 2 (SOX2) as markers. Immunostaining with stem cell marker OCT4 is seen in the nucleus in green; whereas 4′,6-diamidino-2-phenylindole (DAPI) fluorescent stain is used as nuclear stain in blue. The immunostained images have been overlaid with the differential interference contrast image (DIC is the bright field contrast image of the unstained sample) to show the localization of OCT4. Immunostaining with stem cell marker SOX2 is seen in the nucleus as green, whereas DAPI is used as nuclear stain in blue. The immunostained images have been overlaid with the DIC image to show the localization of SOX2.

Peritoneal biopsies were taken and subjected for identification of the progenitor cell using SOX2 and OCT4 IHC markers **(Fig. 14)**.

Day 7 of Neovagina

Immunostaining with stem cell marker SOX2 is seen in the nucleus as green. The expression is scattered in the tissue and in some areas it is seen in parallel distribution **(Figs. 15A and B)**.

Day 14 of Neovagina

The expression of OCT4 is scattered in the tissue. The expression of SOX2 is increased as compared to day 7. The expression is seen in two distribution patterns—(1) tubular and (2) circular **(Figs. 16A and B)**.

Day 21 of Neovagina

Comparing with day 14, OCT4 expression is reduced on day 21, and the SOX2 expression is increased with wide distribution **(Figs. 17A and B)**.

Day 28 of Neovagina

Expression of OCT4 and SOX2 is very low in the day 28 vaginal biopsy.

In seven cases, we were able to connect the utricles to the neovagina and achieve menstrual function. **Figure 18** shows the left utricle almost of normal size, uterus having normal blood flow pattern, and a right rudimentary utricle. Pregnancy was attempted in this patient but failed. However, in three patients, we achieved the pregnancy using surrogacy, thus making this vaginoplasty a fertility-enhancing procedure **(Figs. 19 to 22)**.[2]

Having confirmed the histological metaplastic conversion and identifying the progenitor cell responsible, the research was continued toward evaluation of the neovagina on various anatomical, physiological, and functional parameters.

- The anatomical parameters were histology, cell cytology, and neoangiogenesis.

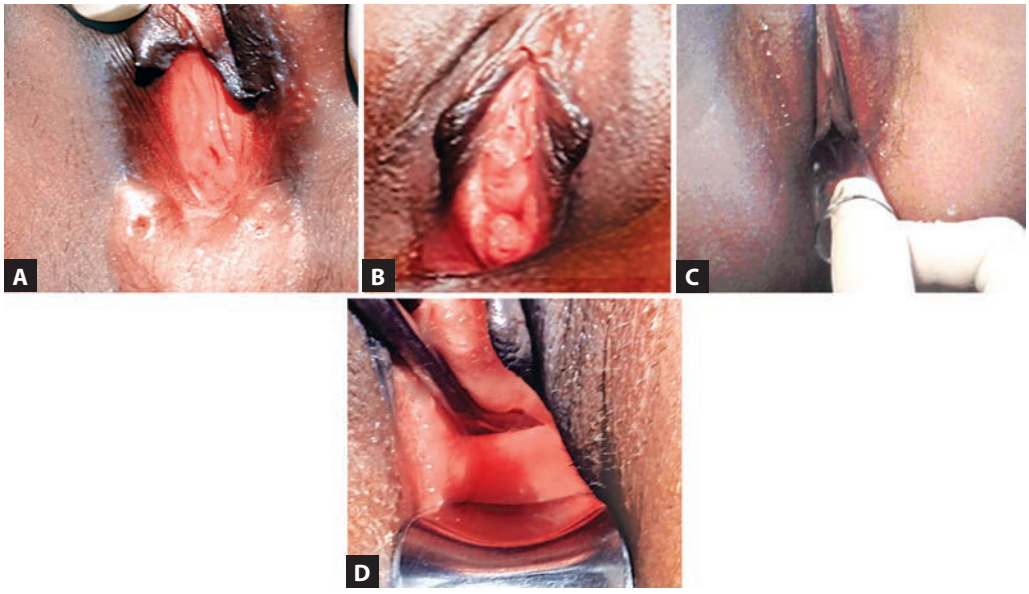

Figs. 21A to D: Pre- and postoperative pictures of dilatation and speculum examination showing near normal look of neovagina.

- The physiological parameters were pH, Doppler blood flow, and USG.
- The functional parameter was applying sexual satisfaction score.

The neovagina was comparable with the normal on all these parameters including the sexual satisfaction score. However, we found a stark difference in the three-dimensional USG studies in the neovagina (**Figs. 23A and B**).

The normal vaginal cavity is a potentially closed space due to the presence of abundant elastic tissue, while the neovagina remains an open space due to lack of elastic tissue (**Figs. 24A and B**). It was observed that the neovagina remains open in the upper half while it mimics normal vaginal contour in the lower half. This is achieved by the contraction of pelvic floor muscles (**Figs. 25A and B**). This fact has led us to routinely teach pelvic floor muscles exercises to all our patients undergoing the vaginoplasty.

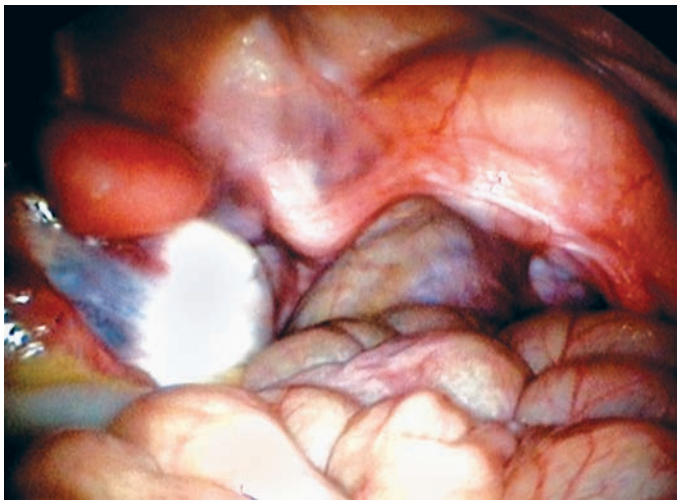

Fig. 22: Second look laparoscopic picture 1 year postsurgery, showing virgin pelvis with no telltale signs of surgery.

These observations and the lacunas due to lack of the elastic tissue prompted for the further research.

The problem was addressed by three different ways:

1. With the idea that a thick peritoneal graft could probably give a good substratum, six cases were subjected to this modified procedure. However, it was noticed that the end results are the same. The disadvantage was increased operating time and comparatively increased blood loss.
2. After using the pelvic floor exercises, a significant difference was noticed in the anatomical contour of the neovagina.
3. Efforts are on developing auto stem cell culture. These mesothelial stem cells will be used for the development of elastic tissue in the neovagina.

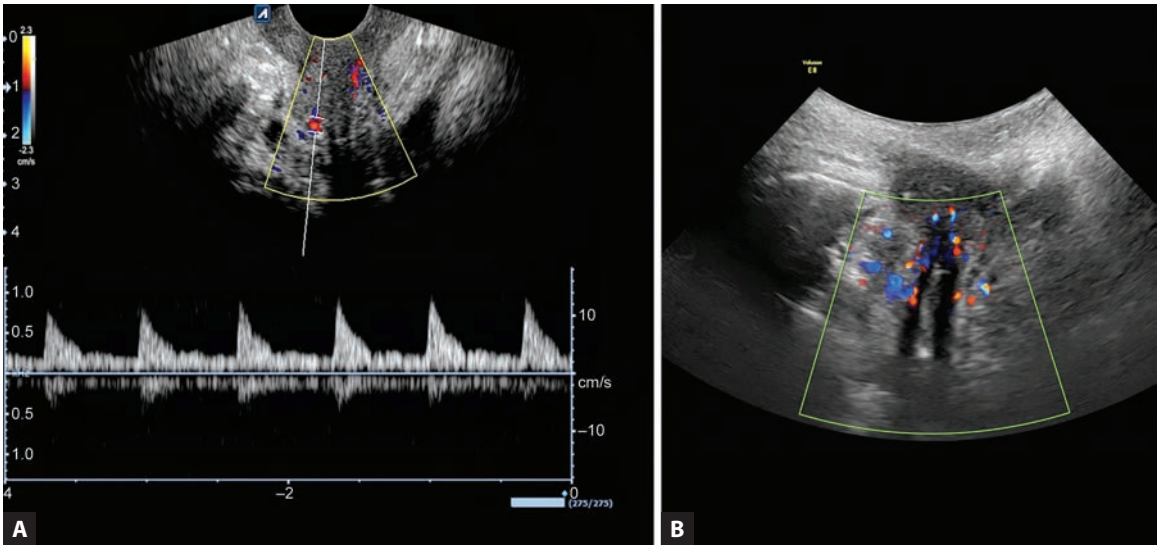
Finally, we have undertaken a pilot study to identify the genes responsible for the Müllerian hypoplasia to offer a genetic solution to this devastating problem.

ROLE OF STEMNESS MARKERS AND TRANSLATIONAL GENES IN CREATING NEOVAGINA

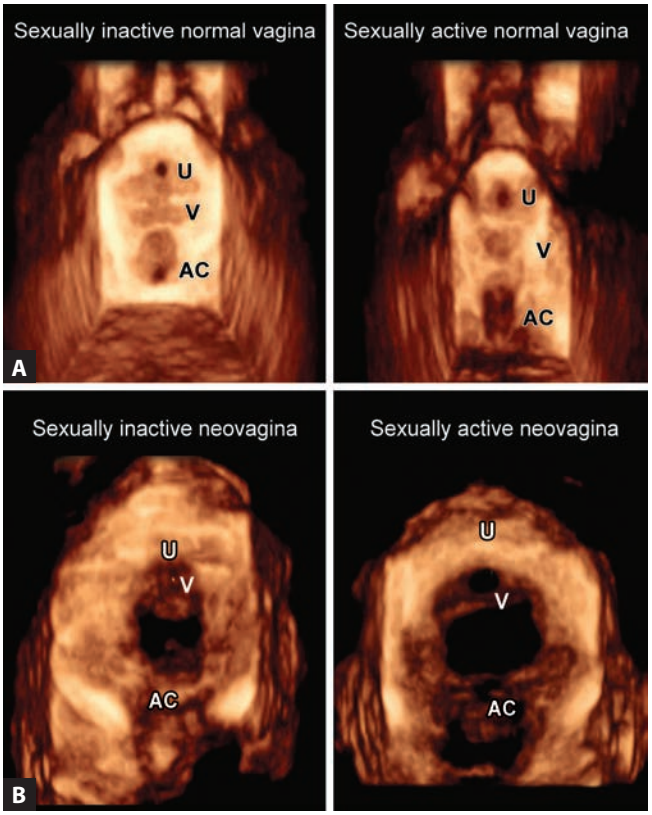
Peter Muller described the Müllerian duct in 1730, almost 300 years ago; however, the genetic information regarding its normal and anomalous development is still ill understood.

Regression of Müllerian duct is an important event in sex differentiation and main genes in formation of reproductive tract in mice are as follows:

- *Pax 2:* Null mice show lack of kidneys, ureters and genital tract.
- *Emx2:* Null mice show lack of kidneys, ureters, gonads and genital tract.
- *Lim1:* Female null mice lack Müllerian duct.



Figs. 23A and B: Functional evaluation of neovagina: (A) 3D USG; (B) Doppler angiogenesis.

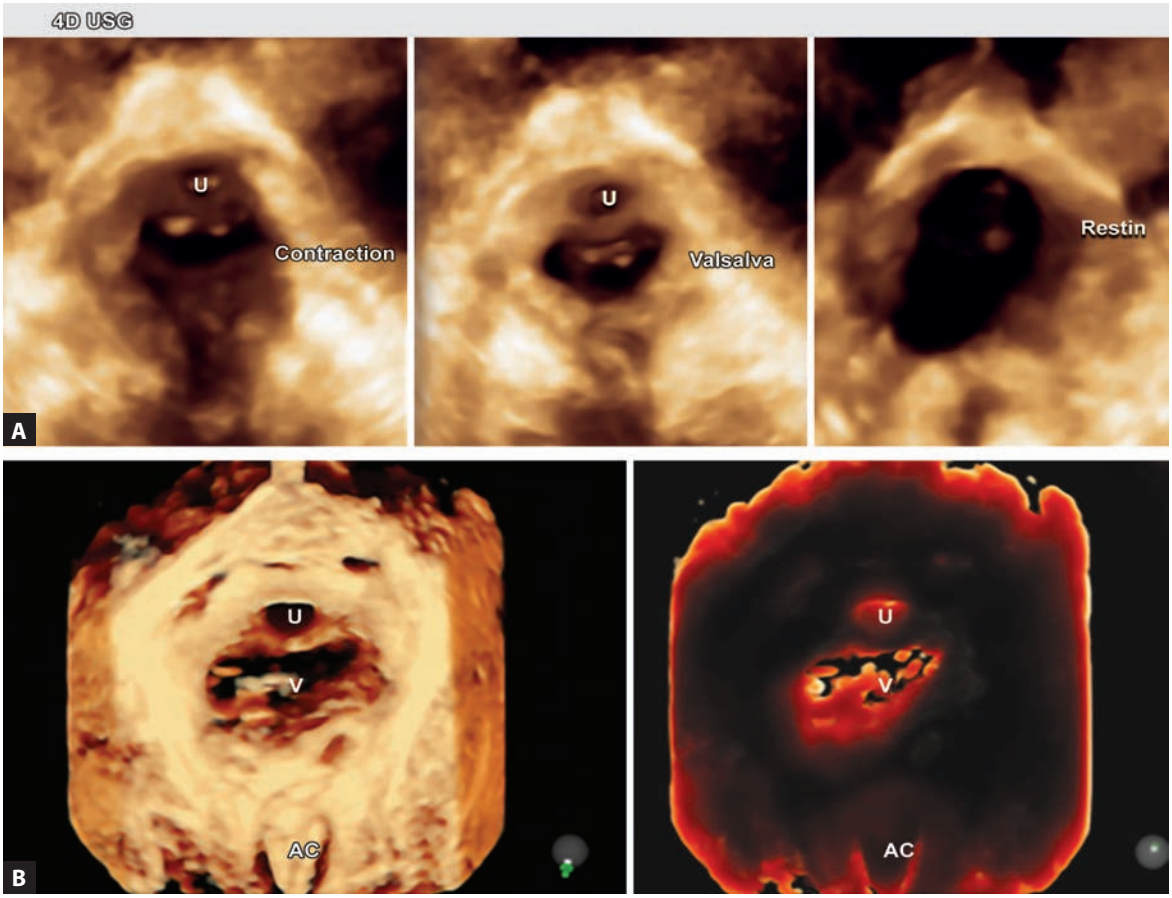


Figs. 24A and B: Comparison of normal vagina and neovagina.

- *WNT4:* It is essential for development of Müllerian duct. Both male and female null mice lack Müllerian duct. It is expressed in the mesonephros at E day 10 and also seen in mesenchyme of indifferent gonads at E day 11 and stays in female gonads and surrounding mesenchyme of Müllerian duct.
- *WNT7A:* This also plays an important role and is expressed in Müllerian epithelium at E day 12.5 and continues through life.
- *WNT5A:* This is expressed in high amount in uterus and has helps the differentiation process of reproductive tract in first 2 weeks of postnatal life.
- *HOXA 10 and 11:* Associated with correct anterior and posterior patterning of reproductive tract.
- Summarizing, *WNT4* initiates the ductal formation and morphogenesis of ductal derivatives, which are regulated by *WNT7*.

Previously, it was assumed that MRKH syndrome has sporadic genetic etiology, but familial cases have been reported in the literature suggesting autosomal dominant inheritance.

The genes involved in the development of the Müllerian tract include Lim homeobox 1 (*Lim1*), wingless-type MMTV integration site family, member 4 (*WNT4*),[3] Paired box 2



Figs. 25A and B: Contraction of pelvic floor muscles.

(*Pax2*), Empty spiracles homeobox 2 (*Emx2*), POU domain-containing transcription factor 2 (*Tcf2*), large homolog 1 (*Dlgh1*), dachshund homolog 1 and 2 (*Dach1 and Dach2*), *Hoxa13, Wnt5a, Wnt7a*, Catenin (cadherin-associated protein), beta 1 (*Ctnnb1*) and forkhead box A2 (*Foxa2*).

Three types of MRKH syndrome have been described in the literature. The first being pure MRKH syndrome, the second being associated with renal, somatic, and cardiac anomalies and the third type is in association with hyperandrogenism. No mutations in AMH or activating mutation of its associated receptor, *WT1, PBX1, PAX2, Hoxa10, Hoxa11*, a cofactor of HOX genes, have been linked to MRKH syndrome.

The third type of MRKH syndrome, which is associated with hyper-androgenism and renal malformations, is implicated to have WNT4 mutation. WNT4 mutation confirms that this signaling molecule is involved in Müllerian development and androgen repression in the ovary, WNT4, HNF1B, and LHX1 have been studied in genetic analysis of MRKH syndrome. A study using whole genome expression was done to identify the etiology of MRKH syndrome and it suggested that increased expression of estrogen receptors 1 (ESR1), Wilms Tumor 1 (WT1), and GATA-binding protein 4 (GATA4) might lead to abnormal development of the female reproductive tract. Ectopic expression of certain *HOXA* genes may also be implicated. There were three microdeletions at 16p11.2, 17q12, and 22q11.2 that were found in syndromic Müllerian aplasia case population was compared to the control population. Ledig et al. found recurrent deletions affecting TBX6, HNF1β, and LHX1 in their cohort of MRKH patients. Duplication in the *SHOX* gene has recently been identified in two daughters with MRKH type I; miRNAs may have an important role in the development and function of the female reproductive tract.

The literature remains inconclusive on genetic etiology of MRKH syndrome. Having identified the progenitor cell an attempt is made to identify the specific translational stemness markers and the activation of specific genomes in the neovagina. In the previous study presence of stemness markers was shown by staining technique using IHC. This was not specific with the DNA material hence RNA latter was prepared from the neovaginal tissue and specific cDNA was obtained. The serial expression and concentration of translational stemness markers (NANOG, OCT4, and SOX2) were identified by using the conventional PCR. The activation of various genes (*HOXA9, HOXA10A, HOXA11, HOX13, WNT4, WNT5A,* and *WNT7A*) and their concentration was identified in neovaginal tissue.

Our current research has shown the following findings:

- The study shows peritoneal metaplastic conversion to normal vagina by laparoscopic peritoneal vaginoplasty. The translational stemness markers (NANOG, OCT4, and SOX2) and expression of the specific genes (*WNT4, WNT5A*, and *WNT7A*) responsible for the neovaginal formation were identified.
- The translational stemness markers (NANOG, OCT4, and SOX2) appearance and concentration at different stages of conversion were demonstrated. The neovagina has shown upregulation of these translational stemness markers. The expression of developmental genes namely *HOXA9, HOXA10A, HOXA11, HOX13* were found to be lesser than the control samples as expected. The expressions of WNT4, WNT5A, and WNT7A were found to be increased compared to the control.
- The study confirms the normal vaginal development by peritoneal metaplasia. This technique should replace current treatment of absent vagina.
- *Research implications:* Furthering this research, manipulating and activating these genes by genetic engineering may lead to treatment of developmental defects of Müllerian duct and developing the rudimentary uterus to normal size, obviating the need of transplant. To the best of our knowledge, this study is the first to show the metaplastic conversion peritoneum to normal vagina, identifying the progenitor cell, expression of translational stemness markers and upregulation of specific genes **(Fig. 26)**.

CHAPTER 83

Genitoplasty

Prashant Puranik

INTRODUCTION

Genitoplasty refers to reparative surgery of genital organs (genito refers to genitals and plasty refers to molding or formation of specified part of body). Female genitoplasty can involve vulva, clitoris, labia, vagina, or a combination of above structures. It can be broadly classified into reconstructive and aesthetic.

Aim of surgical procedures in reconstructive genitoplasty is to reconstruct genital structures in anomalies occurring due to congenital or acquired (traumatic or oncological or dermatological disease) deformities. One of the common congenital genital anomalies encountered in gynecological services is vaginal agenesis.

Recent advances in artificial reproduction techniques have led to noninvasive methods of harvesting of ovum or insemination by vaginal approach. Patients with developmental anomalies or congenital absence of vagina can pose a technical difficulty for the same. This chapter focuses on congenital absence of vagina and its management.

EMBRYONAL BASIS

Vaginal agenesis occurs due to Müllerian dysgenesis, the most common form of it is Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome. In MRKH syndrome, intermediate mesoderm is affected. Intermediate mesoderm provides blastema of cervicothoracic somites and pronephric ducts. Intermediate mesoderm anomalies can lead to coexistence of skeletal and urinary system anomalies. Pronephric ducts differentiate to mesonephric ducts. Mesonephric ducts differentiate to Wolffian ducts and Müllerian ducts. Müllerian duct affection in MRKH leads to incomplete differentiation. This is supported by the presence of Müllerian structures.[1] Cervix and vagina initially form a solid unit embryologically, vaginal agenesis occurs due to lack of cavitation, and cell death needed to form vagina.[2]

ETIOLOGY OF VAGINAL AGENESIS AND CLINICAL PRESENTATION

Mayer–Rokitansky–Küster–Hauser Syndrome

Mayer–Rokitansky–Küster–Hauser syndrome is the most common cause of vaginal agenesis. It is the second most common cause of primary amenorrhea. The most common being gonadal dysgenesis. Other names for MRKH syndrome are Müllerian aplasia, genital renal ear syndrome, or congenital absence of the uterus and vagina. The incidence ranges from 1 in 4,000 to 10,000.[3]

Genetics

Normal female morphology and endocrine status have increased the interest for study of genetic anomalies of MRKH. A wide range of malformations in closely associated organ systems suggest developmental field defect.[4] *WT1*, *PAX2*, *HOXA* cluster genes, and *PBX1* genes are involved in related organogenesis during early embryogenesis.[5,6] Deletion or duplication sequences point to the involvement of *LIM* homeobox 1 (*LHX1*), *HNF1* homeobox B (*HNF1B*), and *T-Box 6* (TBX6). *LHFX1* and *HNF1B* are located on 17q12 chromosome. Haploinsufficiency of *HNF1B* leads to *LHX1* downregulation leading to uterine hypoplasia.[7-9]

WISP2, *HOXA5*, *HOXA9*, *CDH5*, *MFAP5*, and *PEG10* genes are involved in development of female genital tract. Epigenetic abnormalities of *WISP2*, *HOXA5*, *HOXA9*, *GATA4*, and *WT1* have a key role in MRKH syndrome. These epigenetic changes could be due to environmental and stochastic factors. Epigenetic abnormality is further substantiated by development of MRKH syndrome in only one of the monozygotic twins. Chromosomal translocations are a rare cause of MRKH syndrome. Single-gene mutations and epigenetic changes are postulated to be the cause but definitive etiology is still not determined. Hence, prenatal diagnosis and genetic counseling are not useful.

Anti-Müllerian hormone (AMH) plays an important role in pathogenesis by disrupting the formation of Müllerian structures. Activating mutation of AMH gene or its receptor

leads to MRKH syndrome. Estrogen regulates the level of AMH expression. Increased levels of estrogen lead to activation of AMH promoters. *WT1* and *GATA4* genes are involved in regulation of AMH. Endocrine-disrupting agents or high maternal hormonal levels lead to ectopic expression of *HOXA* genes leading to MRKH syndrome.[10-13]

Renal anomalies and skeletal anomalies occur in mothers and relatives of MRKH patients.[14,15] Hence, vaginal agenesis can be a manifestation of a variably expressing genetic abnormality. Incomplete penetrance and variable expression of an autosomal dominant gene or small chromosomal imbalances which are undetectable in standard karyotypes are suggested modes of inheritance. The majority of cases are sporadic,[16] but familial cases are also described.[17]

Mayer–Rokitansky–Küster–Hauser based on the extent of anomaly is categorized into two types. Type I/typical or Rokitansky sequence has only isolated uterovaginal agenesis. Type II/atypical has additionally, other systemic anomalies. Type II is known as *MURCS* association. It is an abbreviation for *MU*llerian duct aplasia, *R*enal dysplasia and *C*ervical *S*omite anomalies. Types 1 and 2 account for 44 and 56%, respectively.

- Urinary system anomalies occur in 40% cases.
  They can be unilateral renal agenesis, ectopic or horseshoe kidneys and pelviureteric junction obstruction.
- Skeletal anomalies occur in 30–40% cases. Vertebral anomalies are the most common.
  They can be Klippel–Feil anomaly, fused vertebrae, cervical scoliosis, or rib abnormalities.
- Auditory defects occur in 10–25% cases.
- Other rare associations are cardiac anomalies and hand anomalies such as syndactyly (fused fingers) and polydactyly (multiple fingers).

Clinical Presentation

The most common presenting symptoms are amenorrhea, inability to intercourse, and dyspareunia. Typically, medical evaluation is sought for the absence of menstruation at the age of 14–16 years. The classical presentation is primary amenorrhea in a normal female phenotype. Secondary sexual characteristics are normal except for absence of menarche. The MRKH syndrome is associated with developmental absence of the uterus and upper two thirds of vagina leading to amenorrhea. 8–10% have functioning uterus with variable development of cervix. This results in concealed menstruation and hematometra. This can present as a large, painful abdominal mass.

Clinical examination reveals well-developed secondary sexual characteristics (pubic hair and breast development are Tanner stage 5) and external genitalia **(Figs. 1A and B)** with primary amenorrhea. The vagina is reduced to a dimple (2–7 cm). There are no signs of hyperandrogenism. Inspection of genitalia at the time of birth can diagnose the condition.[3]

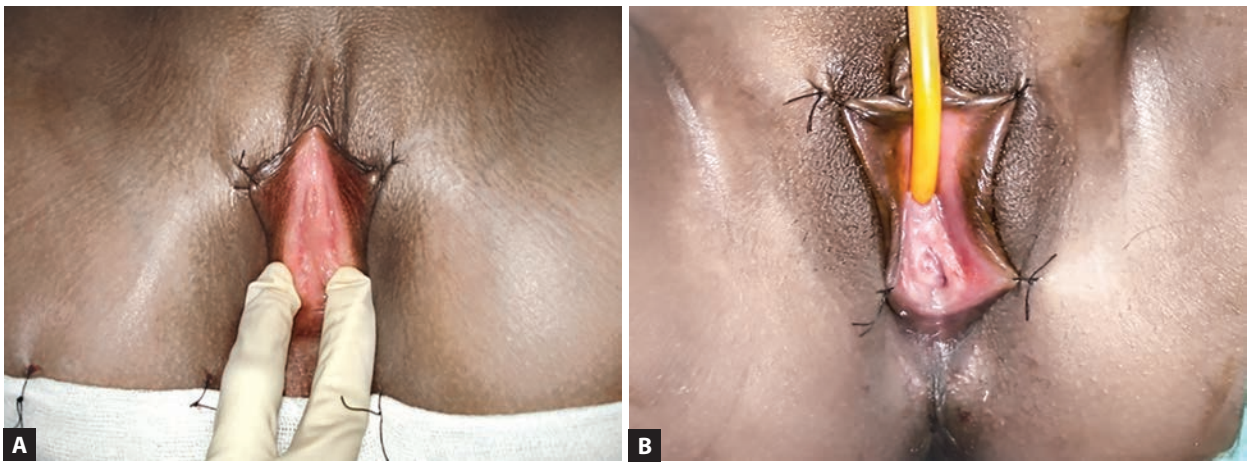
DIFFERENTIAL DIAGNOSIS

Differential diagnosis of MRKH syndrome includes patients presenting with primary amenorrhea and normal secondary sexual characteristics. The differential diagnoses are isolated vaginal atresia, WNT4 syndrome, and androgen insensitivity **(Table 1)**.

Transverse vaginal septum and imperforate hymen are not included. Patients with these latter conditions have normal cervix and uterus, both of which are palpable on rectal examination.[3]

Complete Androgen Insensitivity Syndrome/ Testicular Feminization Syndrome

It is the second most common cause of vaginal agenesis. It is a male pseudohermaphrodite disorder. Incidence is 1/13,000 to 40,000 live births. Androgen insensitivity syndrome is an X-linked recessive disorder with a female phenotype and 46XY karyotype. Mutation in the androgen receptor gene renders receptors insensitive to testosterone and results in female phenotype.



Figs. 1A and B: Vaginal agenesis with normal external genitalia—vaginal dimple in normal position.

TABLE 1: Differential diagnosis of Mayer–Rokitansky–Küster–Hauser syndrome.

	MRKH syndrome	*Isolated vaginal atresia*	*WNT4 syndrome*	*Complete androgen insensitivity syndrome*
Upper vagina	Absent	Variable	Absent	Absent
Uterus	Absent	Present	Absent	Absent
Gonads	Ovary	Ovary	Masculinized testis	Testis
Breast development	Normal	Normal	Normal	Normal
Pubic hair development	Normal	Normal	Normal	Sparse
Hyperandrogenism features	No	No	Yes	No
Karyotype	46XX	46XX	46XX	46XY

Clinical manifestations are normal female breast and external genitalia development with a blind vagina. Müllerian duct structures are absent with abdominal or inguinal testes. Partial androgen insensitivity presents as micropenis with or without hypospadias with gynecomastia.[18]

Isolated Vaginal Atresia

Clinical presentation is pelvic pain with cryptomenorrhea on physical examination. Vaginal atresia can be syndromic as in Winter syndrome (renal, genital, and middle ear defects)[19] or McKusick–Kaufman syndrome (hydrometrocolpos, digital anomalies such as postaxial polydactyly and cardiac malformation). In McKusick–Kaufman syndrome, pathology lies in *MKKS* gene mutations on chromosome 20p12.[20] Vaginal atresia is also a component of Bardet–Biedl syndrome and Fraser syndrome.

Müllerian aplasia of MRKH syndrome leads to irreversible sterility. Surgical correction of isolated vaginal atresia with a normal uterus can lead to pregnancy.

WNT4 Syndrome

This is characterized by XX karyotype with absence of Müllerian structures, hyperandrogenism, and renal dysplasia. Normal female phenotypes with features of hyperandrogenism are pointers to WNT4 syndrome.[21]

DIAGNOSTIC METHODS

Universal principles in the management of congenital malformations should be followed. Congenital malformations can have associated disorders of other organ systems, which also need to be investigated. Complete investigation (genetic and endocrine) with accurate diagnosis is crucial. MRKH is a diagnosis of exclusion and merits thorough evaluation.

Workup would include karyotype, hormonal study, and ultrasound of the abdomen. A pelvic magnetic resonance imaging (MRI) is needed in difficult cases.

Biological Status

The karyotype in MRKH syndrome is 46XX without major genetic abnormality. The karyotype in androgen insensitivity syndrome is 46XY.

Hormonal Studies

These are the indicators of ovarian function. In MRKH syndrome, hormonal studies (follicle-stimulating hormone, luteinizing hormone, and 17-β estradiol) are normal. Androgen levels (plasma level of testosterone, delta-4-androstenedione, 17-hydroxyprogesterone, and dehydroepiandrosterone) are also normal.[22]

Transabdominal Ultrasonography

Transabdominal ultrasonography is the first investigation to evaluate Müllerian structures. Transvaginal, transperineal, or even transrectal ultrasonography can also be performed. It is a simple, noninvasive test. It is characterized by the absence of the Müllerian structures between the bladder anteriorly and rectum posteriorly.

Mayer–Rokitansky–Küster–Hauser type I syndrome has normal fallopian tubes with rudimentary horns. Rudimentary horns are linked with peritoneal fold.[23] MRKH type 2 is characterized by symmetric or asymmetric uterine hypoplasia, accompanied by hypoplasia or aplasia of one or both the fallopian tubes with aplasia of one of the two horns or by a size difference between the two horn rudiments.[24] A quadrangular retrovesical structure, noncavitated vestigial lamina can give a pseudo appearance of hypoplastic or juvenile uterus.[25] Urinary system malformations can be evaluated systemically.

Magnetic Resonance Imaging

Magnetic resonance imaging is a noninvasive technique with higher sensitivity and specificity than ultrasonography. It is the gold standard for evaluation of Müllerian agenesis. It is indicated in an inconclusive ultrasonographic study. It provides an accurate evaluation of Müllerian structures and other pelvic organs. Nonvisualization of ovaries, uterus, or Müllerian rudiments in ultrasound is not confirmatory of their absence. MRI provides an accurate evaluation of uterine aplasia with clear visualization of the rudimentary horns and ovaries. Uterine aplasia is best visualized on sagittal views and vaginal aplasia on transverse section images.[26-28] MRI can simultaneously evaluate for renal and skeletal anomalies.

Laparoscopy

This is an invasive technique requiring anesthesia. It is indicated in cases of diagnostic uncertainty after ultrasonography and/or MRI. Laparoscopy is preferred in cases needing additional interventions. It defines the precise anatomical location and abnormalities of the uterus, tubal remnants, the vestigial lamina, and the ovaries. It can also be used as a therapeutic modality to drain hematometra, excise symptomatic remnants of the Müllerian system, or achieve uterine–vaginal anastomosis with a well-developed uterus.

A systemic evaluation must be done to identify associated malformations. Asymptomatic nature of renal and skeletal abnormalities necessitates at least a screening transabdominal ultrasonography and spine radiography. Intravenous pyelogram may be needed to diagnose urinary system anomalies. Suspected hearing impairment or cardiac anomaly necessitates screening with an audiogram or echography and specialist consultation. In familial cases, investigation of the patient's relatives may be recommended for renal and skeletal malformations.[3]

PSYCHOLOGICAL ASPECTS OF MÜLLERIAN APLASIA

Evaluation of the psychological status of MRKH patients is important. Müllerian agenesis deprives the woman, both coitus and childbearing, thus doubting her femininity. Vaginal agenesis can have significant consequences on self-image and sexual identity, as well as serious social problems considering engagement and marriage. This leads to negative impact on her psychological, sexual, and social well-being. Psychological harm sustained during early adolescent years can lead to difficulty in sustaining relationships. They are also at risk of long-term sexual dysfunction and face difficulties to integrate with society.

Psychological difficulties of adolescence are more complex, making assessment difficult in comparison with children or adults. Intellectual development in adolescence varies widely. There is a complete discrepancy between physical maturity and intellectual maturity. Physical maturity can be attained by the age of 15 or 16 years, but intellectual maturity cannot be reached until the age of 18–20 years. This discordance poses problems in evaluation. This necessitates specially trained psychological counselors.[29]

Physician's lack of appreciation of the difficulties and inability to communicate affect patients negatively.[30] Degree of emotional reactions to the diagnosis and treatment is influenced by age and relationship with her parents and partner. Doubts about gender, inability to fulfill female roles, lead to depression. Infertility is more difficult to accept than coital inability. Prolonged counseling with positive reinforcement is vital and input from psychological services improves the outcome.[31] Group programs can be useful.

Psychological input into the preparation of patients is essential. It helps them to adapt to their abnormality, prepare for neovaginal creation techniques, and address the infertility component. They can achieve good sexual function after treatment and build a genetically related family utilizing in vitro fertilization (IVF) with a gestational carrier.[32-35] Creation of a neovagina helps restore self-confidence. This has been proven in quality-of-life studies.[36] As a general rule, it is useful to counsel patients that after the creation of neovagina, it is possible to have normal sexual activity and build healthy sexual relationships.[37]

Treatment of patients with vaginal aplasia requires psychological support, adequate information to the fulfillment of the complexities of female sexual response, together with the creation of a neovagina to give the patient the prospect of a normal sexual life.

MANAGEMENT

Neovaginal creation can be done by either nonsurgical or surgical techniques. Motivation of the patient and individual needs can be considered to decide the best treatment option for a patient. There is no ideal method of reconstruction, substantiated by multiple treatment options. Treatment consists of creating a neovagina. This must be offered to patients, when they are emotionally mature and preferably starting sexual activity **(Table 2)**.

An ideal neovagina must be satisfying in appearance, function, and sensation. Reconstruction should recreate neovagina in a normal position with normal dimensions directed posterior-superiorly. It should be sensate, at least at introitus level. The technique should be simple, reliable, one staged with minimal morbidity **(Fig. 2)**.[38]

TABLE 2: Procedures to create neovagina.

Nonsurgical creation of neovagina	• Frank method • Ingram method
Surgical creation—traction method	Vecchietti operation: • Laparotomy • Laparoscopic
Surgically created neovaginal lined with or without grafts	• Split-thickness skin graft • Full-thickness skin graft • Amnion • Peritoneum • Buccal mucosa • Absorbable adhesion barriers • Tissue expansion
Neovagina lined with flaps	• Pudendal flap • Gracilis myocutaneous flap • Rectus abdominis flap • Scapular free flap
Vulvovaginoplasty	William's operation
Bowel vaginoplasty	• Sigmoid colon • Ileum • Cecum

Source: Lee MH. Non-surgical treatment of vaginal agenesis using a simplified version of Ingram's method. Yonsei Med J. 2006;47(6):892-5.

NONSURGICAL CREATION OF A NEOVAGINA

Nonsurgical approach is recommended as a first-line therapy. It is noninvasive and complications are rare. These methods can be applied in incomplete vaginal agenesis, when the vaginal dimple is deep (2–4 cm).

Frank Dilator Method

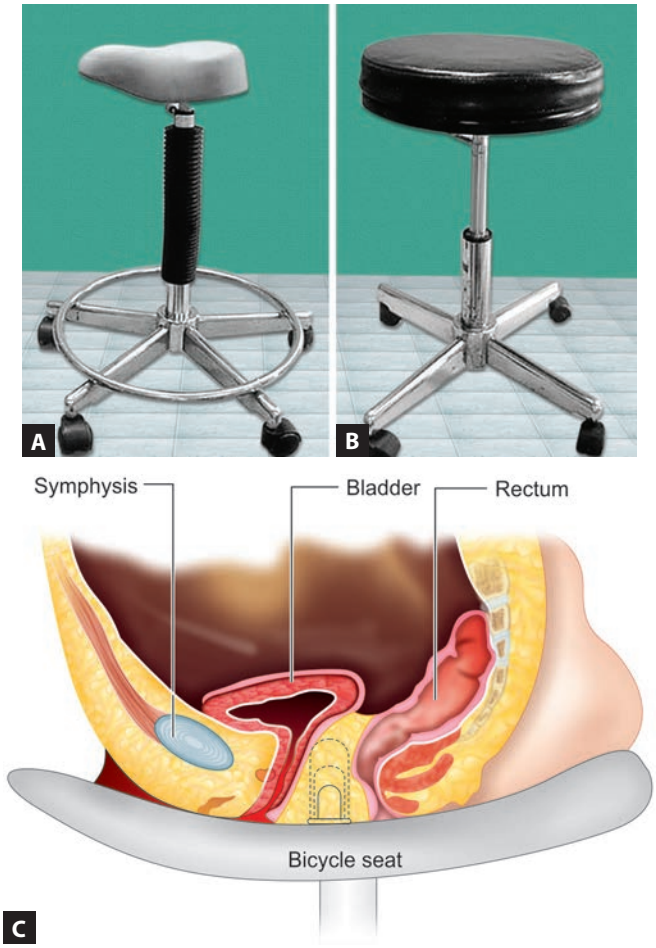
This is the most commonly used nonsurgical method. It is a form of tissue expansion. The technique involves dilatation of the vaginal dimple with progressively increasing dimensions of vaginal dilators or mold with active participation of the patient **(Figs. 3A to C)**. Dilators are placed on the vaginal dimple for at least 20 minutes a day. 6 months is a typical time to attain functional depth and width of neovagina. Regular follow-ups are recommended to evaluate patient motivation and skills in using the dilator.

The dilators come in a number of formats, made of different materials. Well-motivated, well-supported patients achieve good results. In a compliant and well-motivated patient, satisfactory length of the vagina for intercourse can be achieved in 75–85% of cases.[39]

Ingram Method

This variation of Frank's method uses a bicycle stool.[40] Ingram introduced a bicycle seat stool, where the patient could sit and use her trunk weight to hold in place the vaginal dilators and create pressure over the vaginal dimple **(Figs. 3A to C)**. The whole process requires 6 weeks to several months using dilators of increasing size, with a success rate varying from 78% to 92%.[41,42]

The advantages of nonsurgical treatment are outpatient treatment, patient control, cost-effectiveness, minimal morbidity, and complications. If the patient is not able to complete treatment or achieve adequate dimensions, surgical intervention is an option. Patient's familiarity



Figs. 3A to C: Bicycle seat stool or ordinary stool can be used to hold acrylic dilators.
Source: https://www.qrcodematrix.com/ingram-bicycle-seat-stool.

with vaginal mold can also help in postoperative period. Disadvantages include the length of time required to achieve a functional vagina, discomfort, risk of urethritis, cystitis, fistula, and vaginal prolapse.

Common difficulties experienced by patients are cramping, pain, fatigue, lack of comfort, unpleasantness, privacy issues, and lack of time to dilate daily. These lead to poor compliance with higher failure rates, unless patients are persistent and well motivated.[39,43]

SURGICAL CREATION OF A NEOVAGINA

Vaginal reconstruction for vaginal agenesis is a challenging procedure. Failed nonsurgical methods or refusal of nonsurgical treatment is an indication for surgical treatment. Surgery should be done on a mature and motivated patient, ideally starting active sexual life. There is no consensus on the best modality of surgical creation of neovagina. The approach is often based on the surgeon's experience.

Preoperative bowel preparation should be done. Surgical creation of neovagina can be performed in spinal or general anesthesia. Surgery has two components. First is creation of

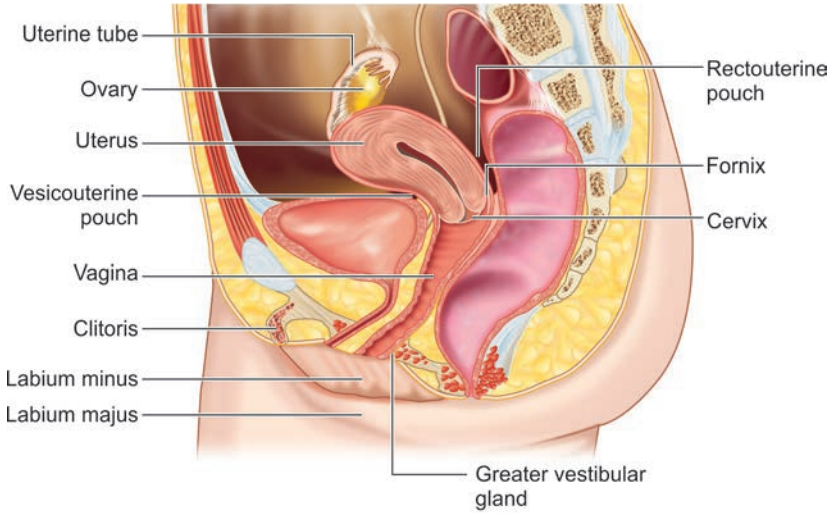


Fig. 4: Anatomical relations of vagina.

neovaginal space between urethra and bladder anteriorly and rectum posteriorly **(Fig. 4)**.

The normal vagina is a fibromuscular tube lined with stratified nonkeratinized squamous epithelium. It is inclined posterosuperiorly measuring 7.5 cm along the anterior wall and 9 cm along the posterior wall. There are no secretory glands in the mucous membrane and it is lubricated by mucus derived from cervical glands.

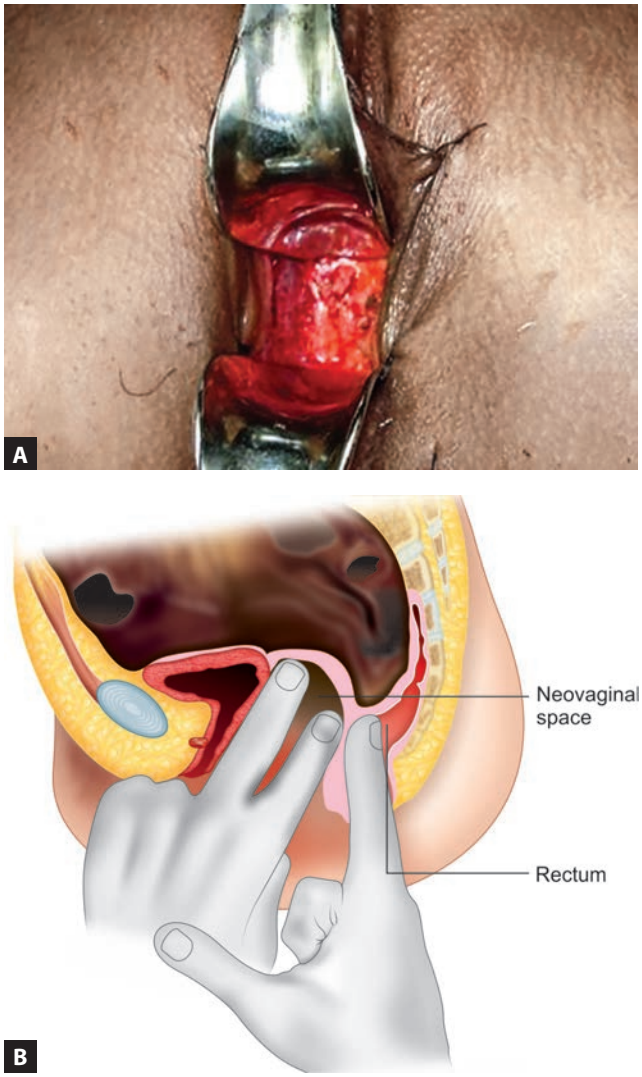
The second component is the lining of this neovaginal cavity with skin or mucous membrane, to maintain neovaginal dimensions and prevent contracture. Surgical creation of the neovaginal cavity is universal for all techniques. The source of the vaginal lining can be diverse. The lining can be a nonvascularized graft or vascularized flap.

Creation of Neovaginal Cavity

Transverse or Y incision is made at the apex of the vaginal dimple and blunt dissection is done between the urethra and bladder anteriorly and the rectum posteriorly. Dissection is done in cephalon-posterior direction. Neovaginal cavity must reach the peritoneum to prevent excessive contracture postoperatively. Depth of dissection should be in the range of 10–14 cm. The risk of injury to the rectum, urethra, or bladder and fistula formation ranges between 0% and 7.6%. Urinary catheter anteriorly and assistant's gloved finger in the rectum posteriorly help to prevent injury to the bladder and rectum. Trendelenburg position during neovaginal cavity creation displaces the bowel from the pelvis and helps prevent bowel injury **(Figs. 5A and B)**.[44]

Abbe–McIndoe Procedure

Abbe–McIndoe operation is an easy and commonly used technique. Neovaginal space is lined with a partial-thickness skin graft. Skin graft is spread over a stent, placing dermal side outward for lining the cavity **(Figs. 6A to D)**.



Figs. 5A and B: Neovaginal cavity creation between urethra, bladder, and rectum.

Two to three sheets of skin graft are needed to achieve the required dimensions. The skin grafts can be harvested from the gluteal region or thigh. Postoperative vaginal dilatation is pivotal for good outcomes **(Figs. 6A to D)**.

Graft take can be unpredictable and mold has to be used continuously for 3 months, at least during nighttimes. Vaginal stents or conformers or molds are used for up to 3–6 months. 3–4 months after surgery, once the skin graft matures, intercourse should be encouraged. If the patient has intercourse two to three times per week, conformer elimination can be considered, else night stenting should be continued. Intercourse acts as an effective obturator.

Historically candle wax, carved balsa wood, gauze packing, syringe casing, dental wax, and hard plastic conformers have been used as vaginal stents. Mold consistency can be soft, semirigid, or rigid. Soft molds have a lower incidence of fistula formation due to reduced pressure and lesser risk of avascular necrosis. An alternative is the use of the inflatable soft stent with reduced risk of hematoma and fistula formation without affecting healing.

All other methods of reconstruction are compared with the traditional Abbe–McIndoe procedure. Skin graft donor-site morbidity, graft contracture, and dryness are the disadvantages of Abbe–McIndoe procedure. Shrinkage of neovagina, especially in the upper third, can lead to partial or total vaginal obliteration. Preferably, patients should use dilated postoperatively for 6 months to 1 year, even with regular sexual activity. Lubrication is required before intercourse.

Modifications of this procedure have been devised to reduce donor morbidity. Absence of external scars (skin graft donor scars) is the main advantage of these modifications. It could be spontaneous epithelialization or the use of different materials such as peritoneum,[45] buccal mucosa, amnion,[46] labia minora grafting, or synthetic materials.[47,48] The use of freeze-dried amnion has been described by Ashworth. Donors should be screened for human immunodeficiency virus and other infectious diseases.[49]

Fasciocutaneous Flaps

Neurovascular pudendal thigh flap or Singapore flap of Wee and Joseph, modified Singapore flap of Karl Podratz and Woods and lotus petal flaps in vulvovaginal reconstruction of Niranjan have been used for vaginal reconstruction. These are inferiorly based axial pattern flaps.

Vascular supply is from posterior labial arteries. Innervation of flaps from posterior labial branch of pudendal nerve and perineal branch of posterior cutaneous nerve thigh provides sensation. Flaps are harvested from the thigh crease lateral to hair-bearing area. Flaps of dimension 9 × 4 cm to 15 × 6 cm are raised on either side. Posterior margin of flap is at the posterior fourchette. Flaps are tunneled under labia majora or after the division at the level of fourchette. Flaps are tubed for neovaginal creation **(Figs. 7A to F)**.

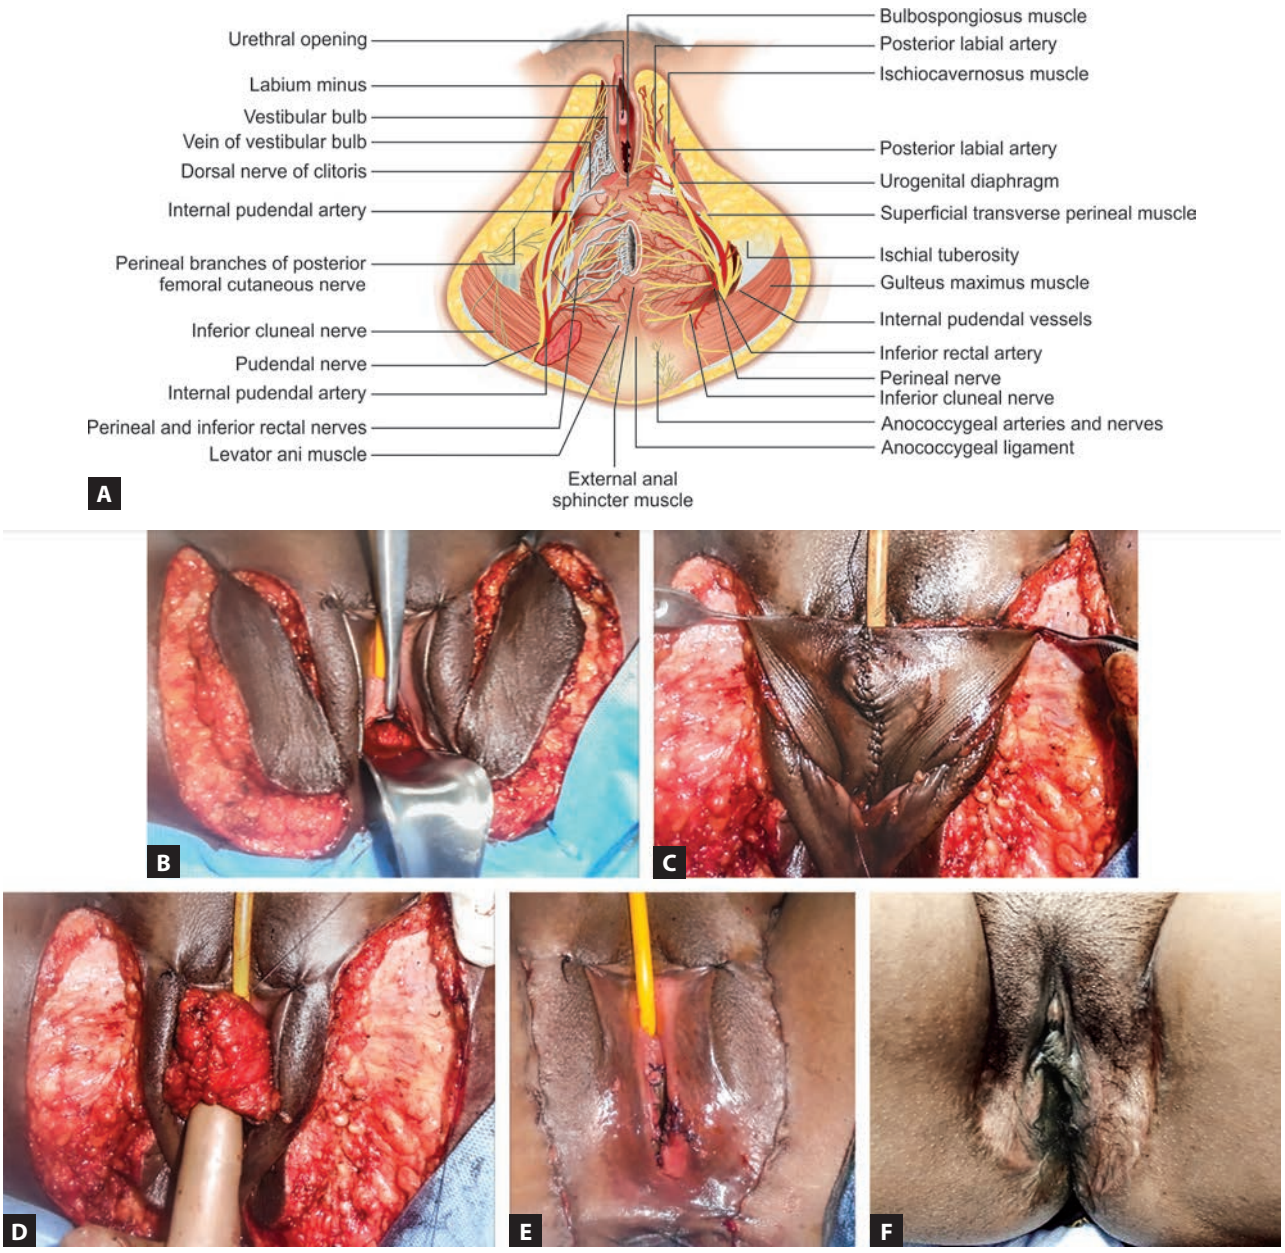
These flaps do not require long-term dilatation of neovagina through mold **(Figs. 7A to F)**.[50]

Skin flaps have the advantage of full-thickness vascularized skin, which resists shrinkage. These flaps are highly vascularized, thin, pliable, and reliable. These flaps are sensate, at least at introitus. The disadvantage of this technique is hair growth in the created vagina, which can result in dyspareunia and discharge. Laser epilation or harvesting flap from nonhearing portion can be done.

Vulvovaginoplasty Procedure

Williams vulvovaginoplasty creates vagina using the labia majora and minora. "U"-shaped flap from nonhair-bearing skin within the labia majora is used to create a new vagina. In O'Brien's vulvovaginoplasty, vulval tissue is used. This flap divides all the neurovascular input coming from the internal pudendal system.[38,51]

Labial tissue transfers distort the external appearance of the genitalia with the conspicuous scar. Abnormal angle may result in dyspareunia in the long term. Neovagina is of smaller diameter; hence, regular use of dilator is advised to increase the dimensions of the cavity.



Figs. 7A to F: (A) Neurovascular pudendal thigh flap; (B) Neural and vascular basis of pudendal thigh flap; (C) Raised bilateral pudendal thigh flap; (D) Formation of tubed neovagina; (E) Tubed neovagina; and (F) Postoperative result: 4 months postoperative result.

Vecchietti Procedure

The Vecchietti operation combines both surgical and nonsurgical techniques. This is similar to nonsurgical dilatation without relying on the patient. Neovagina is created by a traction device placed over the anterior abdominal wall, which exerts traction over the vaginal skin. It can be performed through the open technique or a less invasive laparoscopic approach.

The technique involves placing plastic olive over the vaginal dimple. Sutures anchored to plastic olive pass through rectovesical space and preperitoneally to the anterior abdominal wall skin. These sutures are attached to the traction device. Traction on the suture stretches the vaginal skin through the olive and creates vagina **(Figs. 8A to E)**.

Dilatation is done daily or on alternative days. Vaginal length of 10–12 cm is created over 7–9 days. Vaginal dilators should be used after creation of neovagina to prevent shrinkage **(Figs. 8A to E)**.[52-54]

Main disadvantage is the pain due to the traction device and prolonged hospitalization. Prolonged hospitalization is needed for managing pain. This technique is difficult to perform after failed surgeries.

Intestinal Transfers

Intestinal transfers are generally reserved for more difficult cases where simple vaginoplasties have failed with postsurgical scarring. Previously scarred area is excised and

Obgyn Key: Neovagina Formation by Expansion of the Vaginal Vault. [online] Available from https://obgynkey.com/neovagina-formation-by-expansion-of-the-vaginal-vault/ [Last accessed November, 2022].

neovaginal cavity is created; neovagina is resurfaced with a loop of bowel. Sigmoid colon is the best segment to use.[29]

Surgery involves mobilizing a segment of intestine with its feeding blood supply into the surgically created neovaginal cavity. It can be performed as pedicled transfer or free tissue transfer. In pedicled transfer, a segment of intestine with its intact blood supply is transposed into the neovaginal cavity. In free tissue transfer, blood supply needs to be re-established by anastomosing intestinal blood vessels to the perineal blood vessel.

Baldwin's ileal procedure utilizes the ileal segment of intestine. Constant caliber of the ileum with good lubrication is the advantage. Traumatization of mucosa during intercourse, with bleeding and chronic secretion of mucus, makes it a less popular procedure.

In sigmoidal vaginoplasty or Ruge procedure, neovagina is created by 12–18 cm segment of sigmoid[55] **(Figs. 9A to C)**.

Urinary system anomalies in MRKH syndrome such as single kidney or left pelvic kidney impair this procedure. Restoration of coital function may require prolonged care and support **(Figs. 9A to C)**.[56]

Intestinal transfers require laparotomy or laparoscopy. Anastomotic leaks of bowel anastomosis, adhesive bowel obstruction, and copious mucous secretion which can be foul smelling are the disadvantages. Bowel necrosis and fistula are potential complications. Hiroi et al.[57] recently reported a mucinous adenocarcinoma arising in a neovagina using the sigmoid colon.

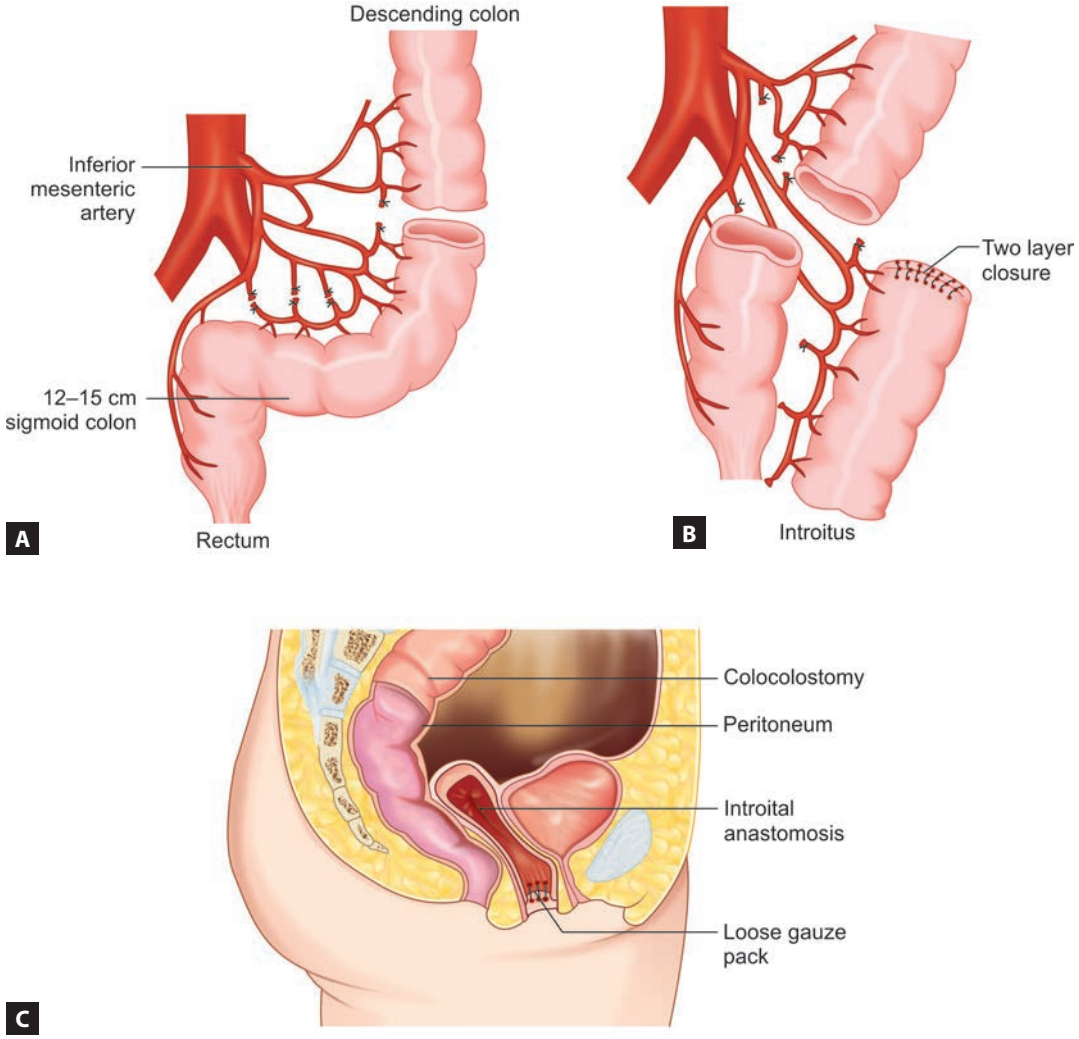
Postoperative Care

Postoperative care would involve complete immobilization for 5–7 days. Low-fiber diet and constipation are advised for 3–5 days. Local hygiene is crucial due to the proximity to anus. First dressing of skin graft is usually done at 5–7 days. Manual support of mold is advised during straining and coughing.

Potential problems are shortening of vagina, fecal contamination, postoperative immobilization, bowel, and bladder injuries.

FUNCTIONAL OUTCOMES

Partner's perception of the neovagina has found that there is a high level of satisfaction and has not been able to identify it as a newly created vagina.[58,59] Sexual satisfaction and length of neovagina are not correlated from the patient's perspective.[31] Highest subjective sexual satisfaction of 97.8% in sexually



Figs. 9A to C: Sigmoid vaginoplasty. (A) Isolation of 12–15 cm of sigmoid mucosa; (B) Sigmoid colon is placed in neovaginal position and anchored to vulvar mucosa; (C) Colocolostomy is completed and peritoneum is closed above transposed bowel. Neovagina between rectum and bladder.

active is found in flap reconstruction cases. Overall, assessing the results and treatment success of various techniques in relation to patient satisfaction is difficult.[60]

MANAGEMENT OF INFERTILITY

Most difficult aspect in MRKH is infertility. MRKH syndrome causes uterine factor infertility, due to absence of anatomical or functional uterus. However, there are rare reports of conception after neovagina reconstruction and establishing continuity with developed uterus. Adoption or utilization of gestational surrogacy is an option to attain a biological child.[61]

Ovaries, due to different embryonic origin, are normal and respond to ovarian hyperstimulation to obtain oocytes.[31-35] Ovarian hyperstimulation for harvest of ovum can be started with random start protocols, since there is no need to collaborate embryo transfer and endometrial lining, similar to oncological patients.[62]

The response to ovarian hyperstimulation is measured by number of oocytes harvested and fertilization rate. The quality of embryos in MRKH syndrome is slightly lower than average. Pregnancy rates are also below the average for infertile patients. Additionally, pelvic anatomy in MRKH patients favors oocyte retrieval via transabdominal route than the transvaginal approach.[34]

Gestational surrogacy in MRKH syndrome is an attractive alternative, even though the reported number of pregnancies after IVF is small. Children of patients born to MRKH mothers have been normal, but due to relative uncertainty of the etiology of MRKH, children born after such procedures should be evaluated. In a series of 162 IVF cycles in MRKH syndrome patients, 34 children were born. MRKH transmission risk is difficult to evaluate as the genetic basis is unclear. However, no congenital abnormalities were found in these offspring ruling out dominant fashion of inheritance.[63] Similarly, Beski et al. have reported similar outcome figures and no congenital abnormalities.[64] Goldfarb et al. in their surrogacy program also had equally encouraging results.[65] Infertility treatment options through IVF can be utilized as part of the long-term care of these patients. Clinicians can therefore consider IVF surrogacy as an option for MRKH patients, who wish to attempt pregnancy. However, counseling of patients about risk should be done till a definitive level of evidence is reached. Gestational surrogacy is currently banned in many countries. Uterine transplant is an emerging treatment for uterine factor infertility.

Uterine transplant is a complex procedure with ethical, moral, cultural, legal, and social concerns. In comparison with other transplants, it risks four parties—donor, recipient, partner of recipient, and the possible future child. Pregnancies are planned after onset and regularization of menstrual cycles following uterine transplantation. During pregnancies, regular monitoring of immunosuppressive drug levels is preferred. Evaluation for rejection, fetal growth, uterine and cord vessel blood flow, and regular cardiotocography are advised.[61]

Uterine transplant for MRKH syndrome was first performed in 2011.[66] First clinical series involving nine patients, from living donor, was performed in Sweden between 2012 and 2013. Seven of them had MRKH syndrome. Live birth after uterine transplantation was first reported in 2014, showing uterine factor infertility is now treatable.[67]

FUTURE SCOPE

Tissue engineering of skin can provide full-thickness skin grafts without donor-site scar morbidity. Modification of McIndoe procedure using autologous in vitro cultured vaginal tissue as a graft for neovaginal creation has been reported.[68] This technique can produce similar vaginal lining tissue without any donor-site scarring.

Organ engineering is advancing rapidly, though in its infancy. Significant efforts are being made to bioengineer the uterus. Organ engineering requires creation of matrix, recellularization of matrix followed by transplant into the recipient. Matrix for organ regeneration can be from synthetic matrix or decellularized donated uterus. Recellularization of the uterine matrix is done by recipients' own stem cells or somatic cells. This bioengineered uterus after transplant would theoretically function as a transplanted uterus without donor morbidity and immunosuppression, as in uterine transplantation. Several scaffolds have been promising. Major limitation is the efficiency of recellularization in vitro and in vivo.[61,69] Successful tissue-engineered uterus supporting pregnancy has been reported in rats. Studies on engineering various components of human uterus on sterile model or animal scaffold are underway.[70-74]

Molecular genetics may identify gene sequences responsible for etiology of MRKH syndrome. This knowledge may help guide treatment and development.

CONCLUSION

- Most common cause of vaginal agenesis is MRKH syndrome.
- Vaginal agenesis can be associated with skeletal and urinary anomalies.
- Evaluation and management of psychological difficulties is crucial.
- Nonsurgical management should be preferred initial treatment.
- Surgery consists of creating neovaginal cavity and lining the cavity.
- Lining can be achieved with skin or mucosal graft, flap, labial tissue or intestinal segment.
- Newer advances in artificial reproduction techniques like oocyte retrieval, gestational surrogacy, uterine transplant give hope of attaining genetic child.

CHAPTER 84

Endometrial Rejuvenation

Satish Patki, Shweta Patki, Surhud S Patki, Aditi M Kunte

INTRODUCTION

Human endometrium is one of the highly regenerative tissues of the body with its regenerative potential comparable to that of the bone marrow, hematopoietic tissue, and epidermis. It is a dynamic tissue, undergoing more than 400 menstrual cycles of regeneration following shedding during a woman's reproductive life.[1,2]

Primarily the increasing levels of the hormone estrogen is the main stimulus behind the rapid proliferation of the endometrium during a span of 8–10 days. The upper two-thirds of the endometrium is called stratum functionalis, which contains glands supported by the stroma and is supplied by the spiral arteries. The lower one-third is the basal layer and contains the lowermost branching portions of the glands and dense stroma with radial arteries at their origin. The basalis layer does not take part in the event of menstruation. However, the process of endometrial regeneration after menstruation is initiated from the basalis layer, which contains mesenchymal stem cells (MSCs) possessing a high potential of differentiation and multiplication under the influence of estrogen produced by the leading follicle.

ROLE OF ENDOMETRIUM IN THE PROCESS OF IMPLANTATION

After the procedure of "embryo transfer (ET)", the successful implantation is dependent on the quality of the endometrium and the quality of the embryo, the concept of "soil and seed". In about 65% cases of the failure of implantation, faulty endometrium is the responsible factor, while in 35% cases, the faulty embryo is the reason.

The quality of the endometrium during ET cycle is best assessed by transvaginal sonography. The parameters studied by vaginosonography are endometrial thickness, endometrial pattern, endometrial volume, and endometrial and subendometrial blood flow.[3,4]

In several studies, the minimum endometrial thickness during the ET was reported to be 7 mm.[5,6] It has been observed that if the endometrial thickness is <7 mm, a successful pregnancy is unlikely. The mechanism explaining the correlation between thin endometrium and inverse in vitro fertilization (IVF) outcome is not yet clear. It has been speculated that in patients with thin endometrium, the oxygen concentration in the basalis layer is higher, which might be detrimental for embryo implantation.[7]

It has been observed that the endometrial thickness <7 mm has a negative predictive value for IVF outcomes[8-10] and clinical pregnancy as well as live birth rates are significantly higher when the endometrial thickness is >9 mm.[11]

Endometrial patterns observed on vaginosonography are classified as:

- Pattern A: "Triple layer", characterized by a central hyperechogenic line representing the empty uterine cavity and hyperechogenic endometrium on either side.
- Pattern B: Isoechoic endometrium with poorly defined outer walls and central echogenic line.
- Pattern C: Homogeneous hyperechoic endometrium.

A triple-line endometrial pattern on the day of progesterone administration in a frozen embryo transfer (FET) cycle is associated with higher pregnancy rates versus a homogenous and hyperechogenic endometrial pattern.[12]

The color Doppler study of the endometrial and periendometrial areas also throws the light on the endometrial receptivity. These areas are divided into four zones:

1. Zone 1: A 2-mm thick area surrounding the hyperechoic outer layer of the endometrium
2. Zone 2: The hyperechoic outer layer of the endometrium
3. Zone 3: The hypoechoic inner layer of the endometrium
4. Zone 4: The endometrial cavity

Chien et al.[13] have shown that the pregnancy rates are significantly higher in the patients with multifocal vascularity in zone 3. Maugey-Laulom et al.[14] have demonstrated that absent endometrial vascularization was associated with a significantly lower pregnancy rate. It has been postulated

that a good endometrial vascularity can lead to better placentation resulting in a higher chance of live births following an ET.[15]

CAUSES AND PATHOPHYSIOLOGY OF THIN ENDOMETRIUM

Thin endometrium is caused by diminished normal endometrial growth. Certain temporary causes like administration of antiestrogenic drugs like clomiphene citrate can cause thin endometrium. In such cases, the superficial layer of functionalis of the endometrium is affected due to suppression of the endometrial components of epithelium, glands, stroma, and vasculature. Impaired epithelial cell proliferation and delayed glandular maturation are often found in endometrial biopsies from the patients treated with clomiphene.[16] The number as well as diameter of the glands are also observed to be lower in such patients.[17] Reducing the dosage of clomiphene, administration of clomiphene in the early part of the menstrual cycle, and addition of estrogens or gonadotropins can help such patients by improving the thickness of their endometrium. In some cases, the treatment with clomiphene citrate needs to be abandoned.

The real problem which is more serious and difficult to treat arises when there is a destruction of the basalis layer of the endometrium. Iatrogenic thin endometrium due to destruction of the basalis layer is caused by surgical procedures such as repeated curettage, polypectomy, laparoscopic and hysteroscopic myomectomies, hysteroscopic septal resection, and lateral wall metroplasty.

Acute infections such as pelvic inflammatory diseases or chronic infections such as genital tuberculosis often result in the destruction of endometrial basalis. In genital tuberculosis, fallopian tubes are affected in 95% cases, while the endometrium and the ovaries are affected in 60 and 20% cases, respectively. The disease starts in the ampullary portion of the fallopian tube. Tubercular endometritis in the initial stage is often focal and pathological changes such as ulceration and caseous necrosis occur later. In advanced stages, intrauterine adhesions result in shrunken uterine cavity. The classical findings of genital tuberculosis on hysterosalpingography are lead pipe, coiled and blocked tubes, smaller and irregular uterine cavity, and intravasation of the dye into the uterine vessels.

Asherman's syndrome, due to the surgical trauma to the endometrium of the pregnant uterus, is often a cause of thin endometrium in patients with secondary infertility. Over enthusiastic curettage during evacuation of the pregnant uterus or repeated events of medical termination of pregnancy by suction and evacuation often leads to intrauterine adhesions. Sometimes, post cesarean section, intrauterine adhesions develop. Such patients often have scanty menses, dysmenorrhea, and sometimes secondary amenorrhea.

Thin endometrium with reduced blood flow, as seen on sonography, is often associated with a partially damaged basalis layer. The glands, radial arteries, and especially the stroma are damaged, with a low potential of regeneration in response to estrogens. Rejuvenation of the endometrium in these patients is a real challenge.

PRINCIPLES OF ENDOMETRIAL REJUVENATION

Since a thin endometrium is a multifactorial condition, its management should be cause related with the aim of increasing endometrial receptivity and ultimately facilitating the process of implantation. Angiogenesis plays a key role in the process of endometrial regeneration, which is regulated by a vascular endothelial growth factor (VEGF), expressed in the stroma of the endometrium.[18] The principle of endometrial rejuvenation is to increase the angiogenesis in the endometrium by using various drugs, cell therapies, and growth factors. The aim is to facilitate endometrial regeneration using medical treatment with or without surgical procedures such as hysteroscopic adhesiolysis, to restore anatomy.

There are various methods of endometrial rejuvenation which can be tried either individually or can be combined, depending upon the cause and severity of the thin endometrium **(Table 1)**. They can be broadly classified as:

- Use of drugs, hormones, and growth factors
- Use of cell-based therapies
- New technologies such as use of extracellular vesicles (EVs).

The endometrial rejuvenation is a challenging job for the infertility specialist and every case has to be individualized for selecting the modality of treatment.

METHODS OF ENDOMETRIAL REJUVENATION

Drugs, Hormones, and Growth Factors

Estrogen

Endometrium is a hormone-dependent tissue. Continuous administration of estrogen is the foundation of endometrial rejuvenation. Estrogen supports the endometrial proliferation by causing contraction of the spiral arteries and decreasing the oxygen tension in the functional layer.[19,20] Estradiol valerate or hemihydrate can be started with the dosage of 4 mg/day and can be stepped up to the dose of 12 mg/day till the endometrium reaches a thickness of 7 mm or above when progesterone can be added and FET can be performed on day 3 or day 5 depending on the stage of the embryo. The duration of the therapy to achieve the desired endometrial thickness can vary from 15 days to 1 month. The estrogen administration should be continued following ET though the dose can be stepped down to 6 mg/day and should

TABLE 1: Methods of endometrial rejuvenation and mechanism of action.

No.	*Method*	*Mode of administration*	*Mechanism*
1.	Estrogens	Oral	• Contraction of spiral arteries, reduction in oxygen tension in functionalis layer leading to proliferation • Priming of progesterone receptors
2.	hCG	• IM/SC injection • Intrauterine instillation	• Upregulation of endometrial VEGF and MMP-9 • Increasing angiogenesis
3.	Aspirin	Oral	Increasing endometrial blood flow
4.	GCSF	• SC injection • Intrauterine instillation	• Mobilization of stem cells from bone marrow • Tissue remodeling and angiogenesis • Autocrine and paracrine role
5.	PRP	• Intrauterine instillation • Subendometrial injection through hysteroscopy • Subendometrial injection using vaginosonography	Secretion of VEGF, EGF, IGF-1, and tissue healing promoting molecules such as fibrinectin and vitronectin
6.	Autologous stem cell from bone marrow/adipose tissue/endometrium	• Intrauterine perfusion • Subendometrial injection through hysteroscopy • Subendometrial injection using vaginosonography • Intra-arterial (uterine circulation) • Tissue engineering	• Angiogenesis • Secretion of growth factors • Tissue regeneration
7.	Extracellular vesicles (EVS) from endometrial stem cells	Subendometrial injection	• Serve as biological cargos of proteins, Lipids, RNAs, and DNAs • Regenerative
8.	Extracellular vesicles (EVs) released from cultured blastocysts	During embryo transfer procedure	• Cell to cell cross talk between blastocysts and endometrium • Endometrial microrejuvenation

(DNA: deoxyribonucleic acid; EGF: epidermal growth factor; GCSF: granulocyte colony-stimulating factor; hCG: human chorionic gonadotropin; IGF-1: insulin-like growth factor 1; IM: intramuscular; MMP-9: matrix metallopeptidase 9; PRP: platelet-rich plasma; RNA: ribonucleic acid; SC: subcutaneous; VEGF: vascular endothelial growth factor)

be further continued after confirmation of pregnancy till 8 weeks when the placentation begins. Additional advantage of estrogen supplementation is that it helps in priming of the progesterone receptors (PR). Transdermal estrogen can be added to oral estrogen.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) plays a local paracrine role in the process of endometrial differentiation by stimulating different cytokines and growth factors.[21,22] Various protocols of hCG administrations are suggested by different researchers. Davar et al. recommend daily intramuscular administration of 150 IU of hCG for 7 days after initial 8–10 days of daily 8 mg oral estradiol valerate. It helps to improve the endometrial thickness and vascularity.[23] The latest studies report that intrauterine injection of 0.04 mL of recombinant hCG just before ET significantly improves pregnancy rates. It is suggested that hCG exerts multiple direct local effects on the endometrium. hCG provokes significant upregulation of endometrial VEGF and matrix metalloproteinase (MMP)-9 leading to angiogenesis.

Aspirin

The effect of low-dose aspirin on the endometrial thickness is still debated in literature. Some studies have reported the positive impact of low-dose aspirin (150 mg) on the endometrial thickness, pattern, and endometrial blood flow.[24] Hsieh et al. have demonstrated a higher percentage of trilaminar endometrium in a group of patients receiving low-dose aspirin therapy than the nonaspirin group.[25]

Sildenafil Citrate

Sildenafil citrate prevents the breakdown of cyclic guanosine monophosphate (cGMP) and increases the effect of nitric oxide on vascular smooth muscles. In combination with estrogen, sildenafil citrate administration causes an improvement in uterine blood flow and proliferation of uterine epithelium.[26] It also elevates VEGF levels leading to

increased radial artery resistance index and endometrial thickness.

In FET cycles, sildenafil can be administered in a dose of 25 mg by vaginal route from the first day of progesterone administration till the day of ET.

Granulocyte Colony-stimulating Factor

Granulocyte colony-stimulating factor (GCSF) is one of the cytokine family members including colony-stimulating factors. It stimulates the mobilization of stem cells from the bone marrow into the systemic circulation and further helps in their differentiation. GCSF plays an important role in tissue remodeling and angiogenesis, which are essential for endometrial growth. GCSF also stimulates various endogenous endocrine mechanisms such as the secretion of endogenous cytokines which act through autocrine as well as paracrine routes.

Granulocyte colony-stimulating factor can be administered by subcutaneous injectable route or direct intrauterine route. During pickup cycles if the endometrium is observed to be thin, 300 μg of GCSF is instilled in the uterine cavity by using an ET catheter on the day of oocyte retrieval if fresh ET is planned. For FET cycles, on day 12–14th of estrogen therapy if the endometrium is thin, then 300 μg of GCSF can be instilled in the uterine cavity and endometrial thickness and vascularity is assessed after 48 hours. The instillation can be repeated if the endometrium still is thin. The progesterone is started after desired endometrial thickness and vascularity, and ET can be done on day 3 or day 5 as per the stage of embryos.

Granulocyte colony-stimulating factor can also be given by subcutaneous route in a dose of 300 μg if the endometrial thickness is observed to be less on the 12th day of estrogen therapy. The same dose can be repeated 48 hours after the first dose if the endometrium is still thin. Once the optimum endometrium is observed, injection progesterone can be started and ET is done subsequently.

Cell-based Therapies for Endometrial Rejuvenation

- Use of autologous platelet-rich plasma (PRP)
- Stem cells therapy for endometrial rejuvenation
- Endometrial micro-rejuvenation by EVs—newer technology under research.

Use of Autologous Platelet-rich Plasma

Platelets are cytoplasmic fragments of megakaryocytes. They are formed in the bone marrow. They contain >30 bioactive proteins which have a role in the process of hemostasis and tissue healing.

Platelets actively secrete seven fundamental protein growth factors, namely VEGF, epidermal growth factor (EGF), fibroblast growth factor (FGF), insulin-like growth factor 1 (IGF-1), platelet-derived growth factor (PDGF), transforming growth factor (TGF), and connective tissue growth factor (CTGF). In addition to these growth factors, platelets secrete important cell adhesion and tissue healing, promoting molecules such as fibrin, fibronectin, and vitronectin.

Activation of the platelets causes the granules present in the platelets to fuse to their cell membranes, leading to active secretion of the proteins and growth factors. The active secretion of the proteins begins within 10 minutes and >90% of the growth factors are secreted within 1 hour.[27,28] The process of regeneration is initiated within 24 hours and continues for 2 months. There are various studies mentioning the minimal requirement of platelet count in the final preparation of PRP. Marx proposed that platelet count of 10 lakhs/mL in 5 mL of PRP is a working definition of PRP for the process of angiogenesis and regeneration.[28]

Types of PRP preparations: The classification of types of PRP is done by Ehrenfest et al.[29] depending on their cell content and fibrin architecture. The important types for clinical use are as follows:

- Pure platelet-rich plasma (P-PRP) or leukocyte poor PRP: These are the preparations without leukocytes.
- Leukocyte-rich PRP (L-PRP): These are preparations with leukocytes.

Protocol for PRP preparation: PRP is prepared by two step or differential centrifugation. The steps are as follows:

1. Collect 30 cc venous blood, which will yield 3–5 cc of PRP. The blood is collected in four different tubes containing anticoagulant acid citrate dextrose A (ACD-A), with the ratio of blood to ACD-A to be 9:1. Follow strict aseptic precautions at each step.
2. Do not chill the blood at any time before or during platelet separation.
3. Blood is centrifuged immediately at 1200 RPM (soft spin) for 12 minutes.
4. After the first spin, the blood separates into three layers: The upper layer that contains mostly platelets and white blood cell (WBC), an intermediate thin layer called buffy coat which is rich in WBCs, and bottom layer that consists mostly of red blood cells (RBCs).
5. For the production of P-PRP, the upper layer and superficial buffy coat are transferred to an empty sterile tube. For the production of leukocyte-rich PRP (L-PRP), the entire layer of buffy coat and few RBCs are transferred to an empty sterile tube, along with the upper layer.
6. Centrifuge the tube containing P-PRP at 3300 RPM (hard spin) for 7 minutes.
7. The platelet pellets are formed at the bottom.
8. The upper two-thirds platelet-poor plasma (PPP) is removed, and the lower one-third platelet-rich plasma is used for therapy.
9. Homogenize platelet pellet by thoroughly mixing with plasma before collecting in the syringe for therapy.

Modes and timing of administration of PRP for endometrial rejuvenation: PRP can be administered by two routes:

1. Intrauterine perfusion of PRP (IU-PRP)
2. Subendometrial multiple injections of PRP during one cycle prior to FET cycle by two techniques (SE-PRP):
   a. Hysteroscopic subendometrial multiple PRP injections *or*
   b. Transvaginal sonographically guided multiple subendometrial PRP injections.

Intrauterine perfusion of PRP (2015): Chang et al. were the first study who reported a pilot study of intrauterine perfusion of PRP in five patients with thin endometrium who had poor response to standard therapies.[30] In this study, all five patients had successful pregnancies. Four women had babies while one aborted.

In the latest study by the same group in 2019, intrauterine perfusion of 0.5–1 mL PRP was performed on the 10th day of the FET cycle in the cases when the endometrial thickness was <7 mm. The procedure was repeated on the day when progesterone was started prior to the procedure of ET. The clinical pregnancy rate in the PRP group was 44.12% as compared to 20% in no PRP group. The clinical pregnancy rate in patients with normal endometrium (10 mm and above) in their study was 50–55%.

Whenever the intrauterine PRP infusion is considered for endometrial rejuvenation, it is given during the FET cycle. It is suggested that the growth factors in PRP stimulate the mitogenesis and proliferation of the endometrial cells and MSCs in the endometrium and then activate endocrine—paracrine pathways to promote the implantation process. Platelets also activate peripheral blood mononuclear cells (MNCs), which release an anti-inflammatory cytokine interleukin-10 (IL-10), which in turn accelerates tissue regeneration.[31]

Hysteroscopic subendometrial PRP injection: This procedure is done one cycle prior to the FET cycle. In this procedure, autologous PRP is injected in the subendometrial area at multiple sites using an ovum pick single lumen needle of 22G size. About 0.5–1 mL PRP is injected per site in about five sites. Latest study by Shawki has shown significant improvement in endometrial thickness in a series of 51 patients,[32] where hysteroscopic subendometrial PRP injection was given **(Figs. 1 and 2)**.

Transvaginal sonography guided subendometrial PRP injection: This procedure is done during the proliferative phase of the menstrual cycle prior to the FET cycle. Autologous PRP is injected under vaginal ultrasound guidance into subendometrial regional multiple sites using a 35-cm 17G single lumen needle. In a latest study, Cakiroglu et al. have shown that subendometrial PRP injections under vaginosonography guidance have resulted in significant improvement in endometrial thickness and higher clinical pregnancy rate (28% vs. 7% in non-PRP group).[33]

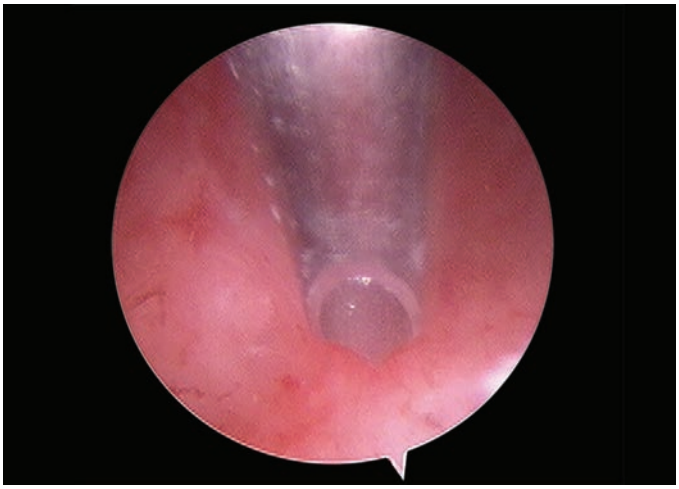

Fig. 1: Hysteroscopic subendometrial injection of platelet-rich plasma (PRP). Needle in the uterine cavity.

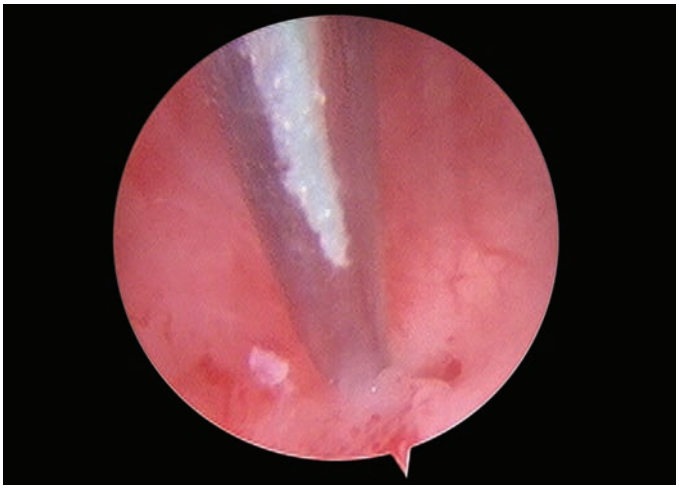

Fig. 2: Hysteroscopic subendometrial injection of platelet-rich plasma (PRP). Needle penetrating endometrial layer.

A recent study by Noushin et al. has shown that PRP treatment definitely improves endometrial thickness as well as clinical pregnancy rates. However, the study has concluded that SE-PRP does not offer any advantage over less invasive intrauterine PRP (IU-PPP) treatment.[34]

Adjuncts to PRP treatment: The drugs which stimulate angiogenesis can be combined with PRP treatment. Noushin et al. have recommended subcutaneous administration of 300 µg of GCSF for three successive days from the day of the procedure (SE-PRP or IU-PRP) to boost WBCs and growth factors production.

Our own experience of adding 300 µg of GCSF and 2,000 IU of hCG to the PRP preparation itself for SE-PRP procedures have shown significant improvement in the endometrial thickness, endometrial pattern, and vascularity in the subsequent cycle of actual FET.

Stem Cells Therapy for Endometrial Rejuvenation

Adult stem cells are pluripotent cells with self-renewal and differentiation potentials. It has been documented that adult stem cells are responsible for cyclical regeneration of the endometrium. The adult stem cells reside in the basalis layer and are even present in the atrophic endometrium of postmenopausal women.

Mesenchymal stem cell is the most important type of stem cell, which is present in the basalis layer of the endometrium. Apart from these tissue residential MSCs, another significant source of endometrial stem cells is bone marrow. There is a trafficking of the stem cells from the bone marrow to the endometrium, which is estrogen dependent.[35]

There are two types of stem cells released from the bone marrow to the endometrium. One is bone marrow MSCs, which along with endometrial MSCs mainly contribute to the regeneration of the stroma, glands, and epithelium. The other important stem cell which is released from the bone marrow is endothelial progenitor cell (EPC), which contributes to the formation of new blood vessels (angiogenesis) in the endometrium.[36]

Apart from the endometrium and bone marrow, MSCs can be harvested from adipose tissue, Wharton's jelly of umbilical cord, amniotic fluid, and menstrual blood.

Mesenchymal stem cells as well as other adult stem cells are used for endometrial rejuvenation inpatients having thin endometrium. There are various mechanisms which are postulated to promote the regenerative effects of stem cell therapy.

Mesenchymal stem cells can secrete several growth factors such as VEGF, hepatocyte growth factor (HGF), and TGF. They also exert anti-inflammatory effects. MSCs are immunomodulatory and regulate the functions and proliferation of T cells balancing the activity of T helper cell type 2 (Th2) and T helper cell type 1 (Th1).

The most common source of MSCs and EPCs used for endometrial rejuvenation is autologous bone marrow.

Methodology of preparation of autologous bone marrow derived stem cells:

- *Invasive method:* Bone marrow aspiration is done under all aseptic precautions from the posterior superior iliac spine under general anesthesia using a J (Jamshidi) needle (13G) and 20 mL. Syringe, prewashed with heparin. Around 150–200 mL bone marrow is aspirated. From this aspirate, around 15 mL bone marrow derived stem cells are separated by optical sensor technology. We have isolated the MNCs, which predominantly contain stem cells by Ficoll centrifugation and buffy coat method. Stem cell counting in the final product can be done by using a flow cytometer or hemocytometer. Usually, the stem cell count varies from 5 to 15 million cells/mL of the final product.
- *Noninvasive method:* In this method, stem cells from the bone marrow are mobilized to the peripheral circulation by administration of injection GCSF (10 MU/kg/day on day-4, -3, -2, and -1). 5 days after injection, isolation of MNCs is performed by apheresis through peripheral venous access using a cell separator. Minimum 50 million CD133+ (EPCs) are required.

Modes of administration of stem cells for endometrial rejuvenation:

- Intrauterine perfusion
- Subendometrial injection of stem cells at multiple sites under hysteroscopy or transvaginosonography guidance
- Intra-arterial injection of stem cells in the catheterization laboratory into uterine or spiral arteries
- Tissues engineering and endometrial reconstruction using collagen scaffolds.

Zhao et al. demonstrated that intrauterine perfusion with bone marrow derived stem cells in rat models resulted in increased endometrial thickness. They also have documented the upregulation of vimentin and cytokeratin which are marker proteins of the endometrial cells.[37]

Stem cells can also be injected at multiple sites in subendometrial areas through hysteroscopy. Wang et al. have shown that the bone marrow derived stem cells repair the damaged endometrium through upregulation of estrogen receptors (ER) and PR expression.[38]

Santamaria et al. have shown that intra-arterial injection of CD133+ bone marrow derived cells in patients with Asherman's syndrome led to increase in the endometrial thickness as well as vascularity.[39] In this study, the femoral artery was approached and the uterine artery was catheterized till the most distal spiral arterioles, where the isolated CD133+ cells were injected. Patients in this study showed significant improvement in the duration as well as intensity of their menstrual flow. Achievement of pregnancy was observed in three patients out of the total series of sixteen patients. Post-therapy hysteroscopic evaluation of remaining patients after 3 months revealed good uterine cavity and vascularized thick endometrium.

Some studies have avoided using bone marrow derived stem cells. They have used MSCs from other sources, such as endometrium or adipose tissue.

Sudoma et al. have used adipose tissue derived stem cells (ASCs) because they could not get adequate endometrium for isolating MSCs in the cases of Asherman's syndrome.[40] In this study adipose tissue was derived by aspiration from the patient's anterior abdominal wall. The cells were cultured "in vitro" for four passages till pure stem cells were finally isolated. These cells were injected in the subendometrial area at multiple sites under vaginosonography guidance using a 17G needle which is used for oocyte retrieval **(Figs. 3 and 4)**.

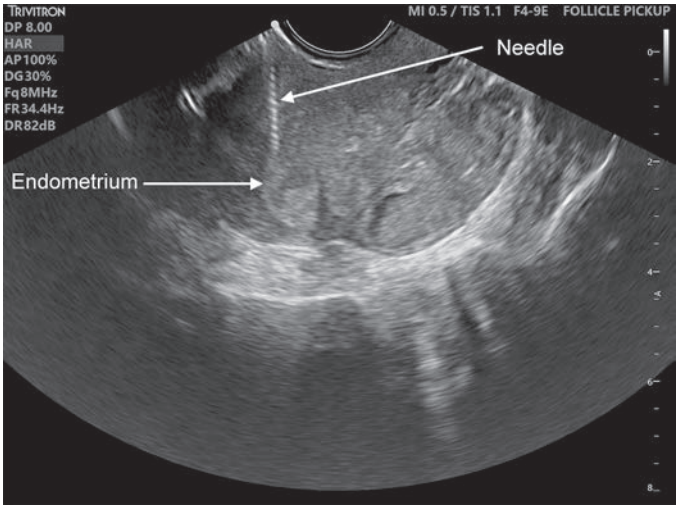

Fig. 3: Vaginosonography-guided injection of cells. Needle in the subendometrial zone.

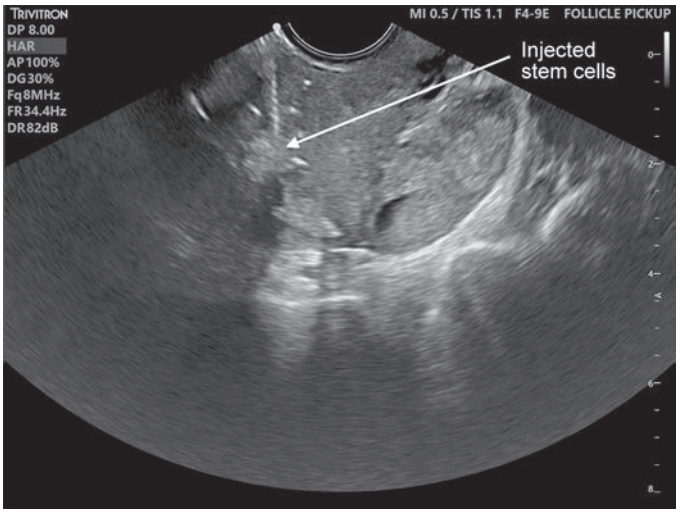

Fig. 4: Vaginosonography-guided injection of stem cells. Needle in subendometrial zone and echogenic areas of stem cells infiltration with vascularity.

There are studies in the literature where umbilical cord-derived stem cells and amniotic tissue-derived stem cells are used for endometrial rejuvenation.

In order to utilize MSCs after transplantation, the tissue engineering techniques such as use of scaffolds or gels loaded with stem cells are under consideration and development.

The collagen scaffolds have a three-dimensional structure which can guide the stem cells to grow rapidly. These scaffolds have good histocompatibility with no inflammation or immune rejection at the endometrial site.

Adjuncts to stem cell therapy for endometrial rejuvenation: Estrogen is an important hormone to promote the mobilization of stem cells from the bone marrow to the endometrium. It also stimulates the proliferation of MSCs in the basalis layer of the endometrium. Hence, cyclical administration of estradiol valerate in the dose of 4–6 mg followed by the addition of progesterone in the last 8 days are necessary for 1 month prior and 2–3 months after stem cell therapy.

Endometrial Micro-rejuvenation by EVs—Newer Technology Under Research

Extracellular vesicles are lipid bilayer enclosed nanoparticles released mainly by stem cells. They are spherical structures with a diameter of 30–80 nm. They serve as biological cargos of proteins, lipids, ribonucleic acids (RNAs), and deoxyribonucleic acids (DNAs). They promote angiogenesis.[41] They have immunomodulatory properties and reduce oxidative stress at cellular levels. EVs are active paracrine components with a high potential for repairing damaged tissues.

They play an important role in intercellular communication by autocrine and paracrine signaling. These signaling molecules stay within the membranes of EVs and hence are protected from degradation by enzymes. They play an important role in the cell-to-cell cross talk of many physiological processes.

Many studies have isolated EVs from cultured endometrial MSCs.[42] The surface markers of EVs, CD9, and CD63 are detected in the supernatants of cultured endometrial stem cells. Recently, it has been documented that the regenerative benefits of stem cell therapy are not due to the stem cells themselves. It is the regenerative mechanism mediated through the EVs secreted by the stem cells. The conditioned culture medium from the endometrial stem cells can be used for endometrial rejuvenation by administering it in various subendometrial regions under hysteroscopy guidance.

The role of EVs in implantation and endometrial micro-rejuvenation: The process of implantation involves a cross talk between the blastocyst and the endometrium. A recent study has demonstrated the important role of EVs secreted by the endometrial stem cells from the maternal side and those secreted by the inner cell mass of the blastocyst in the process of implantation.

The endometrial stromal and glandular cells secrete EVs during the window of implantation. Similarly, the cells, especially from the inner cell mass of the blastocyst also secrete EVs.[43] The EVs secreted from the inner cell mass are also detected in the blastocoel fluid. They play an important role in the development of embryos. The EVs which come out of the blastocyst are playing an important role in the process of immunomodulation and induction of endometrial angiogenesis, which is a prerequisite for the process of implantation.[44]

The time lapse imaging of the process of fertilization from the day of intracytoplasmic sperm injection (ICSI) of an oocyte to the stage of formation of a fully expanded blastocyst on day 5 at our center has shown a rapid expulsion of the cellular matter from the blastocyst during the period

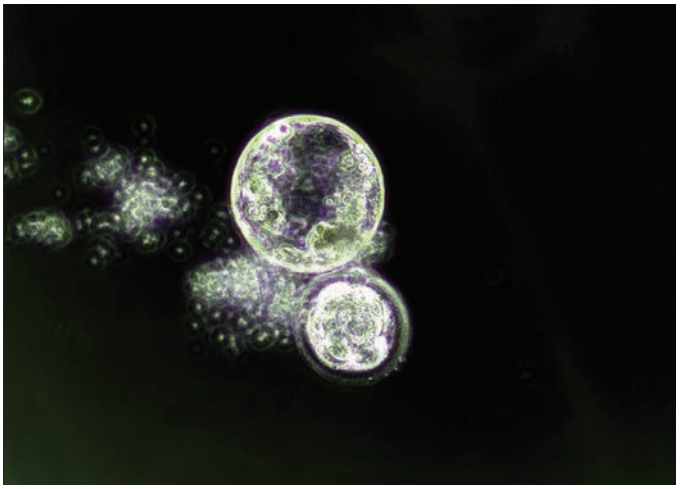

Fig. 5: Microphotograph of expelled cellular matter from blastocyst. Microphotograph showing expulsion of cellular matter from the fully expanded blastocyst. The other embryo is arrested at a stage of morula.

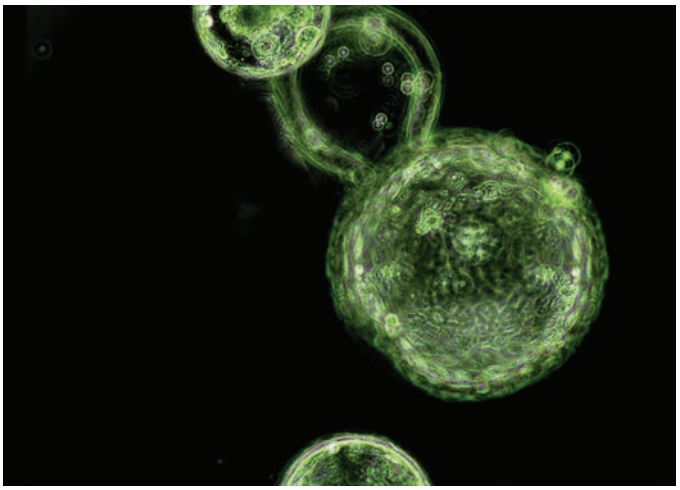

Fig. 6: Hatched blastocyst with expulsion of cellular matter.

of last 2 days of the 5 days culture (microphotograph) **(Figs. 5 and 6)**.

Giacomini in his study has also documented that the conditioned media of the IVF embryos from the period of day 3–5 of the culture contain a significant amount of EVs.[45] He has confirmed their presence by scanning electron microscopy (SEM) and by demonstrating EVs markers CD63 and CD9.

It is thus suggested that the embryos "in vitro", communicate with each other through EVs. This concept favors the culture of the IVF embryos in groups to promote the growth of each other through the mechanism of cell-to-cell cross talk rather than doing the culture of a solitary embryo per droplet of the culture medium.

The conditioned culture medium of the endometrial MSCs rich in EVs, when added to the culture medium in which the embryos are cultured, has been shown to significantly enhance the total number of the embryonic cells and grade of the blastocyst.[43]

It is hypothesized that if the blastocyst transfer is done along with its own autologous conditioned culture medium supplemented with autologous conditioned medium of endometrial MSCs, it should improve the implantation and clinical pregnancy rates of IVF procedures. The EVs thus transferred can bring about endometrial micro-rejuvenation leading to firm implantation and invasion which may reduce the complications such as pregnancy losses and conditions such as pregnancy-induced hypertension (PIH), leading ultimately to higher "take-home baby rates". Further research in this direction is needed on this concept of micro-rejuvenation of receptive endometrium with EVs.

CONCLUSION

- Management of a patient with thin endometrium is really a challenge to Assisted Reproductive Technology (ART) specialists. The implantation rates as well as clinical pregnancy rates are very poor when the endometrium is <7 mm with poor vasculature.
- Genital tuberculosis is the important cause among infective etiological factors of thin endometrium.
- Iatrogenic thin endometrium is due to over enthusiastic curettage of gravid uterus, endoscopic surgeries such as polypectomy, myomectomy and septal resection, and post cesarean intrauterine adhesions.
- Endometrial rejuvenation can be done by medical treatment with or without hysteroscopic adhesiolysis for anatomical correction.
- Estrogens, sildenafil, or GCSF can be used as a first-line treatment in mild cases.
- Autologous PRP, bone marrow stem cells can be administered by various routes for endometrial rejuvenation.
- EVs secreted by endometrial MSCs and blastocysts can be considered for endometrial regeneration.
- EVs in the blastocyst culture medium can be considered for endometrial micro-rejuvenation during ET.
- There is no definitely proven method for endometrial rejuvenation and the subject needs a lot of research.

CHAPTER 85

Ovarian Rejuvenation

Manjunath C Swamy

INTRODUCTION

Due to various causative factors, Infertility is becoming one of the major global concerns. Among the various causes of infertility, premature ovarian insufficiency (POI) and premature ovarian failure (POF) is increasingly becoming common across the globe. Clinics across the globe are reporting more women with loss of oocytes. In India it is more so, maybe because of ethnic/racial differences compared to Caucasian women. Similarly, there are rising trends in infertile men presenting with low spermatogenesis problems or with azoospermia. In case of POI or POF, women can still ovulate and may result in natural pregnancy erratically. The chance of natural conception varies widely among these groups of patients. Generally, many studies have shown 4.5–5% of POI/POF women conceive naturally by erratic ovulation. But the majority of them require medical help.

The only well accepted proven treatment is IVF using donor eggs. Women who wish to have their own genetic material (oocytes) are often met with limited options. Stem cell therapy (cell-based therapy) is increasingly explored with some amount of progress in clinical settings.[1] Even though many studies have shown that less percentage of stem cell treated couples conceive naturally, their hormonal milieu has improved. This may avoid unnecessary low prognostic procedures like IVF in this group of patients.

WHAT ARE STEM CELLS?

Stem cells are specialized pluripotent (means not yet differentiated cells) cells which have capacity to develop into distinct specific cells based on the environmental stimuli, with the purpose to develop, repair or regenerate tissues and organs **(Fig. 1).**

CLASSIFICATION

There are five types of stem cells which vary from less differentiated (but with more potency) stem cells to more differentiated (but with less potency) stem cells.

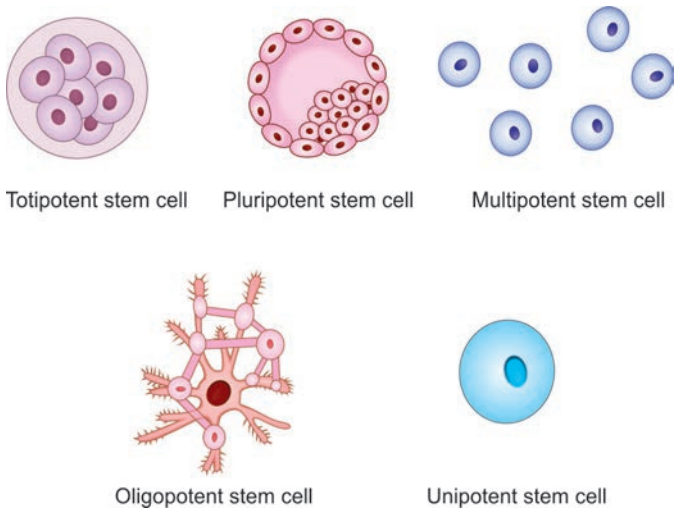

Fig. 1: Stem cell potency.

- Embryonic stem cells (ESCs)
- Induced pluripotent stem cells (iPSCs)
- Mesenchymal stem cells (MSCs)
- Hematopoietic stem cells (HSCs)
- Spermatogonial and oogonial stem cells (SSCs and OSC, respectively).

All these varieties of stem cells are used in different conditions of infertility with varying success **(Table 1)**.

One more way of classifying stem cells is based on potency:

- Pluripotent:
  - Embryonic stem cells (ESCs)
  - Induced pluripotent stem cells (iPSCs)
- Multipotent:
  - Mesenchymal stem cells (MSCs)
  - Hematopoietic stem cells (HSCs)
- Unipotent:
  - Spermatogonial stem cells (SSCs)
  - Oogonial stem cells (OSCs).

Embryonic Stem Cells

Induced pluripotent stem cells (iPSCs) and ESCs are derived from inner cell mass of the blastocyst. These cells

TABLE 1: Different type of fertility issues addressed with stem cells therapy.

	Conditions	*Stem cell types*	*Effects/Reference*
Female fertility issues (Fig. 2)			
Endometrium	• Asherman's syndrome (Partial/complete) • Thin endometrium • Recurrent pregnancy loss • Recurrent implantation failure	• MenSCs (Menstrual-humans) • UCSCs (umbilical cord-humans) • ESCs (epithelial-mouse) • MSCs (mesenchymal)	• Endometrium↑[2] • LBR ↑[3,4]
Ovary	• PCOS • POF	• ADSc (adipose tissue) • AFSCs (amniotic fluid), BMSCs (bone marrow)	↑Follicles, ↑E2[5-8]
Male fertility issues			
Testis	• Azoospermia	• UCSCs (Umbilical cord)	Spermatogenesis↑
	• Aspermia	• MSCs (mesenchymal)	Testicular tissue↑
	• Oligospermia	• iPSCs (induced pluripotent) • ADSc (adipose tissue)	Births↑ (only animal studies)[9,10]

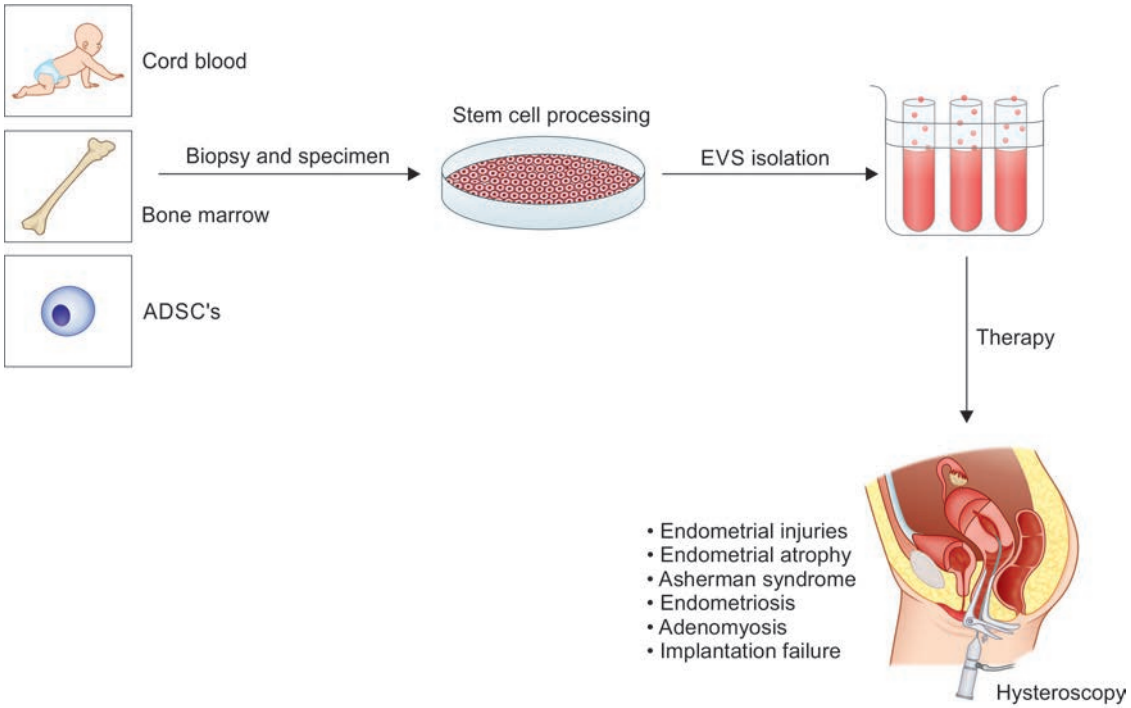

Fig. 2: A schematic representation various sources of stem cells and their application in disorders of female reproductive system.

are pluripotent which means apart from having self-renewal capacity they can differentiate into any cells of three germ layers (endoderm, mesoderm and ectoderm) and germ cells. Many studies have shown iPSCs can be achieved by reprogramming somatic cells. These cells have identical characteristics to ESCs but have advantage of no ethical involvement.[11]

Even though a lot of preclinical/clinical studies focusing on stem cells are underway for many other diseases, none of them are studying infertility management. The in vitro creation of "artificial gametes" from ESCs or iPSCs is still a long way to go in humans.

Mesenchymal Stem Cells

Mesenchymal stem cells are the ones which are widely used for treating infertility conditions. They are derived from mesoderm layers which can be obtained from various adult tissues such as bone marrow, adipose tissue, placenta, umbilical cord (Wharton's jelly) and blood **(Fig. 3)**.[12,13]

Great advantage of these MSCs is that they can be easily isolated from many adult tissues without any ethical issues. Many clinical trials have shown MSCs has potential application for various infertility conditions such as endometrial diseases, ovarian insufficiency and erectile dysfunction.[12,13]

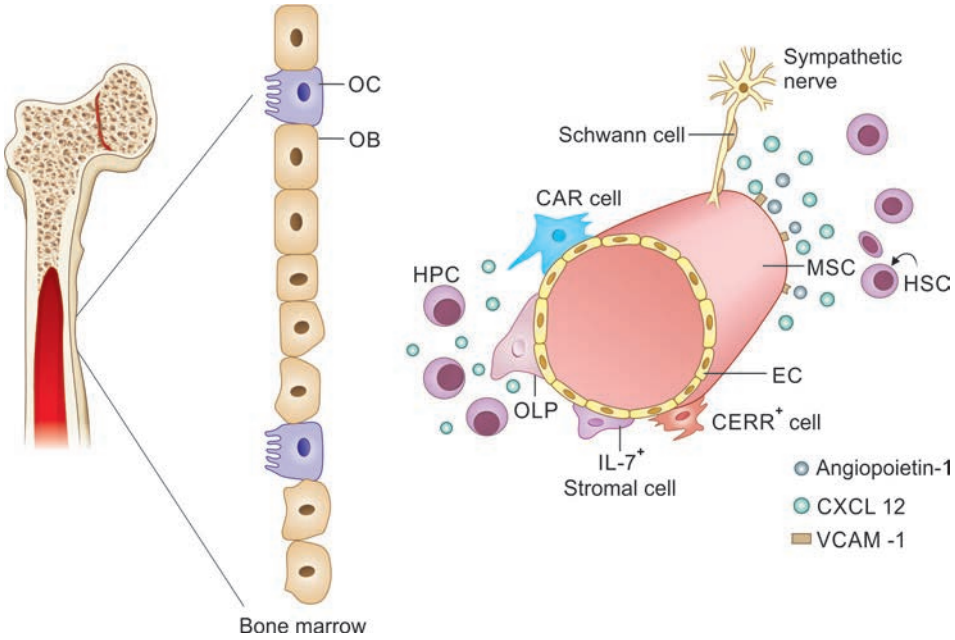

Fig. 3: Bone marrow derived mesenchymal stem cells (MSCs) in repair of injured tissues.

Hematopoietic Stem Cells

These are adult mesoderm – derived multipotent stem cells which can be differentiated into many types of blood cells. Particularly CD 133+ cells from bone marrow have high regenerative capacity. Clinical trials using these CD 133+ cells to treat endometrial disorders have shown promising results.

Spermatogonial and Oogonial Stem Cells

Spermatogonial sperm cells and OSCs are germline stem cells that are unipotent and can give rise to fully differentiated gametes (sperm and oocytes). Biggest drawback is the amount of SSCs and OSCs in testis and ovaries, respectively, is very low which impedes their maintenance and growth in vitro in comparison to other stem cells. Till today there are no human clinical trials using SSCs therapy.

Oogonial stem cells: Many commercial companies are studying the use of OSCs in infertility issues, there is presently no strong evidence of their presence, origin and function.[1]

STEM CELLS "NICHE"

The term "stem cell niche" was first proposed by Schofield in 1978. The self-renewal capacity of stem cells is believed due to the specific microenvironment provided by the neighboring cells of the stem cells. Stem cells niches or the specialized microenvironment in which the stem cells are located are complex structures which include different components.

Components of the Stem Cell "Niches"

- Cellular components (e.g., stem cells and differentiated cells)
- Secreted factors (e.g., chemokines, growth hormones and Wnt)
- Extracellular matrix (e.g., collagen fibers and fibronectin)
- Physical parameters (e.g., shear stress and tissue stiffness)
- Environmental signals (e.g., hypoxia and metabolism) and
- Bidirectional regulation of stem cells and their micro-environment.

In endometrium, these niches are found near rapidly growing spiral arteries which promote the renewal of the stem cells which promotes endometrial cyclical regeneration. In case of ovaries these niches help in the activation of remaining primordial follicles.

STEM CELL BASED THERAPY FOR FEMALE INFERTILITY

Most preclinical trials of stem cells for female infertility have used MSCs and HSCs with varying degree of expected results. Most of them have used autologous MSCs from bone marrow and adipose tissue. Few studies have used allogeneic umbilical cord MSCs for POF. Many studies have reported positive result[14-16] as:

- Improvement of overall ovarian function
- Increase in ovarian volume
- Resumption of menstrual cycle
- Endometrial improvement
- Increase in estradiol concentration
- Improved follicular development
- Increased number of antral follicles.

Premature Ovarian Insufficiency

It is defined as setting of amenorrhea or oligomenorrhea before the age of 40 (In Indian scenario we can take it as

35 years) increase in gonadotropins [follicle-stimulating hormone (FSH)], and decrease in estradiol (E2).[17] Even though older studies have shown that in general it is 2–4%, recently there is an increase in its prevalence. In the majority of POI, the cause is unexplained.

In clinical set up ovarian regeneration is attempted generally by injecting prepared autologous MSCs (mostly derived from bone marrow and adipose tissue) into the ovaries, mostly by laparoscopy and in few studies by transvaginal sonography guided procedure. Bone marrow aspiration is generally done at the iliac crest. The first child born after autologous BM-MSCs is by Edessy et al.[18] After this many clinical human studies have been conducted and many more are still in trials.

Proposed Mechanism of Ovarian Regeneration

Animal studies have shown that transplanted stem cells are not directly becoming oocytes.[19] These stem cells are differentiated into granulosa cells which in turn rescued or directed the oocyte maturation which were otherwise destined to apoptosis. These stem cells decreased apoptosis and pushed them into development. This process of improving ovarian function by MSCs transplantation is due to various molecular mechanisms (inhibition of autophagy of theca-interstitial cells via AMPK/mTOR signaling pathway;[20] activation of PI3K pathway[21] and ECM-development FAK/AKT signaling pathway; improved ovarian metabolome; paracrine activity by releasing different growth factor such as NGF, EGT, VEGT, etc.

The expected results are usually seen after 2–3 months. Many studies have shown that it is better to consider hormonal support after MSCs transplantation. HRT using a cyclical combination of estradiol plus dydrogesterone is considered in many studies.[1]

Proposed Mechanism of Endometrial Regeneration

Endometrium is a dynamic endocrine organ just like the ovary which plays an important role during embryo implantation. Dynamic dialog between endometrium and embryo will determine strong implantation. Adequate thickness (7–13 mm), morphology (triple-like pattern) and good functionality is crucial to achieve a successful pregnancy.[22]

The four components of human endometrium are the epithelium, stroma, vascular network and immune components. There are dynamic changes which continuously keep happening in these components throughout the menstrual cycle and during the implantation process. These four components will form two layers of endometrium, the stratum basalis and stratum functionalis.

Stratum basalis which usually would not shed during menstrual phase contains permanent somatic stem cell population, which is responsible for cyclical regeneration of the functionalis layer. So, this intrinsic capacity of endometrium to regenerate itself is due to the NICHE of stem cells population located in the stratum basalis. This set of cell population aptly called as NICHE of endometrium not only contains, endogenous endometrial stem cells but also bone marrow derived stem cells, extracellular component of stem cells and other structures, which may migrate to endometrium on stimulation such as endometrial injury.[23] Two main endometrial pathologies where stem cell therapy is explored are Asherman's syndrome and endometrial atrophy.

Asherman Syndrome

Asherman syndrome (AS) consists of the presence of intrauterine adhesions (IUAs) which occurs when normal endometrium is replaced by fibrotic tissue. Usual clinical presentations are scanty menstruation, infertility, recurrent miscarriage, abnormal placentation and pelvic pain.[24]

American fertility society (1988) AFS classification of AS includes three groups.

1. *Stage I (mild):* Few flimsy IUAs involving less than one-third of the cavity and normal to mild hypomenorrhea.
2. *Stage II (moderate):* Flimsy to dense IUAs involving one-third to two-thirds of the cavity and hypomenorrhea.
3. *Stage III (severe):* Dense IUAs involving more than two-thirds of the cavity and amenorrhea.[25]

Usually etiology of AS is, genital infections (Tuberculosis common in India), iatrogenic trauma such as D&C, miscarriage, post-partum curettage or hysteroscopic surgery. Other causes are induced uterine artery embolization, cesarean sections, IUD insertions, Mullerian duct malformation.

Endometrial Atrophy

Generally endometrial thickness (measured by TVS—maximum distance between echogenic interfaces at junction of endometrium and myometrium) varies from 7to 13 mm during implantation phase. Clinical consensus is that embryo implantation cannot be achieved if the thickness is below 6 mm[26] (though few cases have achieved pregnancy below this cut-off).

Endometrial atrophy (EA) is caused by decreased endometrial thickness also termed as thin or refractory endometrium. General incidence varies from 2.2 to 4.2% among patients undergoing IVF cycles. Most common causes of EA are inflammatory such as acute/chronic infections or iatrogenic causes such as excessive curettage or hysteroscopic surgeries – all leading to destruction of stratum basalis.

STEM CELL THERAPY FOR ENDOMETRIAL REGENERATION

The presence of bone marrow derived stem cells apart from endogenous endometrial stem cells hypothesize that we can induce BMDSC to accumulate in the endometrium or we can inject these cells directly into the endometrium by process of stem cells transplantation **(Fig. 4)**. This BMDSC hypothesis-postulated to use granulocyte-colony stimulating factor (G-CSF) which pushes stem cell and its progenitor from bone marrow into peripheral blood stream, which in turn gets accumulated in the endometrium. But G-CSF studies remain controversial. Many studies reported that this G-CSF does not significantly increase endometrial thickness. But a meta-analysis of 11 different studies[27] indicated that when G-CSF was used as intrauterine perfusion, it improved endometrial thickness and clinical pregnancy and implantation rate.

Stem cell transplantation for AS or EA involves bone marrow aspiration of 15–20 mL at anterior or posterior iliac crest and the preparation of stem cells using refrigerated centrifuge at 20–21°C. This stem cell mixed plasma is immediately injected into the uterine cavity at multiple sites using hysteroscopy. Injection of these stem cells has to be in the subendometrial zone **(Figs. 5 to 7).** Similarly, in conditions of ovarian impairment such as POF, the prepared stem cell extract is injected laparoscopically into the bilateral rugosed ovaries. Various clinical studies have shown benefits of using these stem cells in the form of increased ET, increased endometrial functionality markers (ER2, Ki67), increase in pregnancy rate in ART, increased LBR, increased vascular density, and increased menstruation duration.

Many studies using BMDSCs have an effect of increase in ET but it was transient. They could see this maximum effect up to 3 months after injection and then it diminished after 6 months. Mechanism of these stem cells effectiveness could be due to the paracrine effect. Stem cells create an immunomodulatory change which drives the regenerative procedure such as proliferation and angiogenesis.[28]

Bioengineering Material Along with Stem Cell

Bioengineering materials are known to strengthen the cell's regenerative actions. Collagen scaffolds (three-dimensional porous biomaterials), polyglycerol sebacate (PGS) scaffolds, lactic-coglycolic acid scaffolds and hydrogels are being used. Ding et al. (2014) mixed BMMSCs and collagen scaffolds and transplanted the mix onto the basal endometrial layer of rats with an injured uterus,[29] and have shown increased endometrial functional markers.

Endometrial regeneration using other sources of stem cells have been attempted using umbilical cord mesenchymal stem cells (UCMSCs), menstrual blood stem cells, amniotic membrane, adipose tissue mesenchymal stem cells have been tried.

DERIVATIVES OF STEM CELLS: EXPLORED FOR REGENERATING ENDOMETRIUM

In general, various studies using stem cells for regenerating endometrium highlighted that regeneration happens because of the stem cells paracrine hypothesis. This also means that the effect of this stem cell action is for shorter duration (low retention of the cells) and also there may be the theoretical risk of teratoma development.[30]

So, researchers are trying to develop therapeutic approaches using derivation of stem cells instead of using direct stem cells for regenerating the endometrium. Few things they are exploring include stem cells secretome, stem cell exosomes (extracellular vesicles paracrine factors) and specific molecules from cells (e.g., cell growth factors, cytokines). Granulocyte-colony stimulating factor is one such cell factor which promotes stem cells progenitors and increases regenerative capacity of endometrium which has been studied extensively in human clinical studies. Others include hepatocyte growth factor (HGF), transforming growth factor-beta (TGF-β), platelet derived growth factor (PDGF), and fibroblast growth factor (FGF). Many of these growth factors are presumably present in plasma rich protein (PRP). The use of PRP for generating endometrium has been studied with varied results.

Platelet Rich Plasma

It is a peripheral blood derived mixture of platelets and its growth factor (which has above average platelet concentration) which has potential to repair and regenerate tissues.[31] PRP mainly consists of α-granules inside the platelets which contain bioactive molecules (which are released after activation) such as cytokine, growth factors, (IGF-1, HCF, FGF) and other biologically active proteins which will actively take part in tissue repairs and regeneration. Prior use of G-CSF 2–3 days before taking peripheral blood for preparation of PRP may increase these regenerating factors.

Various clinical studies using PRP have been published. Most of these studies are smaller in number. Only two randomized clinical trials using PRP have been published. In RCT by Eftekhar M et al., PRP has been used for EA cases, which showed improvement in endometrial thickness, clinical pregnancy rate and implantation rate were observed.[32] In RCT by Javaheri A et al., PRP was used for AS patients. They reported no improvement in endometrial thickness or restoration of menstrual patterns.[33]

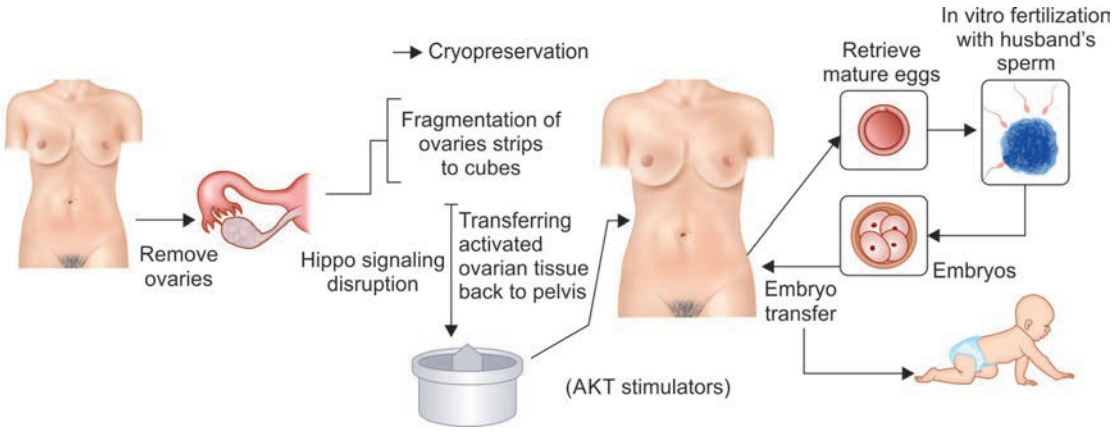

Fig. 8: In vitro activation of the ovary.

Paracrine Factors

Many paracrine factors have been explored along with stem cell therapy to make this regenerative treatment simpler. At present there are varied results in terms of effectiveness and safety. This relatively recent therapeutic approach needs further larger well designed studies. It is prudent to wait for a better understanding on regenerative capacity of these factors.

IN VITRO ACTIVATION OF OVARY

In order to develop mature oocytes, plenty of small primordial follicles (PFs) are constantly activated from the pool of PFs. In many cases as the doctrine of ovarian follicles progresses, the activation of dormant follicles eventually arrests or temporarily stops despite still having a reasonable amount of residual PFs. So, these women with limited numbers of growing follicles present with poor ovarian response and many fail to conceive on their own or on stimulation with ovulogens.

So, this can be addressed by activating their residual dormant PFs using a new method of infertility treatment called in vitro activation (IVA) and drug-free IVA. By doing so it stimulates early gonadotropin-independent stage follicles to grow which may benefit a few POI and POR-DOR patients.

Mechanism of In Vitro Activation

Exact mechanism of how dormant PFs activation happens is not clearly understood. Many intracellular signaling pathways have been described.[34] Three important pathways studied in activation of PFs are phosphatidyl inositol-3-kinase (PI3k-AKT), mammalian target of rapamycin (mTOR) signaling pathways[35] and Hippo signaling pathway.

What is IVA?

This is a procedure in which laparoscopy is used to remove one or both ovaries. Then cortex of the ovaries around 2 mm thickness is removed (since majority of PFs are located within 2 mm of cortex surface) and then immediately this cortical tissue is cut into small strips (1–2 mm thickness) **(Fig. 8)**. Then these cortical strips were cryopreserved for subsequent tissue culture with AKT activators and auto grafting (usually in the pouch created in mesosalpinx-using second laparoscopy). This method of IVA can be treated as conventional IVA or classical IVA.

In drug-free IVA, after removing the ovarian cortex it is fragmented into small cubes (1–2 mm) to just disturb the Hippo signaling pathway. Then immediately grafting them back to remaining ovaries or mesosalpinx pouch.[36] The mechanical disruption is sufficient to disturb the Hipposignaling pathway which is responsible for keeping PFs in dormant state. Hippo signaling disruption alone is sufficient in stimulation of early follicular growth. Few studies have shown clinical improvement with drug-free IVA,[37] but the number of cases is small. Extrapolating this mechanism, a group published the clinical outcome of the disruption of Hippo signaling pathway by ovarian biopsy/scratch in 80 patients with POI women. They were able to get follicle growth with FSH stimulation in almost 14% of patients.[38]

CONCLUSION AND FUTURE PROSPECTIVE

With >43 years of ART development and >8 million babies born so far, new segments of infertility population such as POI, POR, poor endometrium and disturbed spermatogenesis have been added to the infertility pool. These segments of the infertility population require newer therapeutic approaches. One such approach is in considering stem cells and its derivatives as an alternative approach to ART and or to improve the success of IVF outcomes in these couples. Clinical and preclinical studies have shown some light on how stem cell therapy can be of assistance in infertility management. But at present stem cell therapies are largely in the preclinical phase and several ethical issues need to be addressed. Since autologous stem cells are ethical, safe, and nonimmune, the clinical use of these autologous stem cells is more convenient and has great potential in the future.

CHAPTER 86

Batch In Vitro Fertilization

Sandhya Krishnan

INTRODUCTION

Even with an increasing number of in vitro fertilization (IVF) centers, the demand for batch IVF still remains high due to the limited number of senior embryologists available and the better convenience of patients and clinicians. Here, the menstrual cycles of multiple women are programmed such that they can undergo all the processes, from stimulation until embryo transfer around the same time frame. There is sufficient evidence on scheduling cycles with steroids in gonadotropin-releasing hormone (GnRH)-agonist and antagonist protocols without compromising success.[1] This chapter will highlight the clinical concept of scheduling cycles in a "batch IVF" setup.[2]

Batch IVF is a planned process of recruiting a group of patients, such that the stimulation is started on the same day (±1–2 day window) and oocyte retrieval (OCR) falls on the same day (±1–2 day window).[3] The embryo transfer, if in a fresh cycle, falls on the same day (±1–2 day window), day 2, or day 3 following OCR. The aim is to facilitate OCR, intracytoplasmic sperm injection (ICSI), or IVF, and embryo transfer within a designated period when a visiting senior embryologist is available.

In full-fledged laboratories with an in-house senior embryologist, where two batches may be planned in the same month, so that time for laboratory maintenance is available and quality control could be implemented in a better way, all staff are better prepared and media utilization is done to the maximum.[4,5] It is cost-effective in terms of better utilization of media and gonadotropins, and benefits can be passed on to patients as well.

Batching has its advantages and disadvantages, but its necessity in some settings cannot be underestimated. Weekend-free scheduling of procedures without compromising results is important that is appreciated by all hospital staff.[6]

Standard guidelines to facilitate the smooth running of batch IVF are needed to ensure increased success without compromising results and patient care.

Patient selection is crucial for batch IVF for optimum results.

DIFFERENT SETTINGS WHERE BATCH IN VITRO FERTILIZATION IS DONE[1]

- A well-equipped laboratory with in-house senior embryologist and infertility consultant may choose to have IVF in batch in order to optimize the use of media consumables, drugs, incubator operation theater, anesthetist, ancillary staff, etc. Even though there is no time constraint in such laboratories, batching allows them time to recover and audit. Gonadotropins and media can be shared. In centers where other gynecological procedures are practiced, facilities can be streamlined, and a team can be geared up for batch and better-quality control guaranteed. The quality technician can be designated to come a week before the batch to check the laboratory air quality, pH, humidity and temperature, and incubator swab test for infection control.
- A setup with an in-house infertility specialist and visiting embryologist would do batching as per the availability of embryologist. Here also, optimum resource utilization is the advantage. Results can also be optimized if availability of embryologist in case needed is arranged, when a case or two do not get ready on expected batch dates.
- A setup run by a gynecologist with visiting fertility specialist and embryologist coming for a specified duration can do batching. Here, batching is done due to necessity and lack of full-time available specialists. The gynecologist recruits a batch, and stimulation is done as per remote instructions by a fertility specialist who may not be aware of the patient's clinical details. There is the risk of suboptimal stimulation or overstimulation, and results may be compromised. The advantages and disadvantages of batch IVF thus depend on the setting and organization of the batch. Strategies to identify ideal patients and refer or recruit patients with complex issues outside the batch are vital to the batch's success;

for example, poor responders, hyperresponders, and recurrent implantation failure are the groups who need individualized care and are not ideal for batch IVF.

PREPARATION FOR A BATCH IN VITRO FERTILIZATION

Clinical Aspects

- Number of couples to be recruited
- Pretreatment with the oral contraceptive pill (OCP)
- Previous month's depot preparation
- *Protocol*: Agonist versus antagonist
- *Stimulation*: Starting dose of gonadotropins
- Other protocols
- Monitoring
- Advantages
- Disadvantages
- Summary.

The number of couples to be recruited: This depends on:

- Days of availability of embryologist
- The capacity of the laboratory and the number of incubators available.
- Most recommend four patients per incubator, or if a benchtop is available, the numbers may be increased.
- The number of OCRs around five per day is ideal. Maximum is seven to eight OCR per day. The time required for embryo transfers should also be allotted.

The embryologist should be available on the day of OCR, taken as day 0, on day 1 to check fertilization and additional 2 days to plan day 2 or day 3 for embryo transfer. If complex procedures such as testicular sperm aspiration (TESA), MicroTESA, or blastocyst transfer are planned, additional staff and extra time must be allotted.

Pretreatment with OCP: For batch IVF, pretreatment with OCP is a must to facilitate cycle synchronization.

- It helps to avoid cyst formation.
- It prevents premature luteinizing hormone (LH) surge.[7]
- It maintains persistent reduced LH till trigger.
- Serum level of progesterone is decreased to levels incompatible with ovulation.[1,4]
- Sensitization of receptors to follicle-stimulating hormone (FSH).[1,8]

Disadvantages: The endometrial shedding or thinning effect may last until mid of the stimulation cycle.[8]

This may be beneficial in the antagonist cycle, where advanced endometrial maturation supposedly decreases implantation rates.[9] Pill pretreatment does not improve the number of oocytes obtained and may even have a negative effect on outcome.[10] However, studies have shown the effect as the number needed to treat (NNT) = 20 for 1 less number of live birth rate. The use of oral contraceptive pretreatment in antagonist IVF cycles showed a relatively small but statistically significant reduction of ongoing pregnancy when a pill-free interval of 2–5 days is used before starting gonadotropin stimulation. Based on the incidence of ongoing pregnancies in the randomized controlled trials included in this meta-analysis, the NNT to harm is 20 patients [95% confidence interval (CI): 10–100]. For example, for every 20 patients pretreated with oral contraceptives, one ongoing pregnancy will be missed.[11,12]

It may also increase the duration of stimulation and the dose of gonadotropins.[11,12] Profound LH suppression may increase miscarriage rate and reduce pregnancy rates and thus lead to poor oocyte quality in poor responders.[13,14]

The endometrial thinning effect may persist and reduce fresh cycle transfer success rates.[15]

Recent Cochrane on pill pretreatment in antagonist cycle:[16] Among women undergoing ovarian stimulation in antagonist protocols, combined oral contraceptive pill (COCP) pretreatment was associated with a lower rate of live birth or ongoing pregnancy than no pretreatment. There was insufficient evidence to determine whether live birth rates or ongoing pregnancy were influenced by pretreatment with progestogens or estrogens or by COCP pretreatment using other stimulation protocols. Findings on adverse events were inconclusive, except that progesterone pretreatment may reduce the risk of ovarian cysts in agonist cycles, and COCP in antagonist cycles may reduce the risk of pregnancy loss compared with no pretreatment in agonist cycles.[17-21]

The use of estradiol in the luteal phase of the previous cycle is another protocol with the advantage of synchronization of antral follicles and the disadvantage of missing the batch by 1–2 days if not careful.[22]

Previous month's depot preparation:[23] Administration of a single-dose depot of GnRH agonist preparation (leuprolide 3.75 mg) on day 21 of a prestimulated cycle was assessed in a Cochrane review.[24] The authors observed no evidence for differences between the long protocols using depot or daily GnRH agonist for IVF cycles. Nonetheless, depot GnRH agonist is associated with increased requirements for gonadotropins and a longer time for ovarian stimulation.[25,26] If these differences could be shown to decode into economic benefit, depot GnRH agonist would increase the overall costs of IVF treatment which is not in favor of this protocol.

Protocol—agonist versus antagonist: As a routine, the agonist-long protocol was always recommended for batch IVF as timing and synchronization are easier.[27,28]

However, with pretreatment with combined pills, the antagonist protocol is also used with equal efficacy and comparable success rates.[29]

The calendar also shows a typical agonist-long protocol cycle. However, the agonist-long protocol will be disadvantageous for some patients, especially poor responders, last-minute recruits to the batch, and hyperresponders.

The antagonist cycle can be considered where OCP is stopped 5 days before the stimulation date and irrespective of periods.[30]

When patients received the pill for only 12–16 days, and stimulation started after a wash-out period of at least 5 days, no differences could be found in live birth rates. Also, when cycles planned with OCP were compared with cycles pretreated with estrogens only, again, no differences could be found in live birth rates.[31]

Periods can also be induced using PGE1 200 µg 2 doses 12 hours apart or by coring (mechanical aspiration of the endometrium) for the patient's psychological satisfaction.[32]

Stimulation—starting dose of gonadotropin: Initial starting dose of gonadotropin should be individualized to get optimal response and prevention of hyperstimulation.

Consort algorithm: The daily FSH dose may be calculated based on age and two markers of ovarian reserve, namely antral follicle count (AFC) and anti-Müllerian hormone (AMH), with the last two variables being the most significant predictors.[33-35]

However, standard dosing with 150 IU FSH, with the option of increasing or decreasing the dosage as per response, is a standard protocol with triggering final oocyte maturation by a GnRH agonist with or without deferred embryo transfer.[36]

Individualized FSH dosing based on the AFC does not improve live birth rates or reduce costs. Ovarian reserve test-based treatment for the IVF/ICSI population as a whole should, therefore, not be pursued. Women scheduled for IVF/ICSI with a regular menstrual cycle are therefore recommended to a standard FSH starting dose of 150 IU/day.[37]

Ordering for gonadotropins: Once the initial starting dose is calculated for each patient, this is multiplied by 10 to get the amount of gonadotropin to be ordered. An extra 10% of the calculated dose is kept for backup in case of any additional requirement. The choice of gonadotropin depends on the center's experience and personal preference. A trained staff nurse should be available to check the stocks and administer injections to a patient. A separate refrigerator with an uninterrupted power supply is a must for gonadotropins to maintain the cold chain.[38]

Other protocol—microflare for poor responders:[1,38] The microflare protocol is designed to optimize ovarian response in women with a previous poor response to a routine protocol or who have low AMH and AFC. The term "microflare" is derived in two parts: "micro" refers to the use of a diluted dose of Lupron, micrograms instead of milligrams, and "flare" refers to the stimulatory or flare effect of Lupron when given this way—hence the term microflare. Starting on cycle day 3-–two to three (sometimes up to four) weeks of OCPs, then start microdose Lupron (0.2 cc twice daily) 3 days after stopping OCPs, and then add gonadotropins 2 days after starting Lupron. The gonadotropin start day is the cycle start day or stimulation day 1 **(Table 1)**.

Dosage is also based on baseline FSH, AMH, body mass index, age, and AFC.

Additional LH may be added and is helpful in hypogonadotropic hypogonadism and poor responders.[39,40]

Monitoring: Aim for an optimum number of oocytes to avoid overburdening of resources. Most studies put the optimal number of retrieved oocytes between 10 and 15.[41,42]

Use standardized protocol for batches to avoid confusion among staff and easy counseling of patients. Optimal stimulation will avoid ovarian hyperstimulation syndrome (OHSS)[43]

TABLE 1: Microdose Lupron Flare protocol.

Sunday	*Monday*	*Tuesday*	*Wednesday*	*Thursday*	*Friday*	*Saturday*
Combined oral contraceptive pill (COCP) (continue for 2–3 weeks)						
	Baseline sonogram take last OCP			Diluted Lupron 0.02 cc 2 times each day until hCG		Stimulation medication (gonadotropins) Start to continue Lupron two times each
		E2	(Completion of the cycle may vary depending on individual patient's response)	Sono and E2		
	Sono and E2	Sono and E2 hCG (PM)		Oocyte retrieval time in (AM)		

(E2: estradiol; hCG: human chorionic gonadotropin; OCP: oral contraceptive pill)

and provide better endometrial receptivity and endocrine environment.[44]

- Baseline ultrasound
- *Day 2:* Hormone levels to confirm downregulation (optional)
- *Day 2:* Scan to confirm downregulation
- *Day 6:* Scan and hormone level (optional) to confirm optimum dosage of gonadotropins and response to prevent OHSS or suboptimal stimulation.
- *Day 8:* Scan.

Day 10: Scan + hormones assay to check progesterone level (only if planning fresh transfer) on trigger day and decide regarding a fresh transfer.

- *Day 12:* OCR and IVF or ICSI by the embryologist
- *Day 13:* Fertilization check
- *Day 14:* Day 2 embryo check––day 2 embryo transfer or freeze can be done. The sample batch calendar for D2 transfer is given in **Table 2**.
- *Day 15:* Day 3 embryo transfer––day 3 embryo transfer or freeze can be done.
- The batch completes treatment for that particular cycle, and the embryologist leaves to join another center for another batch.

Advantages of the batch IVF compared to regular batch are given in **Table 3**.

Disadvantages of batch IVF compared to a regular cycle are given in **Table 4**.

Suggested checklist for optimum results in batch IVF:

- Detailed clinical and hormonal evaluation of each couple. Better to include prior cycle monitoring to have an idea of the patient's response to stimulation.

TABLE 3: Advantages of batch in vitro fertilization (IVF) compared to regular batch.

	Batch IVF	*Regular IVF*
Availability	It makes IVF available at peripheral centers at an affordable price	Only a few centers are available
Access	Access to more people	Less number of populations covered
Long-distance travel	Traveling distance can be avoided for IVF treatment	Long distance to be traveled for treatment which increases the cost
Quality control	Laboratory gets time to get ready and quality control possible, as enough time is available	Laboratory quality assessment incomplete as no gap time to follow the standard operations for quality assessment and appraisal
Maintenance of equipment	Tasks such as incubator cleaning, calibration, pH assessment, sperm survival test, and maintenance of instruments can be easily undertaken during free time. This is not feasible at centers with ongoing cycles throughout the month	Laboratory cleaning and instrument calibration compromised
Results	The cumulative pregnancy rate in batch IVF is the same as routine IVF if standards and protocols are followed	Success rates are almost the same as a batch for a normal responder

TABLE 4: Disadvantages of the batch in vitro fertilization (IVF) compared to a regular cycle.

	Batch IVF	***Regular IVF***
Flexibility	Lack of flexibility of cycle and days	Days flexible
Time frame	Rigid time frames to be followed	Time frame flexible
Patient response to stimulation	Some patients may not respond as expected, leading to cycle cancellation and unsatisfied patient	Oocyte retrieval date can be adjusted as per response
Protocol	The antagonist cycle may be difficult to control and synchronize. Last-minute cancellation would reduce the number of cases and lead to media wastage	The protocol can be individualized
Privacy	Patients would be well acquainted with each other. If the results are low, they can cause trouble in groups which would be difficult for the doctor to deal with	Privacy maintained for both patient and center
Mishap	If any technical mishap happens, it will affect the whole group	Mishap, if any, would include a few numbers of patients
Skills	Accountability and skills of visiting embryologists may not be assured always	Embryologist and reproductive medicine consultant are accountable and more responsible as they directly deal with the patient
Operator	Operator-induced mistakes are more common due to workload and time constraints	Operator-induced error is less common as the staff is more relaxed with routine work
Sample mixing	More risk of mixing of samples	Mixing of the sample can be avoided
Individualized treatment	Individualized treatment difficult	Individualized treatment possible
OCP pretreatment	OCP pretreatment may affect cycle outcome and increase gonadotropin dose required	Pretreatment not necessary
Minimum number of recruits	If a minimum number of patients are not recruited, the batch may turn as overexpensive	The number of patients does not affect treatment
Incubator overload	Incubator overload is a concern if more patients are recruited and center not prepared	Incubator load not compromised
Cycle cancellation	Cancellation and rescheduling will be expensive, demoralizing, and inconvenient for both patient and the center	The patient feels more confident as embryologists, and reproductive medicine specialists are always available
Embryo transfer	Usually must do D2 or D3 transfer, and blastocyst transfer is not feasible even if indicated. Advanced procedures such as PGD and PGS cannot be done due to short stay of embryologist	Blastocyst culture can always be considered. PGD/PGS feasible in indicated cases
Complex procedures	A complex procedure such as TESA challenging to be implemented	Complex procedures such as TESA, PESA, and microsurgical testicular sperm extraction (microTESE) can always be considered when needed
Freeze–thaw quality	Freezing and thawing compromised due to time constraints	Embryology procedures such as freezing and thawing can be done at ease with no time constraints[45]
Quality control	Quality control may not be up to the mark if the visiting embryologist is dependent upon junior staff to maintain laboratory equipment and incubator	A full-time single-center-focused embryologist would be able to focus more on quality control. They can supervise the juniors directly

(OCP: oral contraceptive pill; PESA: percutaneous epididymal sperm aspiration; PGD: preimplantation genetic diagnosis; PGS: preimplantation genetic screening; TESA: testicular sperm aspiration)

- Individualize dosage and protocol according to patient's age, weight, hormonal, and ultrasound parameters.
- The number of patients per batch is decided as per the center's capacity.
- Have a referral protocol for the patients who need individualized care and for patients where stimulation has started. But patients get ready early or late for the planned dates of OCR–ICSI-embryo transfer in batch IVF.
- Well-trained counselors for patients who need extra time for explanation of cycle cancellation and transfer to other centers.
- It is better to stick to the services of a senior embryologist throughout, ideally a person who has been involved in the setting up of the laboratory so that they are interested in laboratory management/logistics, statistics, and results.

- Ensure availability of additional backup embryologist and ancillary staff in case of emergency leave of designated staff. Ensure additional junior embryologist who can coordinate with senior embryologist regarding laboratory maintenance.
- Well-planned billing system to minimize losses to the patient as well as the center.
- Good counseling services for patient satisfaction and patient feedback.
- Use standardized protocol but also individualize as and when required.
- Regular auditing and implementing corrections
- Records, labels, and documents to be well maintained. Ensure photographic records of the embryology laboratory.
- Avoid overcrowding
- Assistant staff to ensure proper and up-to-date documentation.

PREPARATION FOR A BATCH IN VITRO FERTILIZATION: LABORATORY ASPECTS[2,3]

- Check stocks for disposables, consumables, equipment, and culture media.
- Check the laboratory stocks and keep an adequate supply at least 1 week before the batch.
- Disposables should be stored close to the laboratory, separate but near. This is to off-gas the volatile organic compounds (VOCs). The OCR needles such as single- and double-lumen needles, embryo transfer catheters, and stylets have a long shelf-life and can be stocked in more numbers.
- A laboratory maintenance technician can be hired from outside who does the quality check of equipment and air quality every month, a week before IVF. Also, check uninterruptible power supply (UPS) connections, and an extra pressure pump is always recommended.
- The amount of media needs to be calculated and made available 5 days before the beginning of the batch.
- Media to be kept in separate refrigerators close to the laboratory. All new media to be checked for sperm survival test. Daily, weekly, and monthly readings of humidity, pH, and temperature are to be recorded as routine.
- Temperature and CO_2 control of all incubators and all heated stages to be verified and adjusted.
- Embryo safe cleaning solutions such as Oosafe and Fertisafe to be used as well as embryo culture grade water for cleaning. Excess alcohol can have a harmful effect on embryo development.

Disposables Required Per Patient[38]

- Semen collection container: 1
- Sterile probe cover: 1
- OCR needle: 1
- Embryo transfer catheter with stylet: 1
- Handcare gloves: 5
- Powder-free latex gloves: 5
- Round bottom tube 14 mL: 20
- Round bottom tube 6 mL: 2
- Screening dish 3034: 10
- Serological pipette 10 mL: 2
- Serological pipette 5 mL: 2
- Pasteur pipette 5.0 in.: 3
- Falcon centrifuge tube 15 mL: 2
- BD 7575 pipette 3 mL: 10
- Denuding pipette 170 µm: 2
- Denuding pipette 140 µm: 2
- Diamond microtip: 2
- Disposable BD syringe 1.0 mL: 7
- ICSI dish: 1
- Holding pipette: 1
- Injection needle: 1
- Nunc 4-well dish: 4
- Nunc culture dish: 1
- Goblet: 1
- Cry lock: 3
- Aluminum cane: 1

Amount of Different Media Required Per Patient[38]

- Cleavage media: 2.5 mL
- Extended culture media: 1.5 mL
- Fertilization media: 5 mL
- Sperm rinse: 5 mL
- Flushing media-MOPS: 15 mL
- Hyaluronidase: 0.05 mL
- ICSI polyvinylpyrrolidone (PVP): 0.03 mL
- Double density gradient: 1.0 mL
- Paraffin oil: 12 mL
- Vitrification kit: 4 mL for nine patients
- Warming kit: 4 mL for eight patients.

Optimum Number of Incubators

Minimum two incubators: One incubator is used to store culture media, oil, dishes, and consumables to off-gas before use and the second one is to keep the oocytes after denudation.

Four to five cases can be done at a time with two incubators. So, one extra incubator is needed for every five cases.

If 15–20 cases are in a batch, four to five incubators are needed.

With a benchtop incubator, usually 10 numbers can be done at a time.

Shutting down the laboratory completely in-between batches is not a good practice. Regular inspection of equipment and laboratory cleaning, as well as the air handling unit, need to be monitored regularly in-between

batches.[46-48] An external validation of the laboratory by a quality control expert, if available, would maintain the quality and success of IVF.

CONCLUSION

The outcome of batch IVF depends on laboratory settings, the consultant involved, the clinician, and the embryologist and their availability, planning, and staff. The whole team should be passionately concerned regarding implementing the batch.

KEY POINTS

- Batch IVF still remains in high demand due to the limited number of senior embryologists available and the better convenience of the patients and clinicians.
- Batch IVF is a planned process of recruiting a group of patients, such that the stimulation is started on the same day (±1–2 day window) and OCR falls on the same day (±1–2 day window).[3] The embryo transfer, if in a fresh cycle, falls on the same day (±1–2 day window), day 2, or day 3 following OCR.
- Patient selection is crucial for batch IVF for optimum results.
- Embryologist should be available on the day of OCR, taken as day 0, on day 1 to check fertilization and additional 2 days to plan day 2 or day 3 embryo transfer. If complex procedures such as TESA, MicroTESA, or blastocyst transfer are planned, additional staff and extra time must be allotted.
- Have a referral protocol for the patients who need individualized care and for patients where stimulation has started. But patients get ready early or late for the planned dates of OCR–ICSI-embryo transfer in batch IVF.
- Check the laboratory stocks and keep an adequate supply at least 1 week before the batch.
- Shutting down the laboratory completely in-between batches is not a good practice. Regular inspection of equipment and laboratory cleaning, as well as air handling unit, needs to be monitored regularly in-between batches. External validation of the laboratory by a quality control expert, if available, would maintain the quality and success of batch IVF.

CHAPTER 87

Frozen Embryo Transfer

Hrishikesh Pai, Nandita Palshetkar, Rishma Dhillon Pai, Kinjal Shah, Rohan Palshetkar, Arnav Pai

INTRODUCTION

The field of assisted reproductive technology (ART) has witnessed innumerable developments in the last few decades after the benchmark set by the birth of Louise Brown in 1978 through in vitro fertilization (IVF).

The success in ART depends on multiple factors such as:

- Etiology of infertility and selection of patients
- Multiple follicular stimulations and optimization of stimulation protocols
- Improvements in the oocyte retrieval technique and getting an optimum number of fertilizable oocytes
- Introduction of intracytoplasmic sperm injection (ICSI)
- Proper embryological technique with high-quality embryos
- Dramatic improvements in culture conditions
- Move toward extended embryo culture and blastocyst transfer
- *Efficient cryopreservation program*
- Optimization of laboratory techniques
- Highly receptive endometrium
- Skilled atraumatic embryo transfer (ET)
- Adequate luteal support
- Competent antenatal management.

Cryopreservation means preserving cells and tissues in live condition at such low temperatures that all the cell metabolisms come to a standstill.

The first-ever pregnancy derived from a frozen human embryo was reported by Alan Trounson and Linda Mohr in 1983 (although the fetus aborted spontaneously at about 20 weeks of gestation). The first-term pregnancy derived from a frozen embryo was born in 1984.

Earlier, only the "second best" embryos were frozen after the morphologically best embryos were transferred in fresh cycles. But today with improved cryopreservation techniques, which reduce embryo cryodamage, the confidence in cryopreservation and frozen embryo transfer (FET) has substantially increased. Cohort banking is also becoming a routine after the use of gonadotropin-releasing hormone (GnRH) agonist "trigger" to prevent ovarian hyperstimulation syndrome (OHSS) in high responders. Other reasons for the increased use of FET include an overall reduction in the average number of embryos transferred each time, thus allowing surplus embryos to be cryopreserved. Also, the increased use of genetic screening increases the use of cryopreservation because embryos are often frozen while awaiting test results, and the transfer of confirmed euploid embryos may contribute to increasing FET success rates. Thus, the last decade has seen a tremendous uphill in the use of FET and the live births resulting thereof.

Why should one go for a FET?

The rationale of a FET:[1]

Controlled ovarian stimulation (COS) with exogenous gonadotropins
⇓
Promotes multifollicular development
⇓
Supraphysiological levels of estrogen and progesterone
⇓
Affects endometrial development and maturation

Two frequently observed features in the endometrium after COS are as follows:[2-4]

1. Advanced histology
2. Advanced downregulation of progesterone receptors.

Both are suggestive of an advanced receptive phase resulting in:

↓
↓Endometrial receptivity
↓
Embryo-endometrium asynchrony
↓
Implantation failure

Whether one should go for fresh or FET for a patient depends on several factors such as age, diagnosis, history, follicular stimulation protocol, trigger agent, embryo developmental pace, cryopreservation technique, and its outcome at the respective center.

Although the trends have been rapidly shifting toward cohort cryopreservation and FET on the basis of success rates, there is no standardized single choice for all patients at all centers, and therefore, individualized approach remains appropriate.

Today, ART has progressed to a point where we can offer high success rates to our patients. Our goal must therefore be to give a safe and healthy pregnancy rather than just a pregnancy which may be complicated. One must not take pride in giving multiple pregnancies, but on the contrary, decrease adverse perinatal outcomes by offering single-embryo transfer whenever possible.

Frozen embryo transfers may not be feasible or necessary for all patients, but this approach appears to be an efficient way to decrease morbidity in patients at high risk for adverse outcomes, especially those with high estradiol (E2) levels, early elevated progesterone levels, and those at high risk for OHSS.

INDICATIONS FOR A FROZEN EMBRYO TRANSFER

Frozen embryo transfer can be recommended in the following subset of patients:

- Surplus good-quality embryos
- Follicles >14 on the day of trigger (at high risk for OHSS)
- Fluid in the cavity
- Endometrial thickness is <7 mm or >14 mm
- Previous history of OHSS
- Previous failed fresh transfers
- Spotting on the day of ET
- Serum progesterone is >1.5 ng/mL in normoresponders[5]
- Difficult ET
- Applebaum score <14
- Preimplantation genetic testing
- Before cancer chemotherapy or radiotherapy for fertility preservation.

DIFFERENT METHODS FOR ENDOMETRIAL PREPARATION FOR FROZEN EMBRYO TRANSFER

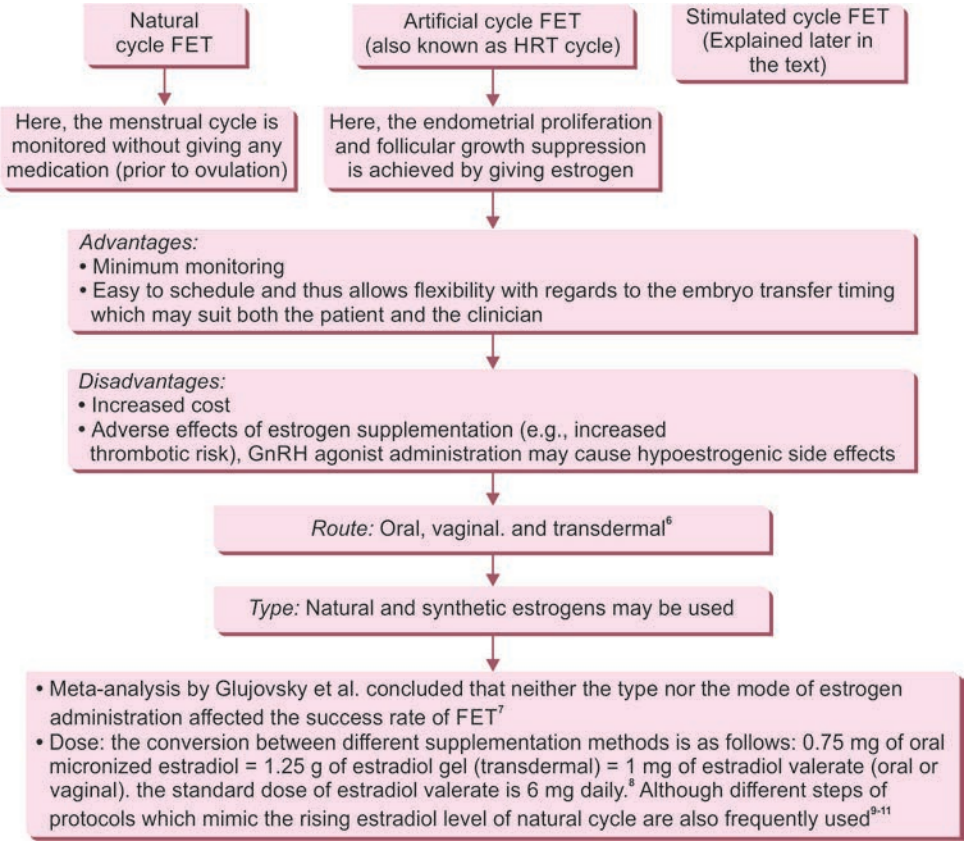
Frozen Embryo Transfer Preparation Methods

Frozen embryo transfer preparation methods are shown in **Flowchart 1**.

Natural Cycle-frozen Embryo Transfer (Table 1)[12]

- Here, no medication is administered to the patient prior to ovulation.
- Replacement of embryos is done in a woman's natural ovulatory cycle with the help of endocrine and ultrasound monitoring.

Flowchart 1: Frozen embryo transfer preparation methods.



(FET: frozen embryo transfer; GnRH: gonadotropin-releasing hormone; HRT: hormone replacement therapy)

TABLE 1: Natural cycle-frozen embryo transfer (NC-FET).

True NC-FET	*Modified NC-FET*
• Here, ovulation is monitored by serial blood luteinizing hormone (LH) or till LH peak is observed, and/or ultrasound • Here, ovulation occurs spontaneously	• Here, triggering of ovulation is done by giving hCG once the dominant follicle is >16 mm

Advantage: Absence of estrogen supplementation

Disadvantages:

- Recommended only in women with regular ovulatory cycles. Cannot be used in women with irregular or anovulatory cycles as in polycystic ovary syndrome (PCOS)
- More frequent visits to the clinic. Only clinics which are functional 7 days a week must offer natural cycle-frozen embryo transfer (NC-FET) to their patients.
- Less cycle control and flexibility
- Higher cycle cancellation rate (up to 6%).[13]

The role of endocrine along with ultrasonography (USG) monitoring is controversial in both true and modified NC-FET. Difficulty arises in assigning an endocrine definition of luteinizing hormone (LH) surge. In clinical practice, many definitions are used including a value of 180% above the latest value of that patient and a continued rise after that[14] to a level of ≥10 IU/L.[15]

Studies comparing the above two types of NC-FET have not shown any significant difference in the clinical outcomes.[16] However, one large retrospective study[17] showed a significant difference in the clinical pregnancy rate (CPR), thus favoring true NC-FET [without luteal phase support (LPS)] compared to the modified NC-FET (with LPS).

But still, we do not have an answer to the best approach.

Is administration of progesterone required in NC-FET?

Prevalence of luteal phase defect (LPD) in normo-ovulatory subfertile patients is around 8%.[18] Here, the serum progesterone level in the midluteal phase is <10 ng/mL.[19]

Overall, the time to initiate LPS in an NC-FET is not clear. Some advocate that starting progesterone soon after the LH surge or human chorionic gonadotropin (hCG) trigger may be too early, thus having a deleterious effect on the window of implantation (WOI). Thus, different protocols will be used in day-to-day practice till further data analysis is obtained.[20]

Stimulated Cycle Frozen Embryo Transfer

- Exogenous mild ovarian stimulation with clomiphene citrate (CC), aromatase inhibitors (AIs), gonadotropins, CC or AI + gonadotropins, and GnRH analogs with hCG trigger with/without LPS has been advocated to increase serum estrogen levels in turn enhancing the endometrial receptivity.
- Here, patients require increased monitoring, are relatively expensive, and do not have the advantages of flexibility with regard to the timing of embryo replacement. Only a few centers use this regimen.
- A recent systematic review[21] concluded that ovarian stimulation with gonadotropins or CC did not increase the live birth rate as compared to the NC.
- Until further research, no strong recommendation can be made for using stimulated cycle FET.

Hormone Replacement with/without Gonadotropin-releasing Hormone Against Downregulation

- In this regimen, the endometrium is prepared with estrogen. It is started on the first or the second of the cycle (which prevents follicular recruitment) in *high-dose fixed regimen* starting with 6 mg/day of E2 valerate or 1.8 mg conjugated equine estrogen (CEE) or 300 μg of transdermal estrogen patches which is given daily for 8–9 days, and then the woman is called for USG or *low variable dose step-up regimen* in which hormones are started with a lower dose and gradually stepped up as the cycle progresses. Tablet E2 valerate may be started at a lower dose of 2 mg once a day for 2 days followed by 2 mg twice a day for 2 days which again is stepped up to thrice a day for 2–3 days. Woman is recalled for endometrial monitoring after 8–9 days of medication for further dose titration. Some clinics also use E2 patches of 100 μg for 2 days followed by 200 μg for next 4 days again stepping up to 300 μg for next 2–3 days.
- Estrogen must be started on day 1 or day 2 of the cycle as starting estrogen after day 3 may cause an LH surge resulting in luteinization of the endometrium. This is especially important when the pituitary is not suppressed with a GnRH agonist.
- Duration of estrogen priming should be minimal of around 8 days and can be extended up to 40–60 days without affecting the cycle outcome.
- This protocol is beneficial for women with irregular cycles.
- Less frequent monitoring required and is more patient-friendly and cost-effective. Also, it allows better control and flexibility of transfer timing.

Downregulated Frozen Embryo Transfer

- This is the most popular method in which endometrial preparation is achieved with exogenous estrogens and progesterone after pituitary downregulation with a GnRH analog so as to prevent spontaneous ovulation.
- This regimen is recommended in women with endometriosis, PCOS, adenomyoma, and history of cycle cancellation in previous FET cycles due to premature luteinization and premature ovulation.

- The advantages include no endocrine monitoring, better patient convenience, and flexibility in scheduling transfer timing. The disadvantages include high cost, risk of hypoestrogenic side effects of the GnRH analog, and long preparation time.
- Ovarian downregulation is started in the previous cycle using daily injections/intranasal dose of GnRH agonist starting from day 21 of previous cycle or 7 days prior to expected menses. Some clinics prefer to use a depot dose 2–3 weeks prior to starting the endometrium preparation using estrogens.

In the hormone replacement, FET with/without prior downregulation, day of initiating progesterone administration corresponds to the day of ovum pick-up (OPU) or the day after OPU for the purpose of synchronization. In the case of day 2 or day 3 cryopreserved embryos, most retrospective studies have commenced progesterone 3 days prior to ET, while in the case of blastocyst transfer, high pregnancy rates have been reported replacing embryos after 5 days of progesterone. Vaginal (gel, suppositories) and intramuscular (IM) routes are common for giving progesterone.

The optimal means of endometrial preparation in frozen–thawed embryo transfer cycles?

A recent meta-analysis by Groenewoud et al.[22] did not find any significant difference in CPR, ongoing pregnancy rate, and live birth rate when comparing NC-FET versus modified NC-FET, NC versus artificial (hormone replacement) cycles, artificial cycles with and without GnRH agonist downregulation, and NC versus artificial cycles with GnRH agonist. Thus, it is not possible to differentiate any particular method of endometrial preparation in FET as being better than the other.

According to the Cochrane database 2008, a significantly higher live birth rate and favorable trends for other outcomes (CPR, endometrial thickness, and cycle cancellation rate) were observed in the GnRH agonist downregulated, hormone replacement FET group as against hormone replacement FET cycles alone.[23]

According to Cochrane Database 2010, which analyzed 22 randomized controlled trials (RCTs), when using GnRH agonist downregulation as against NC-FET, there was no significant advantage demonstrated. There was no evidence of any statistically significant benefit of one GnRH agonist compared to another.[7]

In a Cochrane review by Ghobara et al. in 2017[24] which analyzed 18 RCTs comparing different FET cycle regimens such as NC-FET versus hormone therapy (HT) FET, NC-FET versus HT plus GnRH agonist suppression, NC-FET versus modified NC-FET with hCG trigger, modified NC-FET versus HT FET, modified NC-FET versus HT plus GnRH agonist suppression, HT FET versus HT plus GnRH agonist suppression, and human menopausal gonadotropin (hMG) versus CC plus hMG-induced FET in 3,815 women did not find sufficient evidence to support the use of one cycle regimen in preference to another in subfertile women with regular ovulatory cycles.

IDEAL DURATION OF PROGESTERONE SUPPLEMENTATION BEFORE EMBRYO TRANSFER

In a prospective randomized trial by Van de Vijver et al.,[25] it was shown that when a cleavage stage day 3 embryo (vitrified-thawed) after overnight culture was transferred on the 3rd or on the 5th day of progesterone administration, the CPRs were similar. However, early pregnancy loss was significantly higher in the latter group. Thus, ET of a day 4 embryo (i.e., day 3 embryo warmed the day before, and thus, developed to a day 4 embryo at the time of transfer) on the 3rd day of progesterone administration appears to be almost deleterious.

The risk of early pregnancy loss is increased when progesterone is administered for a duration shorter than the age of the embryo. On the contrary, transferring a day 4 embryo on the 5th day of progesterone supplementation which might be too long, but there is no available evidence about the impact on success rates.[9]

An explanation to the above could be that 3 days of progesterone supplementation is not long enough to induce a sufficiently decidualized endometrium. Also, it could be hypothesized that a delayed embryo has a higher chance of still finding an open WOI and thus implanting but leading to an early pregnancy loss when progesterone was administered for 3 days before ET. Thus, the *optimal timing* has still not been established yet.[26]

It has been advised to commence progesterone from the theoretical day of oocyte retrieval in hormone replacement therapy (HRT), e.g., a day 3 embryo on the 4th day of progesterone written as P + 3, a day 5 embryo on the 6th day of progesterone written as P + 5, and to perform blastocyst transfer at hCG + 7 or LH + 6 in modified or true NC, respectively.[12]

A Cochrane database review by Glujovsky et al. concluded that starting progesterone at a time equivalent to the day of or the day after OPU results in a significantly increased pregnancy rate compared to starting progesterone a day before the day equivalent to oocyte retrieval.[7]

After a failed fresh transfer when can one go for a frozen embryo transfer?

In a retrospective cohort study by Santos-Ribeiro et al.[27] (i.e., <22 days of oocyte retrieval), FET performed immediately after fresh IVF cycles had CPR similar to those postponed to a later date (>22 days of oocyte retrieval). Therefore, postponing FETs may unnecessarily prolong time to pregnancy.

Thus, this above study proved that ovarian stimulation did not seem to have a carryover effect on CPR per FET, thus allowing patients to choose FET without delay or at their

own convenience, thus reducing their frustration associated with the waiting period of IVF treatment.

In clinical practice, commonly followed is:

Previous cycle downregulation with single-dose GnRH agonist 3.6 mg goserelin acetate subcutaneous (SC)

Or

3.75 mg single-dose leuprolide acetate SC/IM
(approximately 10 days prior to expected menses)

↓

Day 2 scan to confirm downregulation
ET <5 mm, E2 <50 pg/mL, absence of any ovarian cyst. To start estrogen 2–6 mg/day

↓

Optimum ET 9–12 mm triple line. Progesterone started depending on the embryonic status.

Limited need for endocrine monitoring in FET. Measurement of serum progesterone (highly controversial)—not usually measured.

TO BRIEFLY UNDERSTAND THE TECHNIQUE OF CRYOPRESERVATION

Cryoprotectant Agents

Both permeable and nonpermeable cryoprotectant agents (CPAs) are used usually in a mixture for freezing either by the slow freezing method or vitrification. They protect the cells from cryoinjuries, stabilize intracellular proteins, lower the intracellular water freezing point, and most importantly, they reduce or eliminate lethal intracellular ice formation. Examples of permeable CPAs are glycerol, ethylene glycol (EG), 1,2-propanediol (PrOH), dimethyl sulfoxide (DMSO), propylene glycol, acetamide, and raffinose. Examples of nonpermeable CPAs are sugars such as sucrose, trehalose and glucose, galactose, polymers such as polyvinylpyrrolidone, polyethylene glycol, ficoll, dextran, hydroxypropyl cellulose, polyvinyl alcohol, and proteins like egg yolk. The strategy to decrease the toxicity of one CPA is to use a mixture of two permeable CPAs. EG and DMSO combination is the most frequently used. EG is an almost indispensable component of all CPAs due to low toxicity, high permeability, and excellent prevention of ice crystal formation. Recently, sucrose has become a standard component in vitrification solutions (VS).

Techniques of Cryopreservation

There are two techniques of cryopreservation:

1. Slow freezing method
2. Vitrification method

Slow Freezing Method (Equilibrium Cooling)

This is a slow-rate freezing method. Here, extracellular ice formation drives cellular dehydration through an equilibrium process.

Embryos are exposed to 1–2 mol/L solutions of permeable and nonpermeable CPAs, and then loaded into straws, sealed and cooled rapidly to –6°C by placing the straws into a controlled-rate freezer. With this low concentration of CPAs, no spontaneous ice crystal formation occurs at this temperature. But ice nucleation is induced by "seeding," i.e., touching the straw with forceps that has previously been immersed into liquid nitrogen (LN_2), which is performed far away from the embryo and this ice grows stepwise toward the embryo. The controlled-rate freezer is adjusted to make a very slow cooling (usually 0.3°C/min to around –30°C) after which the straws are immersed into LN_2 for a final cooling and storage. The slow rate of this procedure permits solution exchange between the extracellular and intracellular fluids without any serious osmotic effects (this fact is reflected in the other method called vitrification).

Problems usually encountered with slow freezing are intracellular ice crystal formation, increased exposure to CPAs as it is a slow procedure, abnormal concentration of intracellular solutes due to excessive dehydration, and ice crystal formation during thawing. Also, the equipment is expensive.

Vitrification Method (Nonequilibrium Cooling)

It is a form of rapid cooling which utilizes very high concentrations of CPAs that solidify without forming ice crystals **(Fig. 1)**.

Procedure: The main purpose of this method is the complete elimination of ice crystal formation in the whole solution containing the oocytes and embryos. The reduction in the ice crystal formation rate can be achieved by either increasing the concentration of CPAs or by increasing the cooling and the warming rates. If the cooling rate is higher, then lower concentration of CPA is required and vice versa. Recent vitrification methods have focused on increasing the cooling and warming rates to decrease the potential osmotic and toxic damage caused by the high concentration of CPAs.

Vitrification process: It involves the use of two cryosolutions: (1) Equilibration solution (ES)—a HEPES

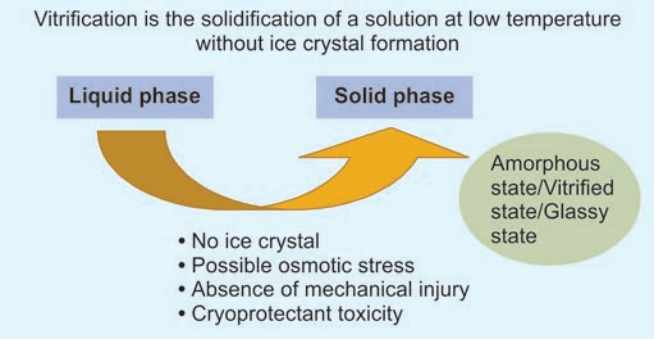


Fig. 1: Vitrification method.

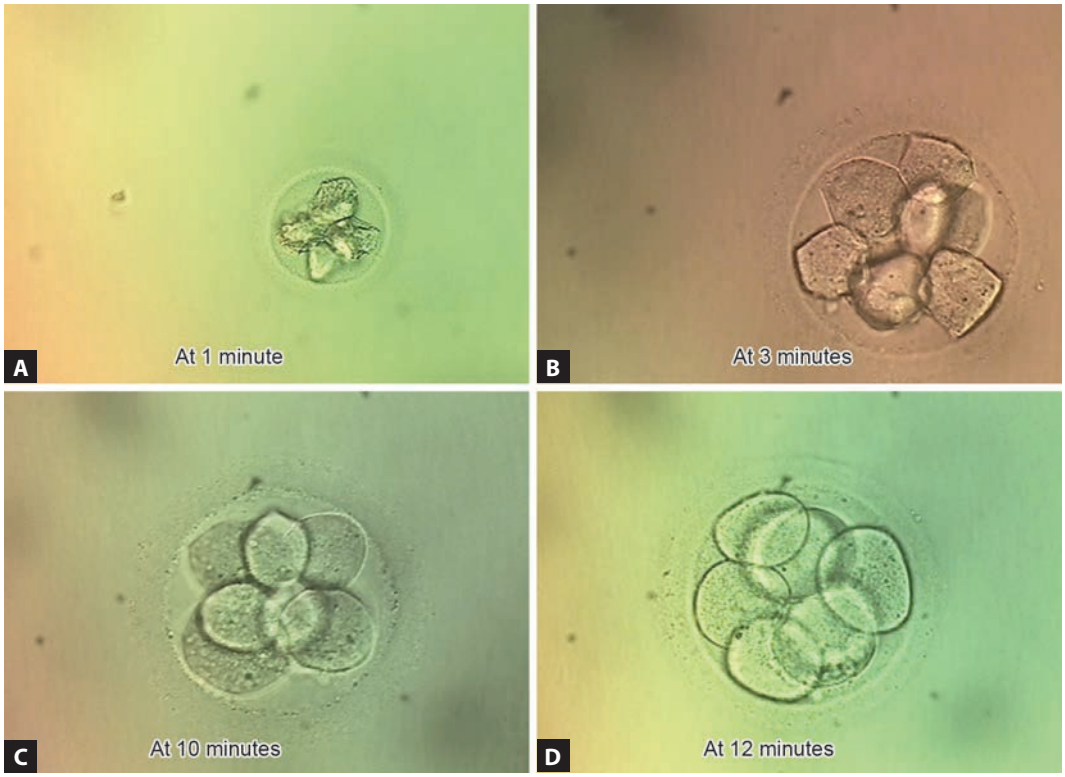
[4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid]-buffered medium containing 7.5% (v/v) of each DMSO and EG and 20% (v/v) of serum protein substitute and (2) VS—a HEPES-buffered medium, 15% (v/v) of each DMSO and EG and 20% (v/v) serum protein substitutes and 0.5 M sucrose. The oocytes/embryos/blastocysts are suspended initially in the ES (approximately 12 minutes for embryos and approximately 15 minutes for oocytes and blastocyst) **(Figs. 2 and 3)** and then washed serially in the VS for approximately 90 seconds. Then depending on the carrier used, it may be open-system freezing (carrier: CryoTop, CryoTech, CryoLock, and CryoLoop) or closed-system freezing (carrier: high security vitrification (HSV) straw and CryoTip).

Cryoinjuries may occur at all phases of the procedure. There is an increasing concern about possible disease transmission between the stored samples mediated by LN_2, even though there are no reported cases in literature involving embryos.

Embryos subjected to cryopreservation may undergo considerable damage during cooling and warming. Fortunately, these embryos have the ability to repair fully or partially this damage and thus continue with normal development.

The main difference between slow freezing and vitrification is that in vitrification, the oocyte/embryo and the surrounding solution solidify in an amorphous structure similar to glass but without ice crystal formation.

Various studies and the meta-analysis by Loutradi et al.[28] proved that vitrification was associated with higher post-thaw survival rate than slow freezing. Today, vitrification as a method to cryopreserve oocytes and embryos has achieved remarkable success due to its multiple advantages such as being rapid, simple, inexpensive, higher survival, and developmental rates.



Figs. 2A to D: Vitrification of embryos showing initial shrinkage and recovery of embryos in equilibration solution (ES).

Figs. 3A to C: Vitrification of blastocyst showing initial shrinkage and recovery of blastocysts in equilibration solution (ES).

There are certain controversial areas with cryopreservation:

- Toxicity and long-term effects of the CPAs used
- Chances of viral transmission in open systems
- Higher miscarriage rate.

Potential sources of contamination include:

- Within the freezing apparatus
- During storage
- From LN_2.

European Union directive dictates that cooling and storage of embryos must be performed in a way that minimizes the risk of contamination. Basic recommendations [Human Fertilization and Embryology Authority (HFEA), 1998] for safe storage are:

- Patient screening for hepatitis B, hepatitis C, and human immunodeficiency virus (HIV)
- Careful hygiene throughout
- Double containment of storage straws
- Use of sealed ampoules.

Regarding the safety of vitrification, no currently available data indicate a higher incidence of malformation, which is reassuring but needs to be confirmed on a large scale. Theoretical risk of disease transmission with the open system is there which can be taken care of by the closed system.

There is no doubt that closed system should be preferred provided the outcome is comparable with open systems. Results achieved by using closed system for cleavage stage embryos and blastocysts are promising.[29,30] Studies have shown that open systems are more likely to produce superior results when oocytes are vitrified and to preserve the original physiological cell condition.[31,32]

FRESH VERSUS FROZEN EMBRYO TRANSFER

A randomized trial has shown that FET has been associated with a reduced risk of implantation failure when compared with fresh transfer. This randomized trial involved conventional slow freezing of entire cohorts of bipronuclear oocytes, with subsequent thaw of the entire cohorts, post-thaw extended culture to the blastocyst stage, and transfer of the two best blastocysts from each cohort. Post-thaw culture was used to ensure that transferred embryos were free of cryodamage, as demonstrated by their resumed development to morphologically acceptable blastocysts. Resumed development is a more rigorous indicator of post-thaw viability than immediate post-thaw survival assessment alone.[1]

Advantages of frozen–thawed ET:

- Separation of ET from the stress and rigors of ovarian stimulation
- Decrease in uterine stress, childhood, and adulthood diseases (Barker hypothesis)[33]
- Transferring embryos in a more physiologic rather than a hyperstimulated environment
- Ideal endometrial receptivity and high pregnancy rates
- An increase in cumulative pregnancy rate
- Lesser monitoring which ensures a better patient compliance
- Decreasing the risk of OHSS (OHSS-free clinic)
- Providing a more objective decision to transfer fewer embryos (or a single embryo)
- Possibility of genetic testing
- Decreasing perinatal and maternal morbidity benefits of FET
- In case of surplus embryos which are cryopreserved, it gives psychological support to the patient and clinician that FET can be done even though the fresh cycle has failed.

Disadvantages of frozen–thawed ET:

- Exposure to high concentration of chemicals
- Exposure to extreme temperature gradients
- Increased manipulation of the embryo
- Long-term studies on effects on pregnancy following vitrification not available
- Some studies have shown that FETs are 1.7 times more likely to result in *spontaneous abortions* than those following fresh ETs.[34]

Frozen embryo transfer with respect to maternal and fetal risks has been shown in **Table 2**.[35]

In a multicenter trial[36] involving randomly assigned 1,508 infertile women with PCOS who were undergoing their first IVF cycle underwent either fresh ET or embryo cryopreservation followed by FET. The primary outcome was a live birth after the first ET. They found FET resulted in a higher frequency of live birth after the first transfer than did fresh ET (49.3 vs. 42.0%), a lower frequency of pregnancy loss (22.0 vs. 32.7%), and of OHSS (1.3 vs. 7.1%), but a higher frequency of preeclampsia (4.4 vs. 1.4%). There were no significant differences between groups in rates of other pregnancy and neonatal complications. The study concluded that in subfertile women with PCOS, FET was associated with

TABLE 2: Comparison of the risks in frozen embryo transfer (FET).

Reduced risks in FET	*Increased risks with FET*
• Ovarian hyperstimulation syndrome (OHSS) • Low birth weight (LBW) (<2,500 g) • Small for gestational age (SGA) • Preterm birth (<37 weeks) • Preterm LBW • Antepartum hemorrhage • Placenta previa • Abruptio placenta • Perinatal mortality	• Placenta accreta • Macrosomia (>4,500 g) • Large for gestational age (LGA) • Increased C-section rate

a higher rate of live birth, a lower risk of OHSS, and a higher risk of preeclampsia after the first transfer than with the fresh ET.

In a meta-analysis of RCTs by Matheus Roque[37] comparing IVF outcomes between fresh and FETs showed that FET resulted in significantly increased clinical and ongoing pregnancy rates. The authors suggest that there is evidence that IVF outcomes may be improved by performing FET compared with fresh ET due to a better embryo-endometrium synchrony achieved with endometrium preparation cycles.

In a meta-analysis,[38] comparing obstetric and perinatal outcomes in singleton pregnancies after a frozen–thawed ET compared to a fresh ET, singleton pregnancies after FETs had better perinatal outcomes compared with those after fresh transfer. The relative risks (RRs) and 95% confidence interval (CI) of antepartum hemorrhage, preterm birth, small for gestational age, low birth weight, and perinatal mortality were lower in women who had FET. This meta-analysis suggested that pregnancies resulting from FET seemed to have better obstetric and perinatal outcomes.

Freeze All: The Debate Continues?

In a prospective cohort study by Matheus Roque,[39] which compared IVF outcomes between fresh ET and FET (the freeze all) where fresh ET was performed only in cases without progesterone elevation, the IVF outcomes were significantly better in the group using the freeze-all policy compared with the group using fresh ET. These results suggest that even in a select group of patients that underwent fresh ET (progesterone levels ≤1.5 ng/mL), endometrial receptivity may have been impaired by COS and outcomes may be improved by using a freeze-all policy.

In a Cochrane review by Wong et al.[40] where four randomized clinical trials were analyzed, there was no clear evidence of a difference in cumulative live birth rate between freeze-all strategy and the conventional IVF–ICSI strategy. The prevalence of OHSS was lower after the freeze-all strategy (1–3%) compared to the conventional IVF/ICSI strategy (7%). There was low-quality evidence to suggest that freeze-all strategy was associated with fewer miscarriages [odds ratio (OR) 0.67, 95% CI 0.52–0.86] and a higher rate of pregnancy complications (OR 1.44, 95% CI 1.08–1.92).

Although the major advantage of a freeze-all strategy is the potential for eliminating OHSS, several other factors also support a move toward this approach in ART. Enhanced cycle scheduling and improved organization of the IVF unit are elements that should not be overlooked. Taken together, these developments may lead to a new era in modern ART. Nevertheless, confirmation of the clinical benefits of a freeze-all strategy through well-designed clinical trials are mandatory prior to shifting our current ART practice.

A recent strengths, weaknesses, opportunities, and threats (SWOT) analysis with freeze all was summarized by Christophe Blockeel[41] in **Figure 4**.

For a successful freeze-all program, it would be mandatory to have the "best" laboratory and vitrification technique to implement freeze all on a routine basis. Although preclinical data suggest an inverse relationship between COS and endometrial receptivity, clinical data are controversial. Benefits of elective FET are likely limited to women with hyperovarian response. Clinical evidence is against elective FET for women with poor/suboptimal ovarian response. Current data regarding ART or obstetric outcome do not support a universal freeze-all strategy.[42]

Also, safety with regards to any long-term implications with FET, primarily due to its technique, is a concern which only will be proven with time.

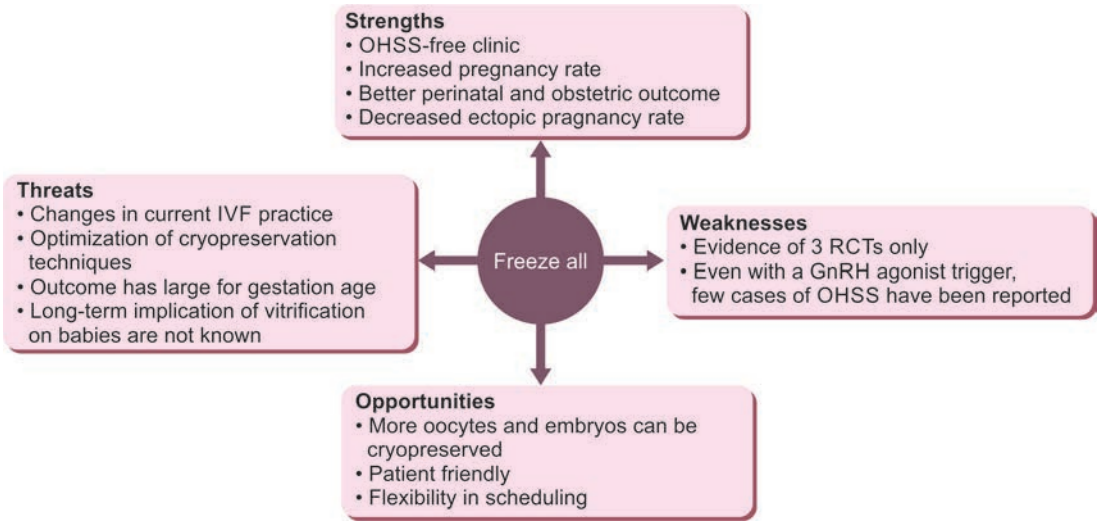


Fig. 4: Strengths, weaknesses, opportunities, and threats (SWOT) analysis. (GnRH: gonadotropin-releasing hormone; IVF: in vitro fertilization; OHSS: ovarian hyperstimulation syndrome; RCTs: randomized controlled trials)

CONCLUSION

- Years ago, cryopreservation techniques were relatively poor, and this balance leaned heavily toward fresh transfer. With the introduction of vitrification, cryopreservation techniques have significantly improved.[43] Vitrification/warming gives a significantly higher survival, fertilization, embryo cleavage and development, and CPRs.[28]
- As there began improvements in this technique, the balance now shifts more in favor of FET.
- Controlled ovarian hyperstimulation in ART cycles causes an asynchrony between the endometrium and the transferred embryos, which may lead to an implantation failure.
- In FETs, this synchrony can be achieved with natural/HRT. This improves the pregnancy rate.
- Increasing numbers of elective single-ETs are also resulting in more frozen embryos (blastocysts) available for subsequent FET cycles.
- In a subset of patients such as high anti-Müllerian hormone (AMH) or out-of-phase endometrium or for prevention of OHSS, FET gives a better pregnancy rate than fresh transfers.
- Time and, hopefully, high-quality research will establish if we are ready to eliminate the transfer of "fresh" embryos in IVF. However, the practice is already shifting.

KEY POINTS

- Natural cycles benefit from vaginal progesterone starting after ET. They are most appropriate for patients with regular ovulatory cycles who are able to comply with strict regimen of frequent urine and blood hormonal measurements.
- Modified natural FET cycles need USG monitoring and blood hormonal testing to decide the optimal time for hCG trigger. Luteal support with progesterone may not be given due to the luteotropic effect of hCG. Thus, progesterone support after ET is optional.
- Programed FET cycles are the most convenient because of limited monitoring requirements and flexibility of scheduling. However, they have not been shown to be superior to properly timed natural or modified natural FET protocols. There is no one single optimal form of progesterone from the available data. Patients' preference, convenience, and cost must be considered when choosing either vaginal or IM progesterone preparations. Alternative options for progesterone supplementation in FET cycles—SC and oral—should be evaluated with adequately powered RCTs.[44]

CHAPTER 88

Evidence-based Practice in Reproductive Medicine

Parimala Chinta, Mohan S Kamath, Korula George

INTRODUCTION

The use of assisted reproductive technology (ART) for the treatment of infertility has been increasing across the world. In view of the limited success following ART, newer treatments and interventions are being introduced in clinical practice at a very rapid pace. In many cases, the effectiveness of these treatments may not be clearly established at the time of introduction in the clinical setting.

In this chapter, we have examined the current evidence status for many of the controversial areas in the field of ART which are of importance in the daily clinical practice of ART.

CONTROVERSIAL AREAS IN PRACTICE

- Preimplantation genetic test (PGT)
- Time-lapse technology
- Screening hysteroscopy pre-in vitro fertilization (IVF)
- Luteal phase support in IVF
- Metformin before IVF
- Freeze-all strategy.

Preimplantation Genetic Testing

Background

One of the reasons for low live birth rate (LBR) post IVF is the transfer of chromosomally abnormal embryos. It is hypothesized that transfer of euploid embryos may increase the LBR.[1] PGT, formerly known as preimplantation genetic screening/preimplantation genetic diagnosis (PGS/PGD), involves an embryo biopsy and screening of embryo for chromosomal abnormalities.[2] This includes PGT for screening aneuploidy (PGT-A), PGT for monogenic or single-gene defects (PGT-M), and PGT for structural rearrangements of chromosomes (PGT-SR).[3] The suggested indications for PGT include women with advanced age, recurrent implantation failure (RIF), severe male infertility, and recurrent pregnancy loss (RPL) that are all likely to be associated with higher aneuploid embryos.[2,4,5]

Evidence

Initial PGT involved cleavage stage biopsy of one or two blastomeres and aneuploidy screening with fluorescence in situ hybridization (FISH). In a large multicenter, randomized, double-blinded trial, investigators included a total of 408 women of advanced age and compared three cycles of IVF with (n = 206) or without PGT (n = 202).[6] The main outcome, i.e., the ongoing pregnancy rate per woman, was significantly lower following PGT compared to the control group [25 vs. 37%; risk ratio (RR) 0.69; 95% confidence interval (CI) 0.51–0.93]. The live birth was significantly lower following PGT (25 vs. 35%; RR 0.68, 95% CI 0.50–0.92). Other trials also obtained lower pregnancy rates following PGT compared to the control group. The reason for lower pregnancy rates was mainly attributed to the limitations of FISH to screen all the chromosomal abnormalities and deleterious effect of blastomere biopsy on LBRs.[7] Hence, uptake of PGT with cleavage stage biopsy using FISH has reduced, and the search for more advanced aneuploidy screening method continued.

Technology for comprehensive chromosomal screening (CCS) was combined with trophectoderm biopsy at the blastocyst stage for PGT.[8,9] A platform for CCS includes array comparative genomic hybridization (aCGH), single nucleotide polymorphism microarrays, quantitative polymerase chain reaction (qPCR), and next-generation sequencing (NGS).[8-11] NGS results have been found to be comparable to aCGH for PGT.[11] NGS has advantages due to potential automation, which reduces human errors and results in higher consistent output.[11] In smaller randomized controlled trials (RCTs) involving women with good prognosis, PGT with CCS has been found to have significantly higher LBRs per cycle in comparison to IVF without PGT.[9,12,13] A systematic review included three RCTs with good prognosis women and found significantly higher ongoing pregnancy rates following CCS with PGT as compared to those women doing IVF without PGT.

The multiple pregnancy rates were significantly lower in PGT group compared to IVF without PGT, though the authors did not present the pooled results in this review.[2] In another systematic review that analyzed RCTs and cohort studies comparing IVF with a normal morphological screening versus PGT screening of embryos, four RCTs were included, but results for clinical pregnancy and ongoing pregnancy rates were available for only two trials. The pooled results showed that the clinical pregnancy (RR 1.26, 95% CI 0.83–1.93) and ongoing pregnancy (RR 1.31, 95% CI 0.64–2.66) rates did not reach a statistically significant difference.[14] The review did show significantly better outcomes following the pooling of results from cohort studies.

A recent multicenter RCT [STAR (Single Embryo TrAnsfeR of Euploid Embryo) trial] has evaluated the use of NGS-based PGT-A (n = 661) for selecting the embryos. The authors concluded that PGT-A showed no improvement in the overall ongoing pregnancy outcomes in women between 25 and 40 years as analyzed per embryo transfer (50% in the PGT-A group and 45.7% in the control group; p = 0.32) or per woman randomized (41.8 vs. 43.5%; p = 0.65).[15] However, in the subgroup of women of age 35–40 years, the ongoing pregnancy rates per embryo transfer were significantly higher (50.8 vs. 37.2%; p = 0.035), but when analyzed by intention-to-treat (ITT), there was no significant difference (41.1 vs. 35.7%; p = 0.35).[15]

A Cochrane update included 13 trials and evaluated the role of PGT-A in women undergoing ART for blastocyst biopsy. Evidence shows that it is uncertain if LBR after the first embryo transfer increases following PGT-A [n = 661, odds ratio (OR) 0.93, 95% CI 0.69–1.27, one RCT] and the quality of evidence is low. Similarly, whether PGT-A reduces miscarriage rate is also uncertain (n = 661, OR 0.89, 95% CI 0.52–1.54, one RCT) and the evidence quality is low.[16] In a multicenter randomized trial, women aged between 20 and 37 years with blastocysts screening done by NGS were divided into PGT-A group (n = 606) and conventional-IVF group (n = 606). The primary outcome was the cumulative LBR after three embryo transfers within a year post randomization. LBRs were 77.2% in the PGT-A group versus 81.8% in the conventional-IVF group [absolute difference (AD), −4.6; 95% CI, −9.2 to −0.0; p < 0.001]. Conventional IVF has shown to have a cumulative LBR similar to the rate following PGT-A among women with three or more high-quality blastocysts.[17]

Overall, the current evidence from large RCTs suggests lack of benefit of PGT-A compared to routine IVF in women. A paucity of high-quality trials comparing CCS with PGT to routine IVF in women with RIF, RPL, and severe male factor has been observed. There have been concerns raised on the widespread adoption of PGT technologies without clear benefits being shown.[18,19] Further, one group reported deliveries of healthy babies following the transfer of mosaic aneuploid blastocysts.[20] This finding raised questions on the practice of not transferring mosaic aneuploid embryos, which potentially influenced the outcomes following PGS.

Evidence Summary

- Earlier, PGT, which involved cleavage stage biopsy and FISH, was shown to have a significantly lower LBR in women with advanced age.
- PGT with newer CCS technologies along with trophectoderm biopsy has shown lack of benefit in good prognosis women as compared to routine IVF.
- Presently, there is a lack of trials comparing ART with and without newer PGT technologies in women with RIF, RPL, and severe male factor.

Practice Point

Currently, PGT can be offered only under the research setting after proper counseling in women with advanced age, RIF, RPL, and severe male factor.

Time-lapse Technology

Background

Time-lapse system (TLS) is a device with a technology that captures multiple images of embryo development at set time intervals. The integrated TLS has time-lapse camera and the incubator in one device. Images that are displayed can be assessed for morphology by the embryologist without taking the embryo out of the incubator. Some of these systems utilize software algorithms using morphokinetic parameters, which help in noninvasive way of embryo assessment and selection.

Evidence

A systematic review critically evaluated morphokinetic parameters as assessed by time-lapse microscopy (TLM) and clinical outcomes. The studies included in the review suggested that the implantation rate was higher among the embryos which cleaved early and those with timely duration of two-cell and three-cell stages, but no single parameter which could predict implantation potential was identified. The review concluded that no high-quality evidence is available to support routine use of TLM for embryo selection.[21]

A systematic review evaluating TLS versus single-point morphological assessment included five RCTs analyzing 1,637 women.[22] The pooled ongoing pregnancy rates (51 vs. 39.9%; p < 0.0001) and LBRs (44.2 vs. 31.3%; p = 0.004) were significantly higher following TLM as compared to conventional incubation, and the quality of evidence was moderate. However, three trials reported live birth as an outcome, and one of the trials was categorized at a high risk of bias.

A Cochrane systematic review compared the effectiveness of TLS with conventional morphology assessment of still images and conventional incubation and embryo assessment. The authors reported no significant differences in the LBR/ongoing pregnancy (OR 0.91; 95% CI 0.67–1.23, three RCTs) or the clinical pregnancy rates (OR 1.06, 95% CI 0.79–1.41, four RCTs) between the two methods of assessment and the evidence quality was low.[23] Comparing TLS utilizing embryo selection software versus conventional incubation of embryos and assessment in women undergoing ART, they found three RCTs involving 1,617 women. It is unclear whether there is any difference in LBR (OR 1.12; 95% CI 0.92–1.36) between TLS versus conventional embryo assessment. It was unclear, based on low-quality evidence, whether there is any difference in clinical pregnancy rates following TLS utilization of embryo selection software and conventional assessment (OR 0.95; 95% CI 0.78–1.16). The review concluded that there is lack of high-quality evidence to choose between conventional incubation systems versus TLS with or without the embryo selection software.[23]

Evidence Summary

- While TLS appears to be a promising tool for noninvasive methods of embryo selection, no single morphokinetic parameter is predictive of higher implantation potential.
- Low-quality evidence suggests higher clinical pregnancy rates following TLS versus conventional incubation.

Practice Points

- It is not clear if the suggested benefit of TLS is due to undisturbed culture condition or improved embryo selection.
- High-quality trials are needed to further validate the effectiveness of TLS and evaluate the cost-effectiveness before it can be adopted in routine clinical practice.

Pre-In Vitro Fertilization Screening Hysteroscopy

Background

Hysteroscopy is a commonly performed diagnostic procedure to evaluate the uterine cavity. It allows simultaneous detection and treatment of uterine cavity abnormalities during the same sitting and the procedure then being called an operative hysteroscopy. During the procedure, a telescope is introduced into the cervix and advanced into uterine cavity, and it can be usually carried out as an outpatient procedure.

Screening hysteroscopy is performed in asymptomatic woman without any abnormalities detected during routine pelvic imaging (e.g., transvaginal ultrasound). It is now being offered commonly before IVF as a screening procedure.[24]

Evidence

Initial randomized trials included women with at least previous two IVF failures, and significantly higher pregnancy rates were reported in women undergoing pre-IVF hysteroscopy versus no hysteroscopy.[25,26] A systematic review (n = 1,691) included two randomized and three nonrandomized trials to evaluate the role of outpatient hysteroscopy prior to IVF.[27] Most of the studies have included women with at least two previous IVF failures, and the pooled results (RR 1.75; 95% CI 1.51–2.03; $p < 0.00001$) suggested that pregnancy rates were significantly higher following hysteroscopy in relation to the control arm. Another systematic review evaluated the role of hysteroscopy in women undergoing their first IVF.[28] It included (n = 3,179) one randomized and five nonrandomized trials. The pooled results suggested a significantly increased clinical pregnancy rate (RR 1.44; 95% CI 1.08–1.92) per cycle with hysteroscopy followed by IVF, while the LBR per cycle did not show any significant difference (RR 1.30; 95% CI 1.00–1.67) after hysteroscopy. A high-quality, multicenter, randomized trial evaluated the role of screening hysteroscopy in women undergoing RIF (at least two unsuccessful IVF ending in embryo transfers) and included 350 and 352 women in hysteroscopy and control arm, respectively.[29] No significant difference was observed between LBR per woman randomized (29 vs. 29%; RR 1.00; 95% CI 0.79–1.25; p = 0.96). During the trial, 26% women had uterine abnormalities detected during hysteroscopy. Another similar multicenter randomized trial evaluated the role of pre-IVF hysteroscopy in women undergoing their first IVF and included 373 women in hysteroscopy and 377 in the control group.[30] The LBR per woman randomized was not significantly different (57 vs. 54%; RR 1.06; 0.93–1.20; p = 0.41) between the two groups. The live birth among women with treated uterine abnormalities as compared to those with untreated abnormalities was not significantly different as well (p = 0.69).

A recent Cochrane systematic review analyzed 10 trials with women who had a screening hysteroscopy (n = 1,836) and women who did not undergo hysteroscopy prior to ART (n = 1,914). Low-quality evidence suggests that screening hysteroscopy before ART may increase LBR (RR 1.26, 95% CI 1.11–1.43; six RCTs). However, analyzing the pooled results from high-quality trials showed no increase in LBR with the intervention (RR 0.99, 95% CI 0.82–1.18; two RCTs). Performing a screening hysteroscopy before ART may show an increase in the clinical pregnancy rate (RR 1.32, 95% CI 1.20–1.45; 10 RCTs), but the evidence quality is low.[31]

Evidence Summary

- While early studies show some beneficial effects with screening hysteroscopy before IVF in RIF, the recent systematic review reported uncertain evidence whether

performing routine screening hysteroscopy increases live birth, either for all women or for those women with two or more unsuccessful IVF cycles
- Current evidence does not support screening hysteroscopy before the first IVF.

Practice Points

Screening hysteroscopy may be considered in a selected group of women with RIF and suspected intracavitary pathology or previous history of difficult embryo transfer.

Luteal Support in In Vitro Fertilization

Background

Following controlled ovarian hyperstimulation (COH) during IVF, the steroid hormones, namely estrogen and progesterone, attain supraphysiological levels. These high levels of steroids lead to negative feedback on the hypothalamic–pituitary axis and consequently lower luteinizing hormone (LH), resulting in withdrawal of support to the corpus luteum and defective luteal phase.[32] This shortened and defective luteal phase, commonly known as premature luteolysis, can reduce pregnancy rates following IVF.

Since levels of progesterone are insufficient due to premature luteolysis, additional progesterone supplement is needed. Progesterone is given either alone or in combination with estrogen. Progesterone levels can be maintained indirectly by administering human chorionic gonadotrophin (hCG) or gonadotropin-releasing hormone (GnRH). Only progesterone is the most common form of luteal support and is usually given by vaginal, intramuscular (IM), or oral routes.

Evidence

The recent Cochrane update evaluated different luteal support protocols and routes of progesterone administration.[33] A single RCT result suggests no difference in LBR per woman randomized to IM versus oral route (OR 0.71, 95% CI 0.14–3.66), and the evidence was of very low quality. Similarly, very low-quality evidence from seven RCTs showed no difference in live birth per woman randomized for IM versus vaginal or rectal route (OR 1.37, 95% CI 0.94–1.99); and vaginal/rectal versus oral route (four RCTs, OR 1.19, 95% CI 0.83–1.69) subcutaneous (SC) versus vaginal gel route (two RCTs, OR 0.92, 95% CI 0.74–1.14) and the quality of evidence was low. The update concluded that no particular route of progesterone administration is superior.

A systematic review comparing oral progesterone (dydrogesterone) versus vaginal route progesterone included eight RCTs.[34] The ongoing pregnancy rates were not significantly different between both the groups (RR 1.04, 95% CI 0.92–1.18, seven RCTs, 3,134 women). Two out of three included studies reported on lower dissatisfaction rates following oral progesterone compared to vaginal option. Overall, the authors concluded that oral progesterone is as effective as vaginally administered progesterone.

A randomized trial compared the efficacy and safety of oral progesterone (n = 520) versus micronized progesterone (n = 511).[35] The ongoing pregnancy rates in oral (37.6%) and vaginal progesterone groups (33.1%) were similar. The authors concluded that since the oral route was more patient friendly, it may replace the vaginal route in clinical practice.

An open-label RCT, which included 800 women, evaluated SC progesterone versus vaginal progesterone.[36] The live birth (41.1 vs. 43.1%) and ongoing pregnancy rates (41.6 vs. 44.4%) were not significantly different in this non-inferiority trial. An individualized patient data meta-analysis compared the effectiveness of SC versus vaginal route and included 1,435 women. The ongoing pregnancy likelihood (OR 0.86, 95% CI 0.69–1.07) between both the groups did not reach statistical significance.[37]

Five RCTs with n = 833 women showed that hCG regimens alone or along with progesterone did not increase the live birth outcomes as compared to progesterone alone (OR 0.95, 95% CI 0.65–1.38).[33] The ovarian hyperstimulation syndrome (OHSS) rate was significantly lower with progesterone alone versus hCG regimens (five RCTs, 1,293 women, OR 0.46, 95% CI 0.30–0.71).

Progesterone alone versus combination of progesterone and GnRH agonist resulted in lower LBR (nine RCTs, n = 2,861, OR 0.62, 95% CI 0.48–0.81) though the quality of evidence was low.[33] There was no difference in LBR when progesterone alone was compared with progesterone with estrogen combination (OR 1.12, 95% CI 0.91–1.38, nine RCTs, 1,651 women). According to the recent European Society of Human Reproduction and Embryology (ESHRE) guideline on controlled stimulation during IVF, in cycles with hCG as trigger, a GnRH agonist bolus along with progesterone for luteal phase support can be used in a clinical trial context only.[38]

In case GnRH agonist is used as trigger instead of hCG, modified luteal support is advocated. In case a fresh transfer is planned, then small bolus of hCG (1,500 IU) is given post-oocyte retrieval, and intensive support of estradiol and progesterone is started.[39]

Use of aspirin during IVF as compared to placebo/no treatment did not show any increase in clinical pregnancy rate (RR 1.03, 95% CI 0.91–1.17, 10 RCTs, n = 2,142).[40] There is a lack of robust evidence favoring use of vasodilators such as sildenafil citrate or heparin as IVF adjuvants.[41] Addition of low-dose prednisolone to progesterone for luteal support has also not shown improved clinical pregnancy rates.[42]

Evidence Summary

- Among vaginal, oral, and IM administration of progesterone, no one route is superior to another for luteal support during IVF.
- Recent studies indicate similar efficacy for oral progesterone versus vaginal progesterone but with the advantage of being more patient friendly.
- Recent studies also indicate the effectiveness of SC progesterone as compared to vaginal progesterone.

Practice Points

- Since all the routes of progesterone administration are similar in efficacy, patient's preference and comfort is an important factor while choosing progesterone support during IVF.
- Vaginal micronized progesterone is most widely used, sometimes alone and other times in combination with IM route.
- Since oral progesterone has been shown to be equally efficacious as vaginal progesterone due to patient-friendly profile, the oral route may gain more widespread acceptance.
- The addition of hCG for luteal support increases OHSS risk and should be avoided in women at risk. The routine addition of hCG to progesterone needs to be avoided.
- The use of GnRH agonist in combination with progesterone for luteal support appears to be beneficial.
- There is no evidence of benefit by addition of adjuvants such as vasodilators (e.g., sildenafil), prednisolone, or heparin for luteal support during routine IVF.

Metformin before In Vitro Fertilization

Background

Metformin is commonly used as a drug of first choice for diabetes. It has got an anti-hyperglycemic effect mainly by inhibiting hepatic glucose production and increasing peripheral glucose uptake and utilization.[43]

It is commonly used in clomiphene-resistant women for ovulation induction and polycystic ovary syndrome (PCOS) women with impaired glucose.[44] Metformin is also used prior to starting IVF in PCOS women to increase pregnancy rates and reduce the risk of OHSS.[45]

Evidence

The efficacy of metformin prior to the long protocol in IVF was evaluated in a placebo-controlled double-blinded study.[46] The clinical pregnancy rates did not differ between the groups. However, spontaneous pregnancies were higher prior to starting IVF in the metformin group. Hence, when an ITT analysis was done, LBR was significantly increased with metformin (48.6 vs. 32%, p = 0.03). Another RCT evaluated metformin's role in reducing OHSS in PCOS group with GnRH antagonist protocol.[47] There was no significant reduction in moderate–severe OHSS rate in metformin group as compared to the placebo (16 vs. 12.2%, p = 0.66). However, the LBR was significantly reduced in the metformin group (27.6 vs. 51.6%, p = 0.02).

A systematic review observed the effectiveness of metformin in PCOS group (10 trials, n = 845) undergoing IVF and noted no significant difference in LBRs after metformin. There was a significant reduction in OHSS rates following metformin (OR 0.27, 95% CI 0.16–0.46) in relation to the control group.[48]

The updated Cochrane review included 13 RCTs and 1,132 women. The analysis was stratified based on the type of protocol, i.e., long agonist (six RCTs), antagonist and short protocol (one RCT), and included studies which reported live births. In the long protocol GnRH-agonist subgroup, an uncertain effect of metformin on LBR per woman was observed when compared with the control (RR 1.30, 95% CI 0.94–1.79; n = 651), and the quality of evidence was low. Only one trial used GnRH-antagonist protocol and reported LBR. The authors reported that metformin may reduce LBR in the antagonist protocol group versus control (RR 0.48, 95% CI 0.29–0.79; one RCT; n = 153). However, low-quality evidence also showed that metformin may lower the incidence of OHSS (RR 0.46, 95% CI 0.29–0.72; 11 RCTs; n = 1,091) in the long protocol GnRH-agonist ovarian stimulation protocol, but not in the antagonist ovarian stimulation protocol. There is uncertain evidence on miscarriage rate per woman in metformin versus placebo (RR 0.86, 95% CI 0.56–1.32; eight RCTs; 821 women). Intake of metformin increases the risk of side effects (RR 3.35, 95% CI 2.34–4.79; eight RCTs; 748 women).[45]

A recent systematic review and meta-analysis was done to investigate the association of metformin with pregnancy outcomes in PCOS women undergoing IVF. The risk of OHSS in women (n = 1,123, 12 RCTs) randomized to metformin was lower compared to control arm (OR, 0.43; 95% CI, 0.24–0.78), although this difference lost significance for women with a body mass index (BMI) of <26 kg/m^2 (OR, 0.67; 95% CI, 0.30–1.51). Among the 11 trials included, 10 trials used long agonist protocol and no significant difference was observed in clinical pregnancy rate (OR, 1.24; 95% CI, 0.82–1.86) or LBR (OR, 1.23; 95% CI, 0.74–2.04). However, in a post hoc analysis with a BMI of ≥26 kg/m^2, metformin treatment showed higher clinical pregnancy rates (OR, 1.71; 95% CI, 1.12–2.60).[49]

Evidence Summary

- Use of metformin pre-IVF in PCOS women does not increase LBRs.
- Metformin may reduce OHSS risk in PCOS women undergoing IVF on long agonist protocol.

- There is no clear evidence showing reduction of OHSS in PCOS women on GnRH antagonist protocol.
- Metformin may be associated with increased clinical pregnancy rates in PCOS women with higher BMI.

Practice Points

- Metformin can be started in 3 months pre-IVF in PCOS women who are planned for long agonist protocol.
- Benefits of metformin may not be substantial if PCOS women are on GnRH antagonist protocol which is a preferred option for women who are at OHSS risk.
- Metformin has gastrointestinal side effects, and long-term use may cause vitamin B12 deficiency.

Freeze-all Strategy

Background

The freeze-all strategy consists of cryopreserving all the embryos from an ART cycle and transferring them later in either a natural cycle or a hormone-primed replacement cycle, thus avoiding a fresh embryo transfer. This is mainly to avoid the deleterious effects of supraphysiological levels of hormones during COH, which may negatively impact endometrial receptivity and consequently embryo implantation.[50] The subtle rise in progesterone levels during COH may also lead to the advancement of endometrial receptivity, and consequent asynchrony may lower the implantation.[51] In women at high risk of OHSS, the freeze-all strategy along with antagonist protocol with an agonist trigger is considered an effective option to reduce OHSS risk.[52]

Due to the above stated reasons, the freeze-all embryos strategy has been incorporated into the routine clinical practice.

However, the long-term impact of freezing and cost implications are not yet clear.

Evidence

Earlier trials by Shapiro et al. evaluated the freeze-all strategy at the blastocyst stage in high responders and normoresponders in two separate trials.[53,54] In the trial involving high-responder women, a total of 122 women were randomized (62 in fresh and 60 in frozen).[51] The ongoing pregnancy rate per transfer between fresh versus frozen cycles did not show any significant difference (65.4 vs. 77.6%; $p = 0.19$). In the trial consisting of normoresponder women, a total of 53 fresh and 50 frozen cycles were analyzed.[54] The ongoing pregnancy rates were significantly lower in fresh compared to frozen (50.9 vs. 78%; $p = 0.007$). The authors suggested altered endometrial receptivity as the likely reason for lower pregnancy rates in the fresh cycles. In another RCT, fresh versus freeze-all strategy was compared involving day 3 stage embryos in PCOS women.[55] The trial involved a total of 1,508 women. The LBR after the first transfer was significantly higher following freeze-all versus fresh day 3 transfer (49.3 vs. 42%, $p = 0.004$), and pregnancy losses were significantly lower (22 vs. 32.7%, $p < 0.001$). While the OHSS rate was significantly lower after freeze-all strategy (1.3 vs. 7.1%, $p < 0.001$), the preeclampsia rate was significantly increased after freeze-all strategy (4.4 vs. 1.4%, $p = 0.009$).

The recent Cochrane review included 15 studies and a total of 4,712 women. The results show minimal or no difference in cumulative LBR (OR 1.08, 95% CI 0.95–1.22; eight RCTs) and cumulative pregnancy rates (OR 0.95, 95% CI 0.75–1.19; four RCTs, 1,245 women) between the freeze-all versus conventional ART strategy and the quality of evidence was moderate. Low-quality evidence suggests that women might develop less OHSS after the "freeze-all" strategy compared to the conventional strategy (OR 0.26, 95% CI 0.17–0.39; six RCTs, 4,478 women). There is uncertain evidence regarding the difference in miscarriage rate as the evidence is of very low quality (Peto OR 1.06, 95% CI 0.72–1.55; two RCTs, 986 women).[56]

A pragmatic two-arm parallel RCT (E-Freeze) included a total of 619 women between ages ≥18 and <42 years and evaluated the effectiveness of elective freezing versus fresh transfer.[57] The treatment outcomes following elective freeze compared to the fresh embryo transfer showed no significant difference in healthy baby rate (20.3 vs. 24.4%; RR, 95% CI: 0.84, 0.62–1.15); live birth (28.3 vs. 34.3%; RR, 99% CI: 0.83, 0.65–1.06); miscarriage rate (14.3 vs. 12.9%; RR, 99% CI: 1.09, 0.72–1.66), and OHSS rate (3.6 vs. 8.1%; RR, 99% CI: 0.44, 0.15–1.30). The participant adherence was lower, and the cost was higher in freeze-all group.

Summary

- The current evidence suggests that freeze-all strategy reduces OHSS risk in women at high risk compared to fresh transfer.
- The evidence is not clear regarding the benefit of freeze-all strategy on cumulative live birth compared to the conventional IVF strategy.
- There is some evidence which suggests that higher pregnancy complications following frozen transfer as compared to fresh transfers.

Practice Points

- For women at high risk of OHSS (e.g., PCOS), freeze-all strategy can be offered to reduce the risk.
- Since the present evidence is unclear with regard to the impact of freeze-all strategy on cumulative live birth, routine use of this strategy for all IVF cycles is not advised.
- Long-term effect of freezing on perinatal outcomes and cost implications has to be considered before wider use can be recommended.

CONCLUSION

The incorporation of newer interventions or adjuncts must be based on evolving evidence. Changes in the practice should be guided by the improvement in the pregnancy outcomes with patient safety and cost taken into consideration.

KEY POINTS

- PGT with newer CCS technologies along with trophectoderm biopsy has shown lack of benefit in good prognosis women as compared to routine IVF.
- TLS appears to be a promising tool for noninvasive methods of embryo selection, though no single morphokinetic parameter is predictive of higher implantation potential.
- Evidence shows lack of benefit with routine screening hysteroscopy before the first IVF.
- Among vaginal, oral, and intramuscular administration of progesterone, no one route is superior to another for luteal support during IVF, hence the choice can be decided according to patient comfort, compliance, and physician's discretion.
- Use of metformin pre-IVF does not increase the live births in PCOS women, but OHSS risk might be reduced in women with long agonist protocol.
- For women at high risk of OHSS, freeze all strategy can be offered.

CHAPTER 89

Ethical, Legal, and Social Issues of Modern Assisted Reproductive Technology Practice

Petra De Sutter, Pankaj Talwar

INTRODUCTION

Infertility is still considered a social stigma for both men and women in India, damaging their mental, social, and physical experiences. While assisted reproductive technology (ART), including in vitro fertilization (IVF), has given hope to millions of couples suffering from infertility, it has also introduced countless ethical, legal, and social challenges. Surrogacy guidelines were laid out in 2002 by the Indian Council of Medical Research (ICMR). Further, "National Guidelines for Accreditation, Supervision and Regulation of ART Clinics in India" were described by ICMR in 2005, which prescribed the conditions that ART clinics need to comply with. No legislative backing was there for both the initiatives. In 2008, the ART Bill was first proposed, with the final version being brought out in 2017.[1-3]

ASSISTED REPRODUCTIVE TECHNOLOGY (REGULATION) RULES, 2022[4,5]

Assisted Reproductive Technology Clinics and Banks

There shall be two levels of clinics, namely:

- *Level 1 ART clinics,* where only intrauterine insemination (IUI) procedure is carried out as part of treatment.
- *Level 2 ART clinics*, where the procedures, or as the case may be, techniques, that attempt to obtain a pregnancy shall be carried out by any or all of the following, namely:
  - Surgical retrieval of gametes
  - Handling the oocyte outside the human body
  - Using sperms for fertilization of oocytes
  - Transfer of the embryo into the reproductive system of a woman
  - Carrying out storage of gametes or embryos or performing any kind of procedure or technique involving gametes or embryos.

ART banks shall:

- Be responsible for screening, collection and registration of the semen donor, and cryopreservation of sperms
- Perform screening and registration of oocyte donor
- Operate as semen banks or oocyte banks or both
- Maintain the records or data of all the donors and shall regularly update the National Registry.

Requirements and Qualifications of the Staff in the Assisted Reproductive Technology Clinics

- *ART level 1 clinic:* Minimum one gynecologist
- *Qualification:* The gynecologist shall be a medical postgraduate in Gynecology and Obstetrics.
- *ART level 2 clinic:* ART level 2 clinic shall have a minimum of one gynecologist, one anesthetist, one embryologist, and one counselor.

  The additional staff at the level of director and andrologist may be employed by the ART level 2 clinics.
- *Qualification of staff in ART level 2 clinics* shall be as follows:
  - *Gynecologist:* The gynecologist will be a medical postgraduate in Gynecology and Obstetrics and should have a record of performing 50 ovum pickup procedures under the supervision of a trained ART specialist with at least 3 years of working experience in an ART clinic under supervision. (In the case of gynecologists practicing ART or IVF and are working in ART clinics before the commencement of this Act, a postgraduate degree in Gynecology and Obstetrics with at least 3 years' experience and record of 50 ovum pickup procedures shall be acceptable.)

    Or

    A medical postgraduate in Gynecology and Obstetrics with super specialist Doctorate of Medicine or fellowship in reproductive medicine with experience of not <3 years of working in an ART clinic.

- *Andrologist:* The andrologist in a clinic or a bank will be a MCh or DNB in Urology with special training in diagnosing and treating male infertility.
- *Embryologist:* From the date of commencement of these rules, clinics will hire embryologists only with the following qualifications and experience, namely:
  Postgraduate in Clinical Embryology (graduated with full-time program with minimum four semesters) from a recognized university with additional 3 years of human ART laboratory experience in handling human gametes and embryos
  Or
  PhD holder or doing full-time PhD project shall be related to clinical embryology or ART or fertility from a recognized university with an additional 1 year of human ART laboratory experience in handling human gametes and embryos
  Or
  Medical graduate (MBBS) or Veterinary graduate (BVSc) with a postgraduate degree in Clinical Embryology (full-time program) from a recognized university with additional 2 years of ART laboratory experience in handling human gametes and embryos
  Or
  Postgraduate in Life Sciences or Biotechnology with a minimum of 1 year of on-site, full-time clinical embryology certified training in addition to 4 years of experience in handling human gametes and embryos in a registered ART level 2 clinic.
  Note: As a one-time measure, all embryologists working in ART or IVF clinics before the commencement of these rules, with the below-mentioned qualifications and experience, may be allowed to continue as an embryologist. However, after the commencement of these rules, all clinics will hire embryologists with any of the above-mentioned qualifications and experience as criteria: Graduate in Life Sciences or Biotechnology or Reproductive Biology/Veterinary Science with at least 5 years of working experience in a registered ART or IVF clinic, who have performed at least 500 IVF laboratory procedures (including intracytoplasmic sperm injection and at least 100 cycles of cryopreservation of embryos).
- *Counselor:* A person who is a graduate in Psychology or Clinical Psychology or Nursing or Life Sciences
- *Anesthetist:* Anesthetist will be a medical postgraduate in Anesthesia
- *Director:* The director shall have a postgraduate degree in Medical or Life Sciences or Management Sciences

- *ART bank:* The ART bank shall have a minimum of one Registered Medical Practitioner trained in the handling, preparation, and storage of semen samples.

Minimum Equipment in Assisted Reproductive Technology Clinics and Banks

- *ART level 1 clinics:*
  - Microscope
  - Centrifuge
  - Refrigerator
- *ART level 2 clinics:*
  - Microscope
  - Incubator (minimum two in number)
  - Laminar airflow
  - Sperm counting chambers
  - Centrifuge
  - Refrigerator
  - Equipment for cryopreservation
  - Ovum aspiration pump
  - Ultrasonography (USG) machine with transvaginal probe and needle guard
  - Test tube warmer
  - Anesthesia resuscitation trolley
- *ART banks:*
  - Centrifuge machine
  - Incubator
  - Microscope
  - Laminar airflow.

Registration Fees

Every application for registration shall be accompanied with a fee of:

- ₹ 50,000 for level 1 ART clinic
- ₹ 200,000 for level 2 ART clinic
- ₹ 50,000 for ART bank

If an application for registration of any ART clinic or ART bank has been rejected by the appropriate authority, no fee shall be required to be paid on resubmission of the application by the applicant for the same clinic and the application fees once paid shall not be refunded.

Provided further that no fee shall be required to be paid by the establishments run by the institute under the control of the Government.

Donor Gametes

All donors, both male and female, must be recruited through a registered ART bank.

Age of Donor and Recipient

Age of the recipient: Female: 21–50 years, male: 21–55 years

Age of the donor: Female: 23–35 years, male: 21–55 years.

Sex and Marital Status of Recipient

The recipient can be married or a single woman.

A bank shall not supply the sperm or oocyte of a *single donor* to more than *one commissioning couple.*

An *oocyte donor* shall be an ever-married woman having at least one live child of her own with a minimum age of 3 years and can donate oocytes only once in her life; not more than seven oocytes shall be retrieved from the oocyte donor.

All *unused oocytes* shall be preserved by the banks for use on the same recipient, or given for research to an organization registered under this Act after seeking written consent from the commissioning couple.

The gamete of a donor or embryo shall be *stored for a period of not more than 10 years,* and at the end of this period, the embryo or gamete shall be allowed to perish or be donated to a research organization registered under this Act for research purposes with the consent of the commissioning couple or individual, in the manner as prescribed.

Medical Examination of Donor

The sperm or oocyte donor shall be tested for the following communicable diseases, namely:

- Human immunodeficiency virus (HIV), types 1 and 2
- Hepatitis B virus (HBV)
- Hepatitis C virus (HCV)
- *Treponema pallidum* (syphilis) through Venereal Disease Research Laboratory (VDRL).

Insurance Coverage/Guarantee for Oocyte Donor

- The intending couple or woman will purchase a general health insurance coverage in favor of oocyte donor for a period of 12 months from an insurance company or an agent recognized by the Insurance Regulatory and Development Authority established under the provisions of the Insurance Regulatory and Development Authority Act, 1999, for an amount which is sufficient enough to cover all expenses for all complications arising due to oocyte retrieval.
- The intending couple shall sign an affidavit to be sworn before a Metropolitan Magistrate or a Judicial Magistrate of the first class.

Retrieval of Number of Oocytes from Donor

The clinics should make efforts to retrieve not more than 7–15 oocytes from the donor during one cycle. All formed follicles may be retrieved; however, the clinics shall ensure the controlled ovarian stimulation of donor women in order to prevent ovarian hyperstimulation. It is preferred over a coasting strategy in patients at risk of ovarian hyperstimulation syndrome (OHSS).

Other Duties of Clinics

The ART clinic shall:

- Ensure that all unused gametes or embryos shall be preserved by the ART clinic for use on the same recipient and shall not be used for any other couple or as the case may be woman.
- Allow cryopreservation of oocytes and sperms for oncofertility patients undergoing treatment and for other such conditions, for duration longer than 10 years with the permission from the National Board.
- Ensure the controlled ovarian stimulation of woman in order to prevent ovarian hyperstimulation.
- Ensure that preimplantation genetic testing shall be used to screen the human embryos for known preexisting heritable or genetic diseases and when medically indicated.
- Ensure that no preimplantation genetic testing shall be done for sex selection for nonmedical reasons or selection of particular traits due to personal preferences of the prospective parents or to alter or with a view to alter the genetic constitution of an embryo.
- A woman is not treated with gametes or embryos derived from more than one man or woman during any one treatment cycle.
- A clinic shall never mix semen from two individuals for the procedures specified under this Act.
- The embryos shall not be split and used for twinning to increase the number of available embryos.
- The collection of gametes posthumously shall be done only if prior consent of the commissioning couple is available.
- Maintain the following consent forms, namely:
  - Consent form to be signed by the couple or woman as specified in Form 6
  - Consent for IUI with husband's semen or sperm as specified in Form 7
  - Consent for IUI with donor semen as specified in Form 8
  - Consent for freezing of embryos as specified in Form 9
  - Consent for freezing gametes as specified in Form 10
  - Consent for freezing of gametes, sperm, or oocytes and parental consent as specified in Form 11
  - Consent for oocyte retrieval as specified in Form 12
  - Consent from oocyte donor as specified in Form 13.

The ART banks shall maintain the following, namely:

- Record of use of donor gametes as specified in Forms 14, 14A, and 14B
- Consent form for the donor of sperm as specified in Form 15.

Grievance Redressal

Every clinic and every bank shall maintain a grievance cell in respect of matters relating to such clinics and banks and the manner of making a complaint before such grievance cell be as specified in Form 5.

Number of Embryos to be Transferred

The gynecologist may transfer preferably one, and not more than two embryos; in cases with explainable circumstances,

three embryos can be placed in the uterus of a woman during the treatment cycle.

Donor Embryos

Both donor gametes are allowed but only recommended for the same recipient.

Sale, Transfer, or Use of Gametes

The sale, transfer, or use of gametes, zygotes, and embryos, or any part thereof, or information related thereto, directly or indirectly to any party within or outside India, shall be prohibited except in the case of transfer of own gametes and embryos for personal use with the permission of the National Board.

SURROGACY (REGULATION) RULES, 2022[4,6]

Age of the Recipient Couple

Female: 23–50 years, male: 26–55 years
Surrogate: 25–35 years.

Insurance Coverage

- The intending woman or couple shall purchase a general health insurance coverage in favor of the surrogate mother for a period of 36 months from an insurance company or an agent recognized by the Insurance Regulatory and Development Authority established under the provisions of the Insurance Regulatory and Development Authority Act (41 of 1999) for an amount which is sufficient enough to cover all expenses for all complications arising out of pregnancy and also covering postpartum delivery complications.
- The intending couple/woman shall sign an affidavit to be sworn before a Metropolitan Magistrate or a Judicial Magistrate of the first class.

Number of Attempts of Surrogacy Procedure

The number of attempts of any surrogacy procedure on the surrogate mother shall not be more than three times.

Consent of a Surrogate Mother

The consent of a surrogate mother shall be as specified in Form 2.

Number of Embryos to be Implanted in the Uterus of the Surrogate Mother

The gynecologist shall transfer one embryo in the uterus of a surrogate mother during a treatment cycle.

It is only in special circumstances that up to three embryos may be transferred.

Medical Indications Necessitating Gestational Surrogacy

A woman may opt for surrogacy if:

- She has no uterus or missing uterus or abnormal uterus (such as hypoplastic uterus or intrauterine adhesions or thin endometrium or small unicornuate uterus, T-shaped uterus) or if the uterus is surgically removed due to any medical conditions, such as gynecological cancer.
- Intended parent or woman who has repeatedly failed to conceive after multiple IVF or intracytoplasmic sperm injection attempts (recurrent implantation failure).
- Multiple pregnancy losses resulting from an unexplained medical reason and unexplained graft rejection due to exaggerated immune response.
- Any illness that makes it impossible for a woman to carry a pregnancy to viability or pregnancy that is life threatening.
- Single woman (widow/divorced).

Offenses and Penalties

The offenses shall be punishable with a fine which shall not be less than 5 lakh rupees but may extend to 10 lakh rupees for the first contravention and for subsequent contravention, or shall be punishable with imprisonment for a term which shall not be less than 8 years but may extend to 12 years, or with fine which shall not be less than 10 lakh rupees but may extend to 20 lakh rupees.

TIMELINE OF ASSISTED REPRODUCTIVE TECHNOLOGY AND SURROGACY RULES (2021–2022)

The *Assisted Reproductive Technology (Regulation) Bill, 2017* was enacted by the Parliament in the 71st year of the Republic of India to establish the national board, the state boards, and the national registry for the regulation and supervision of ART clinics and ART banks, for prevention of misuse, for the safe and ethical practice of ART services, and for matters connected therewith or incidental thereto. This Act may be called the Assisted Reproductive Technology (Regulation) Act, 2017. It extends to the whole of India. It shall come into force on such date as the Central Government may, by notification in the Official Gazette, appoint an "appointed day" meaning the date with effect from which the National Board is established under subsection (1) of section 3. The Assisted Reproductive Technology (Regulation) Act of Parliament received the assent of the President on *December 18, 2021*, and this Act may be called the *Assisted Reproductive Technology (Regulation) Act, 2021*. In *March 2022*, the Central Government hereby makes the rules which may be called the *Assisted Reproductive Technology (Regulation) Rules, 2022*. They shall come into force on the date of their publication in the Official Gazette.

The *Surrogacy (Regulation) Bill, 2016* was enacted by the Parliament in the 72nd year of the Republic of India to constitute National Assisted Reproductive Technology and Surrogacy Board, State Assisted Reproductive Technology and Surrogacy Boards, and appointment of appropriate authorities for regulation of the practice and process of surrogacy, and for matters connected therewith or incidental thereto. The Surrogacy (Regulation) Act of Parliament received the assent of the President on *December 25, 2021* and this Act may be called the *Surrogacy (Regulation) Act, 2021*. In *March 2022*, the Central Government hereby makes the rules which may be called the *Surrogacy (Regulation) Rules, 2022*. They shall come into force on the date of their publication in the Official Gazette.

April 21, 2022: The Central Government hereby notifies the establishment of the National Assisted Reproductive Technology and Surrogacy Registry under the Department of Health Research for the purposes of *the Assisted Reproductive Technology (Regulation) Act, 2021 and the Surrogacy (Regulation) Act, 2021*. The said National Registry shall be in operation with effect from April 22, 2022.

May 4, 2022: The Central Government hereby notifies that the appropriate authority in respect of each Union Territory (UT) for the purposes of the Assisted Reproductive Technology (Regulation) Act, 2021 and the Surrogacy (Regulation) Act, 2021 consists of the following functionaries of respective UT:

- An officer of or above the rank of the Joint Secretary of the Health and Family Welfare Department as Chairperson, ex officio
- An officer of or above the rank of the Joint Director of the Health and Family Welfare Department as Vice Chairperson, ex officio
- An officer of the Law Department of the UT concerned not below the rank of a Deputy Secretary as a member, ex officio.

May 4, 2022: The Central Government hereby notifies that *composition of National Assisted Reproductive Technology and Surrogacy Board* for the purposes of the Assisted Reproductive Technology (Regulation) Act, 2021 and the Surrogacy (Regulation) Act, 2021 is as follows:

- The Minister-in-Charge of the Ministry of Health and Family Welfare as Chairperson, ex officio
- The Secretary to the Government of India in charge of the Department of Health Research as Vice-Chairperson, ex officio
- Dr Kakoli Ghosh Dastidar and Dr Bharatiben Dhirubhai Shiyal, Members of Lok Sabha as Members, ex officio
- Dr Rakesh Gupta, Joint Secretary, Ministry of Women and Child Development, Government of India, and Dr NR Battu, Joint Secretary and Legislative Counsel, Legislative Department, Ministry of Law and Justice, Government of India as Members, ex officio.
- The Director General of Health Services of the Central Government as Member, ex officio.
- The Chairpersons of the State/UT Boards:
  - Andaman and Nicobar Island
  - Andhra Pradesh
  - West Bengal
  - Uttarakhand as Members, ex officio.
- The Joint Secretary, Department of Health Research, Ministry of Health and Family Welfare, in charge of Surrogacy Division as Member Secretary, ex officio.

May 4, 2022: The Central Government hereby notifies that the UT Board in respect of each UT without Legislature for the purposes of the Assisted Reproductive Technology (Regulation) Act, 2021 and the Surrogacy (Regulation) Act, 2021 consists of the following *functionaries of respective UT*:

- Lieutenant Governor/Administrator of UT as Chairperson, ex officio
- The Secretary-in-Charge of the Department of Health and Family Welfare as Vice-Chairperson, ex officio
- Secretaries or Commissioners-in-charge of the Departments of Women and Child Development, Social Welfare, Law and Justice and Home Affairs or their nominees as members, ex officio.
- Director General of Health and Family Welfare of the State Government as member, ex officio
- An officer not below the rank of Joint Secretary, in charge of Family Welfare as Member Secretary, ex officio.

May 13, 2022: Assisted Reproductive Technology (Regulation) Rules, 2022 and Surrogacy (Regulation) Rules, 2022 are yet to be notified for the purposes of the Assisted Reproductive Technology (Regulation) Act, 2021 and the Surrogacy (Regulation) Act, 2021.

June 7, 2022: The Central Government hereby makes the rules which may be called the Assisted Reproductive Technology (Regulation) Rules, 2022.

June 21, 2022: The Central Government hereby makes the following rules which may be called the Surrogacy (Regulation) Rules, 2022.

August 4, 2022: The Central Government hereby makes the following order to remove the said difficulties, namely:

- This Order may be called the Assisted Reproductive Technology (Regulation) and Surrogacy (Regulation) (Removal of Difficulties) Order, 2022.
- It shall come into force with effect from July 25, 2022. Accordingly, the ART clinics, ART banks, and surrogacy clinics, falling under the jurisdiction of the 17 states as indicated below, are allowed to conduct counseling or procedures pertaining to ART and surrogacy beyond July 24, 2022 and up to a maximum period of 3 months (i.e., up to October 24, 2022):
  - Assam

- Bihar
- Chhattisgarh
- Goa
- Gujarat
- Haryana
- Himachal Pradesh
- Jharkhand
- Karnataka
- Manipur
- Meghalaya
- Nagaland
- Rajasthan
- Sikkim
- Tripura
- Uttar Pradesh
- Uttarakhand.

August 4, 2022: The Central Government hereby notifies the *appointment of the following experts as members of the National Assisted Reproductive Technology and Surrogacy Board* for the purposes of the Assisted Reproductive Technology (Regulation), Act 2021 and the Surrogacy (Regulation) Act, 2021:

- Dr Nitiz Murdia, Embryologist
- Dr Shubha Phadke, Medical Geneticist
- Dr Neeta Singh, Gynecologist and Obstetrician
- Dr RG Patel, Gynecologist and Obstetrician
- Smt. N Lalitha, Social Scientist.

October 10, 2022: The Central Government hereby makes the following rules, further to amend the Assisted Reproductive Technology (Regulation) Rules, 2022, namely:

- These rules may be called the *Assisted Reproductive Technology (Regulation) Amendment Rules, 2022*
- They shall come into force on the date of their publication in the Official Gazette.
- In the Assisted Reproductive Technology (Regulation) Rules, 2022, sub-rule (ii) of Rule 12 shall be substituted as under: (ii) The intending couple/woman shall sign an affidavit to be sworn before a Metropolitan Magistrate or a Judicial Magistrate of First Class or an Executive Magistrate or a Notary Public giving guarantee as per the section 22 (4) (ii) of the Assisted Reproductive Technology (Regulation) Act, 2021.

October 10, 2022: The Central Government hereby makes the following rules, further to amend the Surrogacy (Regulation) Rules, 2022, namely:

- These rules may be called the *Surrogacy (Regulation) Amendment Rules, 2022.*
- They shall come into force on the date of their publication in Official Gazette.
- In the Surrogacy (Regulation) Rules, 2022, sub-rule (2) of Rule 5 shall be substituted as under: (2) The intending couple/woman shall sign an affidavit to be sworn before a Metropolitan Magistrate or a Judicial Magistrate of First Class or an Executive Magistrate or a Notary Public giving guarantee as per the clause (q) of subsection (1) of section 2 of the Surrogacy (Regulation) Act, 2021 (47 of 2021).

ETHICAL, LEGAL, AND SOCIAL ISSUES[7-9]

Donor Gametes

- All donors, both male and female, must be recruited through a registered ART bank, but there are no registered ART banks formed yet.
- A bank shall not supply the sperm or oocyte of a single donor to more than one commissioning couple; however, this will increase the cost of IVF cycle.
- The intending couple or woman will purchase a general health insurance coverage in favor of an oocyte donor for a period of 12 months from an insurance company, but no donor compensation is recommended.
- The intending couple shall sign an affidavit to be sworn before a Metropolitan Magistrate or a Judicial Magistrate of first class; however, anonymity is not maintained.
- Known donor or anonymous donor is not clearly mentioned in the rules.

Donor Embryos

Both donor gametes are allowed but only recommended for the same recipient; however, this will increase the cost of IVF cycle.

Assisted Reproductive Technology Banks

All donors, both male and female, must be recruited through a registered ART bank, but there are no registered ART banks formed yet.

Surrogacy

- Only gestational surrogacy is allowed in India.
- Single/divorced women can opt for surrogacy, but same-sex couples cannot apply for surrogacy.
- A woman can become a surrogate only once in her lifetime and only for one commissioning couple.

CONCLUSION

Assisted reproductive technology has resulted in a tectonic shift in the way physicians and the general population perceive infertility and ethics. ART is directly challenging the society to reevaluate the way in which human life, social justice and equality, and claims to genetic offspring are viewed. Furthermore, these issues will force legal systems to modify the existing laws to accommodate the unique challenges created by ART. Society has a responsibility to ensure that the advances achieved through ART are implemented in a socially responsible manner.

CHAPTER 90

Quality Management in Assisted Reproductive Techniques Laboratory

Surbhi Gupta, Divyashree PS

INTRODUCTION

"Quality of the IVF laboratory is invisible when it is good but impossible to ignore when it is bad".

The practice of in vitro fertilization (IVF) has evolved into a well-established routine treatment of infertility since its inception 40 years ago. It involves the integration of individuals from various disciplines, such as embryology, ultrasonography, medicine and nursing, and requires them to work together in a safe and productive atmosphere to ensure that the service is being delivered in the best way.

A quality management system (QMS) is a process within an organization to ensure that the service is provided consistently and with as little variation as possible.[1]

Total quality management (TQM) is a management approach of an organization centered on quality, based on the participation of all its members and aiming at long-term success through customer satisfaction and benefits to all members of the organization and society. It is restricted not only to IVF laboratory but also to every function in the assisted conception unit.

The markers of good quality of an IVF laboratory are:

- Highest patient care in the form of caring for their gametes
- Highest success rate.

The requirements involve organization, management, personnel, equipment and materials, facilities/premises, documentation, records, and quality review and include the following:

- Defining the responsibilities of each personnel
- Having validated and written standard operating procedures (SOPs) including those for adverse events
- Ensuring full traceability for everything including cells, tissues, equipment, and records
- Confirming that quality assays are being performed as and when required
- Ensuring proper and periodic maintenance, service, and calibration of equipment
- Reviewing performance to ensure continuous and systematic improvement
- Providing risk assessment analysis for all laboratory activities
- Record maintenance and upgradation.

Hence, QMS consists of:

- Quality control (QC)
- Quality assurance (QA)
- Quality improvement.

Quality Control

Quality control is a process that includes all activities or operational techniques carried out in order to meet the quality requirements. The main goal of QC is to evaluate the effectiveness of various policies and procedures, identify and correct problems, ensure the accuracy and precision of procedures, and monitor the performance of the laboratory staff.[2]

It is product oriented and ensures that what you have done is what you expected.

Quality Assurance

Quality assurance is the sum total of all the activities required to establish the confidence that the product or the service is meeting the determined quality requirements. QA is more expansive and involves monitoring and control of the ongoing and overall quality in laboratory processes.[2]

It is process oriented and ensures that you are doing the right thing in the right way.

- Association of Clinical Embryologists 1996—Accreditation Standards and Guidelines for IVF laboratories
- ISO 15189/2012—Medical laboratories—particular requirements for quality and competence[1]
- European Society of Human Reproduction and Embryology (ESHRE) 2015—Guidelines for good practice in IVF laboratories[3]

- American Society for Reproductive Medicine (ASRM) 2008—Guidelines for human embryology and andrology laboratories.[4]

MODELS FOR QUALITY MANAGEMENT[2]

- Total quality management based on Deming's cycle or plan-do-check-act (PDCA) cycle
- European Foundation of Quality Management (EFQM) based on radar logic.

Total Quality Management

The concept of PDCA **(Fig. 1)** was given by W. Edwards Deming who is known as the father of modern QC. It is based on the principle that once a hypothesis is confirmed (or negated), executing the cycle will extend the knowledge further and repeating the PDCA cycle can bring its users closer to the goal, usually a perfect operation and output.

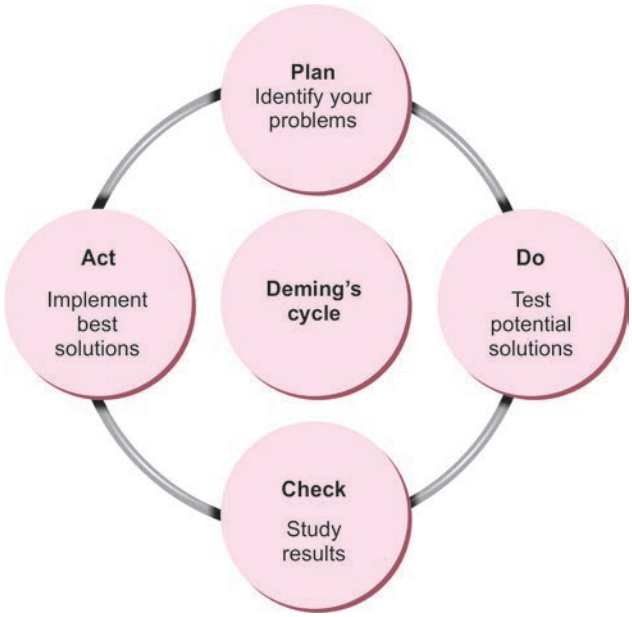

Fig. 1: Plan-do-check-act (PDCA) cycle.

European Foundation of Quality Management

The EFQM model allows organizations to determine their current "level of excellence" and where they need to improve their efforts. It provides a set of performance improvement tools in order to achieve and sustain success. The model is regularly reviewed to incorporate new ideas, concepts, and learning. It is based on RADAR logic **(Fig. 2)**; continuous improvement cycle is used by EFQM.

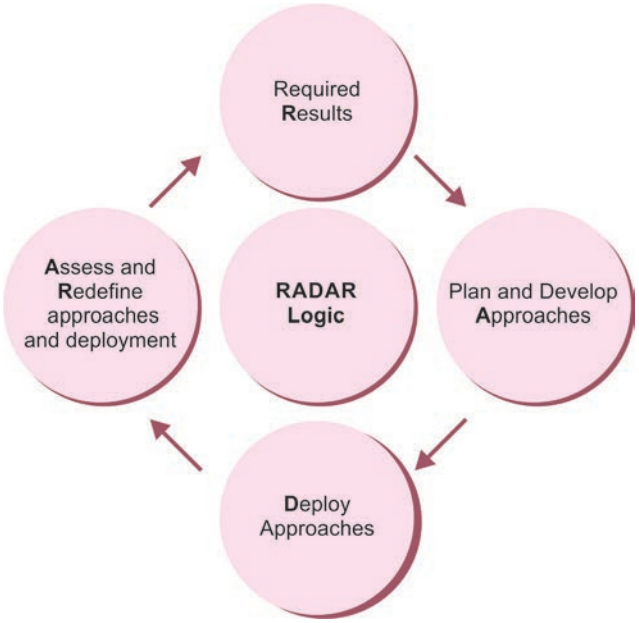

Fig. 2: European Foundation of Quality Management model using RADAR logic.

COMPONENTS OF QUALITY CONTROL PROGRAM

The components of QC program are depicted in **Flowchart 1**.

Laboratory Personnel

Laboratory personnel are one of the most important parts of an IVF laboratory and should be appropriately qualified, experienced, and responsible with the required expertise in the field of embryology and biological or medical sciences **(Table 1)**. The number of laboratory staff should reflect the number of cycles performed per year **(Table 2)**. There should be continuous upgradation for both new and senior embryologists by attending at least 12 hours of accredited continuing medical education (CME), conferences, and workshops annually.

Laboratory Safety and Equipment

Laboratory Design

- The IVF laboratory should be designed such a way as to minimize any damaging effects on gametes and embryos and to ensure good laboratory practice.[5]
- The laboratory should be in a low-traffic area, physically isolated from other laboratories, and in close proximity to the procedure room to ensure that oocyte or embryo viability is not compromised during transportation.
- The materials of the walls and floors should be easily washable and sterilizable. The materials used in laboratory construction, painting, flooring, and furniture should have minimized volatile organic compound (VOC) release and embryo toxicity. Low ceiling, granite wall, and vinyl floor are acceptable. Nontoxic, nonvaporizing paints such as epoxy paint should be used for floor, wall, and ceiling. There should be no carpeting.
- There should be optimal workflow over minimal distances while handling reproductive cells.

Flowchart 1: Components of quality control program.

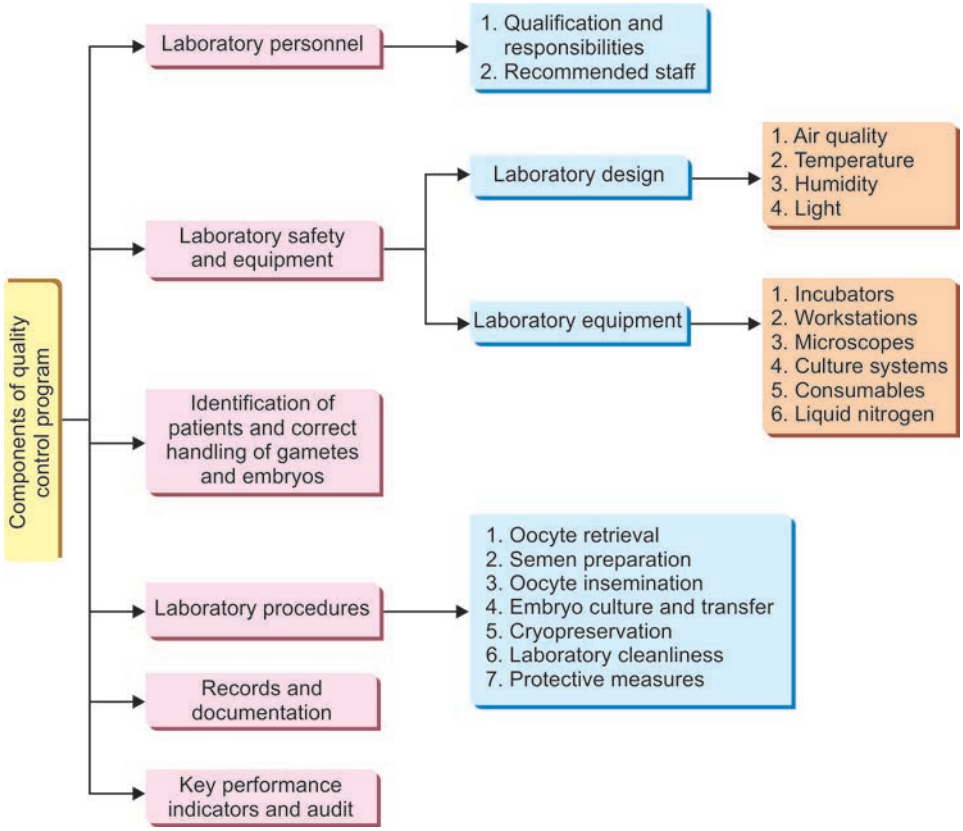

TABLE 1: Laboratory personnel and their responsibilities (ESHRE Guidelines 2015).

Position	*Qualification*	*Experience*	*Responsibilities*
Director	PhD/MD	2 years with minimum of 60 ART procedures	• To reach the highest standards in clinical IVF • Implementation of quality management system • Implementation of risk management and prevention policy • Ensuring sufficient staff members with appropriate skills • Management of staff training and continual scientific and biomedical education • Implementation and review of key performance indicators • Reporting of clinical data and adverse events • Approval of research projects
Supervisor	Master's/ Bachelor's	6 months with minimum of 60 ART procedures	• Efficient organization of daily work • Effective communication with laboratory staff and clinical colleagues • Continuous improvement wherever possible • Structured training of staff members and students
Technologist/ clinical embryologist	Master's/ Bachelor's	• Minimum of 30 ART procedures • 3 years experience as clinical embryologist • 6 years experience as senior clinical embryologist	• First-line of participation in daily clinical practice, communication, and organization • Execution of standard operating procedures • Contribution to laboratory clinical decisions • Training of staff members and students

(ART: assisted reproductive technique; IVF: in vitro fertilization)

- The laboratory access should be restricted only to laboratory personnel.
- There should be separate areas each for changing clothes, administrative work, cleaning and sterilization of materials, media preparation, and handwashing which should be outside the laboratory.

Air Quality

- Air quality monitoring consists of listing of particles and microorganisms, both in rest and in activity.
- Monitoring at rest **(Fig. 3)** ensures that the environment is ready for the forthcoming activity and aseptic process

TABLE 2: Recommended staff according to volume (ASRM guidelines 2008).

Number of laboratory cycles	*Minimum number of embryologists*
1–150	2
151–300	3
301–600	4
>600	1 additional embryologist per additional 200 cycles

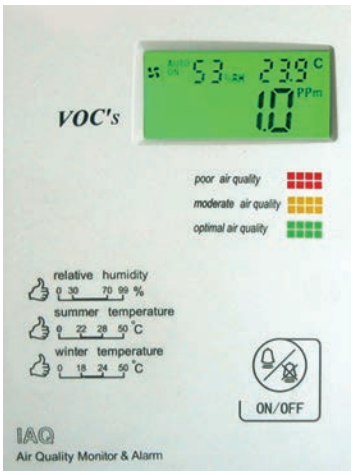

Fig. 3: Air quality monitor showing relative humidity (RH), temperature, and volatile organic compound (VOC) in the in vitro fertilization laboratory.

monitoring safeguards that the people, processes, and the environment remain under control during operation.

- Particulate matter (PM) and VOCs have effects on fertilization failure rate, delayed embryonic development, reduction in viability, implantation, and pregnancy rates.
- Positive pressure in the laboratory, high-efficiency particulate air (HEPA), filtration of laboratory air, filtration for VOCs, and the use of chemically active compounds are essential for high performance in IVF laboratories.

Air quality is divided into three parts: Air exchange, particle counts, and VOCs.

1. *Air exchange:*
   a. There should be an adequate number of air exchanges per hour in the laboratory so as to maintain positive pressure in the laboratory.
   b. It is calculated by dividing the cubic feet per minute of air exiting all the ducts by the total cubic feet of the room and multiplying by 60 minutes.
   c. Positive pressure air modules, such as Coda tower **(Fig. 4)**, within the laboratory are used to eliminate dust particles and microbes suspended in the laboratory air.
2. *Particle counts:*
   a. Bacteria and other contaminants attach themselves to particles and constitute the particle count.

Fig. 4: Inline Coda filter.

   b. Individual and mean counts for different sizes (0.3, 0.5, and 5 μm) are measured.
   c. Decrease in particles equates to an increase in air quality and is done by adding HEPA or ultra-low penetration air (ULPA) filter to the heating, ventilation, and air conditioning (HVAC) systems.
   d. HEPA filter is 99.97% effective in removing particles with >0.3 m diameter. Laminar air flow equipped with HEPA filter is used for the manipulation of gametes.
   e. One study concluded that increased nitrogen dioxide (NO_2) is consistently associated with lower live birth rates. Fine $PM_{2.5}$ during embryo culture was associated with decreased conception rates, whereas no association was found with sulfur dioxide or large PM_{10}.[6]
3. *Volatile organic compounds:*
   a. VOCs are natural or synthetic chemicals that can vaporize under normal atmospheric conditions.
   b. HVAC systems can be equipped with filters embedded with charcoal and potassium permanganate to remove VOCs.
   c. Charcoal traps compounds such as benzene and formaldehyde, and potassium permanganate oxidizes alcohol and ketones.
   d. Oil overlays of culture media capture VOCs as they are oil soluble.
   e. Qualification is mostly done on a yearly basis and the maintenance schedule for service and replacement of filters is defined by particle count for HEPA filters and analysis of filter saturation for active carbon and chemical VOC filters.
   f. The records for filter replacement dates and batch numbers should be maintained.

Temperature

- The absolute value of ambient temperature in the clean room should not be >25°C.

- Elevated temperatures can increase the number of polar bodies formed and reduce oocyte and embryo competence, whereas lower temperatures can alter the cytoskeleton of oocyte, spindle fibers, and other organelles.
- Thus, for optimal laboratory performance, it is essential to keep ambient temperature constant and avoid fluctuations in the surface temperature of equipment (heated stages and incubators).
- The ambient temperature should be monitored and alarmed.

Relative Humidity

- Relative humidity (RH) is the amount of moisture in the air as compared to the maximum amount of moisture that the air will hold at the same temperature.
- The ideal RH of the clean room should be between 40 and 50%.
- RH >50% increases the risk of bacterial growth, whereas RH <35% promotes static electricity, personal discomfort, and irritation of mucous membranes and eyes.

Light

- The direct sunlight and the hard white fluorescent light, specifically the blue region (400–500 nm) of light, directly damage the gametes and the embryos. They can lead to impaired cell proliferation or alteration of DNA due to photooxidation.
- The use of green filters in microscopes is recommended.
- The use of plasticware also reduces light exposure because it absorbs almost all light waves <300 nm.
- The amount of light exposure can also be lowered simply by lowering light intensity in the room and on the microscope.

Laboratory Equipment

- The laboratory should be adequately and optimally equipped and the equipment must be easy to clean and disinfect (e.g., microscopes suitable for oocyte recovery, determination of fertilization, micromanipulators, devices to maintain temperature and pH of media, eggs, and embryos).
- Equipment should be appropriately validated and calibrated. Validation, calibration, maintenance, and repair must be documented and records should be retained.
- All critical equipment such as incubators and cryostorage units should be continuously monitored and must have alarm systems and an automatic emergency backup power system. There should be a minimum of two incubators.
- Gas cylinders should be located outside the laboratory **(Fig. 5)**. High-purity gas and inline HEPA and VOC filters **(Fig. 4)** are highly recommended.

Fig. 5: Monitoring of CO_2 tank pressure with alarm system and autochange for gas cylinders.

TABLE 3: Types of incubators.

Box type	*Bench top*	*Others*
1. Water jacketed, 2. Air jacketed, e.g., Heracell incubator	1. Built in gas mixer: K-system 2. Premixed gases: 1. Minc 2. Planer BT 37 3. FIV-6	Mini incubator Portable incubator

- Heating devices to maintain the temperature of media and reproductive cells should be installed.
- Accepted ranges of use for all parameters should be determined and recorded.
- Malfunctioning equipment must be labeled as "out of use."
- For every equipment, an instruction manual should be available.
- All laboratory chemicals and reagents should be labeled including date of receiving, date of opening, and shelf life, wherever applicable.

Incubators: Incubators are the heart of the IVF laboratory. They are vital in providing a stable and appropriate culture environment for optimum embryo development and clinical outcome. The various types of incubators are ennumerated in **Table 3**.

Benchtop incubators **(Fig. 6)**

- They allow direct transfer of heat through the contact surfaces to the embryo culture dish.
- Rapidly equilibrate temperature and pH
- Heated chamber base plate and lid
- Compact size
- Digital record system for temperature and gas flow (24 hours)
- Time-stamped alarms
- Physiological culture environment is maintained by minimum premixed gas.

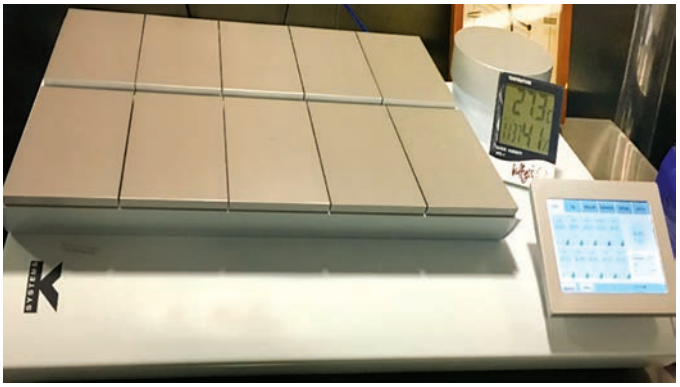

Fig. 6: K-system bench top incubator.

Fig. 7: Air jacketed (Heracell incubator).

The advantages of benchtop incubators are:

- Easy sterilization
- Less power consumption
- Cheaper to run than tri-gas big-box incubators
- Better embryo quality as compared to tri-gas big-box incubators as they can achieve low pO_2 culture easily.
- Less prone to fungal and bacterial contamination.

Most commonly used benchtop incubators are K-System G-185 and Minc. These are triple gas incubators with a built-in gas mixer. The concentrations of gases are 6% CO_2, 5% O_2, and 89% N_2.

Box incubators **(Figs. 7 and 8)**: Box incubators can be water jacketed or air jacketed **(Table 4)**.

The important environmental conditions that affect embryo culture are:

- Temperature
- Humidity
- Gas composition and pH
- Air quality.

Quality control of incubators[3]

- There should be a minimum of two incubators in any facility regardless of the type of incubator and the patient load and incubators must be connected to a 24-hour alarm system, monitoring all critical parameters.

Fig. 8: Water jacketed incubator.

TABLE 4: Types of box incubators.

Water jacketed	***Air jacketed***
1. Retain heat longer in case of incubator opening or power failure	Warm up quickly but do not retain heat for longer periods
2. Heavy	Smaller size and light weight
3. Higher power consumption	Less power consumption
4. Preservation of chamber temperature is satisfactory	Preservation of chamber temperature is satisfactory
5. More chances of contamination and it may arise from the water jacket	Less chances of contamination
6. Decontamination cycles not possible	Decontamination cycles are possible
7. Maintenance is challenging	Maintenance is easy

- The temperature should be set at 37°C and should be monitored daily with an accurate and independent external thermometer.
- The humidity should be >90% (ideal 100%) inside the incubator.
- The pH should never exceed 7.4, even while evaluating embryos outside the incubator. The pH probe should always be calibrated with buffers and calibration should take place at the target temperature (37°C).
- Media pH is checked in each incubator for each new lot of media.
- Calibrated measuring devices should be used daily to monitor incubator temperature, CO_2 and O_2 concentrations, and RH levels. CO_2 settings should be determined based on pH measurements of culture media. Conventional incubators are equipped with infrared CO_2 sensors.
- All supply gases (CO_2, N_2, premix) to the incubators should pass through HEPA, activated carbon and permanganate

TABLE 5: Cleaning and disinfection of incubators.

Wipe/spray disinfection	***ContraCon decontamination***
Three stages: • Predisinfection: – Remove all samples – Pump the water off – Spray disinfectant (usually soft odorless soft solution to remove culture media and protein) • Cleaning: – Thoroughly remove dirt residues and wipe the surfaces clean using a clean cloth and plenty of clear water – Wipe accessories thoroughly dry • Final disinfection: – Spray disinfectant again (70% methanol to remove oil followed by distilled water) onto the work space, the shelf system, and the removed components and wipe them clean – Allow the disinfectant to react as specified by the manufacturer – Reinstall the shelf system The use of halogens such as bleach solution or betadine is contraindicated as they can persist for extended period and can potentially harm embryo cultures.	• Principle: – Takes approximately 25 hours – A hot and humid atmosphere at 90°C at 0% CO_2 with highly decontaminating effect is created in the work space • Procedure **(Figs. 9A and B):** – After cleaning, reinstall the shelf system components – Fill the floor pan with 350 mL processed water – Turn the device on – Activate and start the decontamination routine (90°C for 25 hours) – After the decontamination routine has been completed, remove the remaining water using a sterile cloth – Turn the device off or resume operation – Calibration is done using auto start at 5% CO_2 and 37°C for 9 hours and confirmed using sperm survival test.

filter. Monitor CO_2 supply cylinders regularly, and ensure that autochangers are functional **(Fig. 5)**.

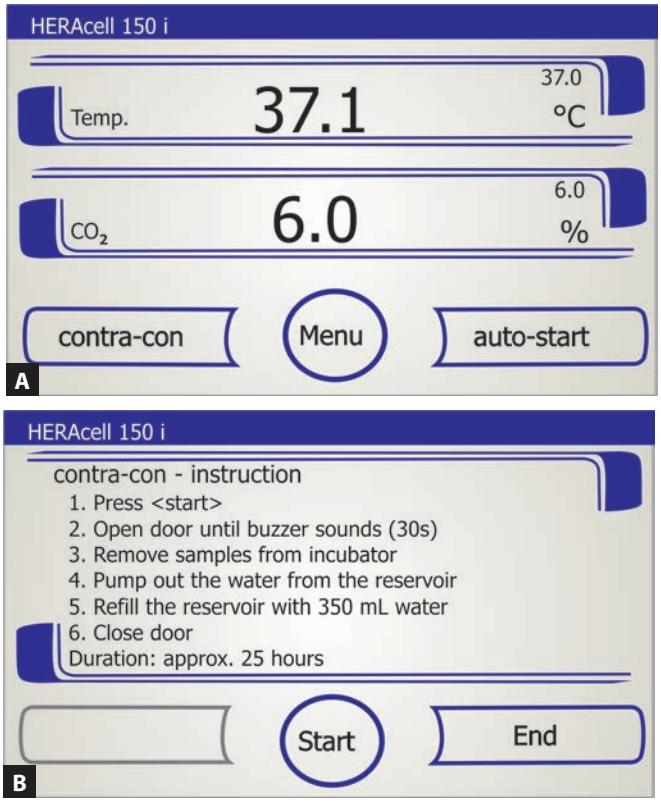
- Water in the incubator pan (to maintain humidity) must be regularly changed before the new batch starts.
- Shelves should be changed every other week.
- Internal incubator filters, including VOC filters, are changed yearly.
- Coda filters are attached to medical-grade gas cylinders **(Fig. 4)**.
- A sperm survival test before every batch to ensure proper functioning of incubator or two-cell mouse embryo assay tests with 80% blastocyst rate are performed quarterly.
- Annual maintenance contract with the supplier for servicing must be regularly maintained.
- Incubators should not be opened frequently and widely. Consecutive opening and closing two to three times within 5 minutes can cause a significant fall in CO_2 concentration and temperature which will be detrimental for both the oocytes and embryos.
- Incubators must be regularly cleaned and decontaminated.

Cleaning of incubators: Regular cleaning and disinfection of CO_2 incubators should be performed once every 3–6 months. It can be done in two ways **(Table 5)**:

1. Wipe/spray disinfection
2. ContraCon decontamination.

In vitro fertilization workstations: The IVF workstations can be of three types:

1. *Open workstations:* Traditional flow cabinets and microscope stages
2. *Closed workstations:* To maintain the gas phase, controlling the CO_2 concentration, and improving the temperature control



Figs. 9A and B: ContraCon™ decontamination of Heracell incubator.

3. *Time-lapse video systems:* Culture systems where the embryos can be manipulated without taking them outside the incubator.

Quality control of open (laminar airflow) workstations: The traditional workstation unit consists of a vertical laminar

Fig 10: Laminar airflow workstation with stereomicroscope.

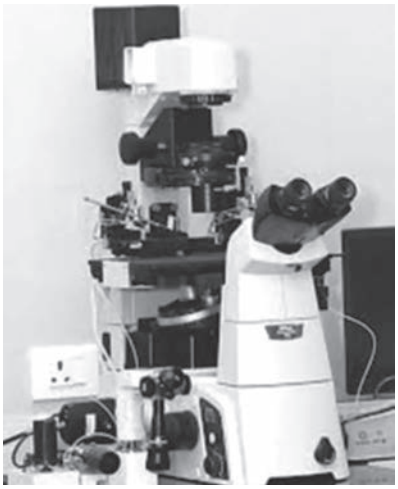


Fig. 11: Micromanipulator with inverted microscope.

flow cabinet **(Fig. 10)** together with a HEPA filter, a continuous heated surface with a stereomicroscope embedded, a working incubator inside or near the cabinet, and an inverted microscope on an antivibration table. Usually, under the heated surface are the aluminum blocks heated by a water-based system or electric resistance system.

- This station is used for handling oocytes and embryos.
- These must be placed in such a way so as to minimize the distance and optimize the transport of gametes or embryos during assessment or manipulation.
- The laminar airflow should be vertical to prevent cross infection and to protect the operator from any kind of liquids or aerosols.
- Vertical laminar airflow should be switched on 1 hour before ovum pick-up (OPU). It must be run throughout the day and switched off when the day's work is over.
- The filter should be changed every 6 months.
- Regular cleaning is to be done with surface disinfectant after the day's work.
- If there is any soiling/spillage that happens during work, it should be cleaned with 70% alcohol. A minimum of 30 minutes gap should be given, to resume the work after exposure to the alcohol.
- Laminar hood should not be placed near the incubator, as the air flow can cause dramatic changes in the osmolarity of the media inside the incubators.
- Regular servicing and cleaning of HEPA filter are a must.
- Ensure that the HEPA filter is working properly by testing the density of the PM in the air.

Quality control of closed workstations

- Closed workstations control temperature and pH and there is no need for HEPES buffer.
- There is a warm heated stage and a closed-circuit airflow which is also heated and sterile filtered (HEPA, VOC).
- Cleaning and decontamination are more complicated than laminar flow workstations.
- If methanol is used for cleaning, the workstation should be stopped and opened to prevent fumes from recirculating inside the workstation.

Microscopes: Microscopes used in an IVF laboratory are as follows:

- *Ordinary binocular microscope:* For evaluating semen parameters
- *Stereomicroscopes* **(Fig. 10)**: Workhorse of assisted reproductive technique (ART) laboratory. It is used when low magnification is needed, during cumulus isolation, washing and denuding, and embryo handling.
- *Inverted microscopes with micromanipulator* **(Fig. 11)**: Used for doing intracytoplasmic sperm injection (ICSI), and for oocyte and embryo assessment.

Quality control of microscopes

- Daily measurement of the temperature of the stage warmer should be done.
- Lack of clarity should be noted and rectified.
- Procedures for alignment of the optical path should be readily available.
- QC of image quality should be recorded and documented daily.
- Regular cleaning with surface disinfectant after each procedure must be followed.

Culture systems: The optimum environment of the culture systems is essential for the growth of embryos. The important conditions to control for providing an apt environment are:

- Temperature
- Culture media and pH
- Osmolality
- Oxygen tension
- Water quality
- Oil overlay
- Volume of culture media.

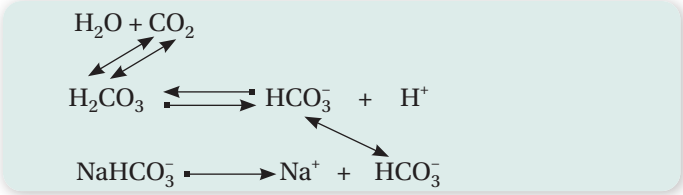
Temperature

- As discussed above, maintaining optimum temperature is very crucial for the gametes and the embryos.
- The human meiotic spindle is extremely sensitive to the variations in temperature and maintenance of temperature at 37°C is important for spindle integrity and thus normal fertilization and embryo development. The suboptimal temperatures should be avoided as the temperature effects are irreversible.[7-9]
- Temperature issues can occur during follicle puncture, on heated stages, in incubators and during embryo transfer.
- Temperature should be measured in culture dishes and in tubes with suitably calibrated probes. Thermistors with 0.1°C are widely available.

Culture media and pH

- The hydrogen ion concentration or pH is very important for embryo development. There is no ideal pH for culture media but is usually kept between 7.2 and 7.4.
- pH is dynamic and depends on association and dissociation of compounds in solution. It occurs in three phases in the laboratory: Equilibration, set point, and stabilization.
- Both extracellular pH (pHe) and intracellular pH (pHi) have to be regulated.

pH is extracellular (pHe) which is a balance between concentrations of CO_2 in the cell culture incubator and the amount of bicarbonate in the media. To regulate the set point of media pHe, CO_2 value is controlled on the incubator. This is an inverse relationship, pHe decreases as CO_2 concentration increases.[10]



- Regulation of pHi is an important cellular function necessary to maintain intracellular homeostasis. Cells contain various mechanisms to regulate pHi. Short-term regulation of pHi is achieved by the physiochemical buffering capacity of the cytoplasm and proteins.
- Common regulatory systems to combat intracellular acidosis include the sodium-dependent HCO_3^-/Cl^- exchanger (HCE) and the Na^+/H^+ antiporter, which add and remove, respectively, bicarbonate and hydrogen ions from within the cell. To combat alkalosis, cells may contain the HCE.[7]
- The commonly used bicarbonate-buffered media added to culture media to regulate pH are N-(2-hydroxyethyl) piperazine-N′-(2-ethanesulfonic acid) (HEPES) or 3-(N-morpholino) propanesulfonic acid (MOPS). This is controlled by the amount of CO_2 dissolved in culture media which in turn is regulated by the partial pressure of CO_2 in incubator air.[11]
- The pH has a potential impact on the meiotic spindle. It affects embryo actin cytoskeletal elements and oocyte cytoskeleton responsible for positioning of the meiotic spindle. It affects both oocyte and embryo metabolism.[10]
- Presently, the culture media are built around 6% CO_2 instead of 5% CO_2. The 1% increase has been reported to increase blastocyst cell numbers and implantation rates.[8]
- On exposing the culture medium to ambient air, the pH starts rising immediately. However, if the lid is left on the culture dish after removing it from the incubator, the pH starts rising after 10 minutes; hence, lids should be left on the culture dishes during zygote and embryo scoring.
- For QC, the pH of each batch of culture medium after proper equilibration should be measured.
- A conventional pH meter with a glass electrode can be used (samples for measurement have to be removed from the incubator, measurements should be done at 37°C, and measurements have to be done in ambient air). Other methods are continuous pH recorders in incubators or the use of a point-of-care blood gas analyzer.

Osmolality

- The ideal osmolality is yet to be determined as it is dependent on cell stage and embryo quality but ranges from 255 to 298 mOsm/kg for the commercial media.[12]
- Osmolality measurement gives a sense of accuracy with which media was prepared and hence each laboratory should have a freezing point depression osmometer.
- It has been demonstrated that 3 mL of culture medium left out at room temperature for as little as 30 minutes causes osmolality to rise by 5%.[11]
- Each batch of culture media should be tested for osmolality before use.

Oxygen tension

- The two most commonly used O_2 levels are 5 and 20–21%.
- Oxygen is converted to superoxide radicals, which can be deleterious to cells.
- The O_2 level in the fallopian tube is 2–8%.[13-15]
- The best level for O_2 inside the incubator is shown to be 5%. Thus with less oxygen, there would be less chances of damage to gametes and embryos through free radicals.

Water quality

- Water is one of the most important ingredients in culture media.
- Water is purified with the use of carbon filtration and reverse osmosis and should be tested for bacterial endotoxins to ensure the levels <1.5 pg/mL.

Oil overlay

- Oil is often layered over culture media.
- The benefits include decreased media evaporation, heat loss, pH shift, and protection from outside contaminants. It can also extract harmful substances from the culture media.[16-18]
- However, it may contain contaminants that may affect embryo development.[19-22] To prevent this, before using, the media should be washed with various salt and protein solutions.[16,18,23-25]

Volume of the culture medium: The amount of culture medium used is based on three factors:

1. Type of culture vessel
2. Sperm density
3. Embryo culture (single or in groups).

As per one study, motile sperm concentration was more important for fertilization than the total number of sperms.[26] Another study reported that increased sperm concentration can reduce the pH because of sperm metabolism leading to increased CO_2 production.[27]

Group culture has been proven superior to single-embryo culture in terms of blastomere numbers and embryo quality.[28-34]

A smaller volume of culture medium should be used as it has been linked to increased fertilization rates[35-37] and better embryo quality.[29-31,38] This is because of the autocrine and paracrine factors produced by each embryo and thus the cross talk between them in a small volume of medium.[35,39]

Consumables: The various consumables in the IVF laboratory include oocyte retrieval needles, culture dishes, ICSI needles, transfer catheters, culture media, oil, pipettes, and other plastic wares. The QC of all the consumables is mandatory and should be provided by the manufacturer.

The various assays assess the ability to sustain sperm or achieve highly developed embryos. It is assumed that the optimal conditions for these assays mimic the conditions that are optimal for the maintenance of human gametes and culture of human embryos. But there is very little standardization of these assays in different laboratories. Bioassays must be capable of detecting any and all agents that are detrimental to gametes or embryos. At the same time, bioassays should be specific for agents that affect human embryos and not the nonhuman gametes used for testing. The assays commonly used are as follows:

- Hamster sperm motility assay
- Human sperm survival assay
- Mouse embryo assay (MEA)
- Limulus amoebocyte lysate (LAL) test.

Hamster sperm motility assay

Description

- *Hamster epididymis held in the medium*: Sperm allowed to swim through several lacerations
- *Test cultures*: Tyrode's solution modified by adding bovine serum albumin, lactate, and pyruvate[4]
- *Control cultures*: Prepared with a medium known to perform well in the assay previously
- *All media (testing and control)*: Added with polyvinyl alcohol, penicillamine, hypotaurine, and adrenergic agent (epinephrine or isoproterenol)
- *Sperm cultured* at a concentration of 1–2 mill/mL in 2 mL of medium, under oil, in an incubator at 37°C, 5% CO_2
- *Sperm examined* with a dissecting stereomicroscope after 4 hours (a time when sperm are expected to show maximal hyperactivation)
- *Motility score* calculated by multiplying percentage motility and quality of motility[4]
- *Assay relies upon* the timely appearance of hyperactivated sperm in high quantities, to achieve adequate scores.
- *Sperm motility scores compared* between test and control conditions using statistical comparisons of three or four replicates.

Sensitivity

Motility scores are affected by albumin. This assay's sensitivity is improved by using solutions without albumin.

Advantages

- Brief
- Requires only 4–6 hours for results
- Detect differences between media prepared with different water sources.

Disadvantages

- Requirement of hamsters
- Focuses only on hyperactivation (only one of the sperm function)
- May not represent the sensitivity of human sperm or embryos to culture conditions
- Requires nonculture constituents to be added to the medium
- Addition of albumin is detrimental to sperm hyperactivation.[4]
- Values for percentage motility and quality of motion not well defined: Need competent personnel.

Human sperm survival assay

Description

- Human sperm obtained from patient samples donated for research[40-46] or frozen sperm samples[47] are used.
- Sperm prepared for culture by separating from seminal plasma and cryoprotectants: By centrifugation of semen over density gradient media.
- *Control solution* which has previously supported the prolonged culture of sperms
- Sperm allotted to test solution and control solution in equal concentration
- Cultured for several minutes to days at constant room temperature (37°C)

- *Principle:* Sperm survival declines over time. Both test and control solutions are assessed at specific times.
- *Assessment of survival:* By determining percentage of motile sperms[41,47] or percentage of sperm with progressive motility.[40,43,44] (Vitality can also be assessed by using vitality stain exclusion or hypoosmotic swelling test, morphology, or mitochondrial function.)
- Statistical comparisons between sample replicates of the test group and control group done
- *Survival level:* Control solutions support motility of 70–85% of the initial motility. A defined survival level of 75% in the control is used as a threshold to measure.
- *If the sperm in the test solution is above the threshold value:* Test condition suitable for use in human gamete culture
- *Assay considered valid*: If control solution supports motility of 70–85% of initial motility after 48–96 hours

Sensitivity
- Duration of exposure and duration of culture improve sensitivity.
- Culture at 37°C improves sensitivity at shorter time intervals.
- Omission of protein/albumin from medium and decreasing concentration of sperm cultured have also shown to improve sensitivity.

Advantages
- Clinically applicable (uses human sperm)
- Ethical
- Detects conditions that are detrimental to human sperm survival, e.g., oil overlay, gloves, and probe covers which are not detected by other assays.

Disadvantages
- Sperm samples vary from male to male.
- Except survival, other functions of sperm in IVF (capacitation, hyperactivation, fertilization, oocyte activation) are not assessed.
- Qualitative scoring of motility is arbitrary and needs trained personnel.
- Sperm survival for 48 hours or more is not relevant in IVF (fertilization occurs within few hours of insemination).

Mouse embryo assay

Description
- *Mouse embryos:* Obtained by superovulation, mating and harvesting fresh embryos, or by thawing frozen embryos[44,45]
- *Culture of mouse embryos:* In test and culture media maintained at 37°C and 5% CO_2 in an incubator-like condition from early stages (one-cell or two-cell stage) to blastocyst stages
- Minimum of 69 mouse embryos in each (test group and control group)
- *Quantification:* Generally in the form of percentage of the embryos that achieve the advanced stage, and compared between test and control media
- If the percentage of embryos achieving the advanced stage is significantly lower in the test medium than in the control medium: Test conditions unsuitable for use in IVF laboratories.

Sensitivity

It is associated with
- *Strain of the mouse generating the gametes:* Inbred mice are less sensitive.
- *Starting stage of the embryos:* Embryos introduced as zygotes are more sensitive.
- *Stage that must be attained:* Reliance upon more advanced stages increases the sensitivity.

Advantages
- Tests the ability of embryos to undergo sustained development through the early stages and to result in embryos of a particular quality
- Conditions are quite similar to those used for culture of human embryos.
- Able to detect the presence or absence of pyruvate in the culture medium, the presence or absence of protein supplementation in the medium, and the quality of maternal serum used for supplementation.

Disadvantages
- May not be sensitive to the same array of culture conditions that may affect human embryo development
- Requires a lengthy duration of culture
- Not able to assess the ability of the conditions to support implantation, fetal growth, and delivery.

Limulus amoebocyte lysate test

Description
- Aqueous extract of blood cells (amoebocytes) from the horseshoe crab and limulus polyphemus
- LAL reacts with bacterial endotoxin or lipopolysaccharide (LPS), which is a membrane component of gram-negative bacteria.
- This reaction is the basis of the LAL test, which is used for the detection and quantification of bacterial endotoxins.

Advantages
- Simple and easy to perform
- Results obtained in a few hours
- Animals not used in testing.

Disadvantages
- High emphasis on the precise implementation of the test procedure
- Slight disturbances could influence the outcome of the test.[40]

Quality control of consumables

- There is no consensus on how these tests should be performed and different variables have an effect on their sensitivity.[48] Reagents, media, and consumables should be used prior to the expiry date.
- Sterile single-use disposables should be used.
- Appropriate refrigeration facilities for storage of media and reagents should be available and the maintenance of correct temperature during the shipment to the clinic must be verified.
- Documentation of QC is a must. The supply of commercial media should correspond with a delivered batch. A stock management system for media, oil, and consumables stating batch number, date of entry, shelf life, and date of expiry should be maintained **(Fig. 12)**.
- The protein source for medical use should be strictly defined. Use of blood-based media or blood-based media supplement (human fetal cord serum, maternal or donor serum, follicular fluid) is not allowed.
- Risk assessments should be done on all consumables.

Liquid nitrogen levels

- Liquid N_2 levels are measured using a measuring stick.
- The stick is lowered to the bottom of the tank and also allowed to cool for a few seconds. It is then taken out and shaken. Frost or condensation takes place when the measuring stick had contact with liquid N_2. The highest point of condensation value is recorded as the height of liquid nitrogen.
- The level should not be allowed to drop <5 inches as lower levels of liquid nitrogen could allow some of the product stored to thaw.
- Levels <2 inches are critical.

Electronic monitoring of liquid nitrogen

- Early alarm and alarm of sound and light for liquid N_2 level

Fig. 12: Quality control of consumables (oocyte retrieval needle) on the cover.

- Temperature display, digital temperature adjustment, and calibration
- Threshold-crossing alarm signal should be set accurately.

Identification of Patients and Correct Handling of their Gametes and Embryos

- A proper and accurate system to correctly identify the patient and trace and locate their reproductive cells during each step is essential in ART treatment.
- Written SOPs **(Fig. 13)** should be made which should be followed strictly for correct identification and verification **(Figs. 14A to C)** of patients (or donors) and their tissues or cells.
- Proper documentation for products and materials coming into contact with them should be available all the time.

Laboratory Procedures

Semen Analysis

- Semen should be collected into sterile, plastic containers (tissue grade, sperm toxicity tested). Use of spermicidal condoms, creams, and lubricants must be avoided.
- The container must be properly labeled and correct identification **(Fig. 14A)** should be confirmed by the patient.
- Semen analysis and preparation should be commenced within 1 hour of collection as prolonged sperm exposure to seminal plasma is not recommended.
- Semen analysis should be performed according to World Health Organization (WHO) 2010 guidelines.
- Semen preparation is also advisable so as to suggest the most adequate insemination technique.
- Proper records should be maintained for each semen analysis.

Semen Preparation

- Before stating a treatment cycle, at least one diagnostic semen analysis should be performed according to WHO 2010 criteria. A frozen back-up sample should be kept if difficulty in semen collection is anticipated on the day of oocyte retrieval.
- Protocols for semen collection should be documented.
- Records should be maintained on the type of container used, time and place of collection, time interval between collection and analysis, use of medication in previous months, sample origin (ejaculate/epididymal/testicular, donor/partner, fresh/frozen), preparation method, and pre- and postpreparation sperm parameters.
- Sterile technique and universal precautions should be observed in all procedures.

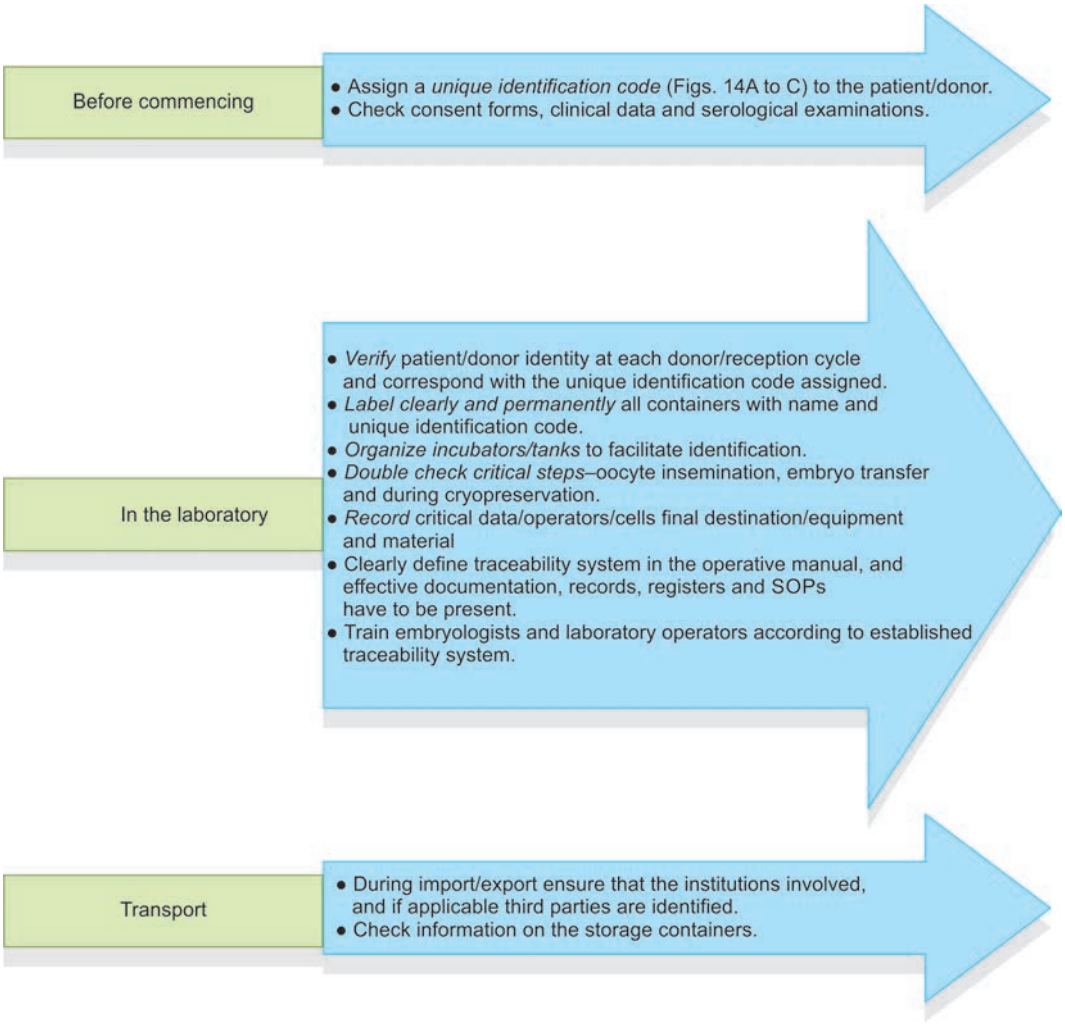


Fig. 13: Standard operating procedures for correctly identifying patients and handling their gametes. (SOP: standard operating procedures)

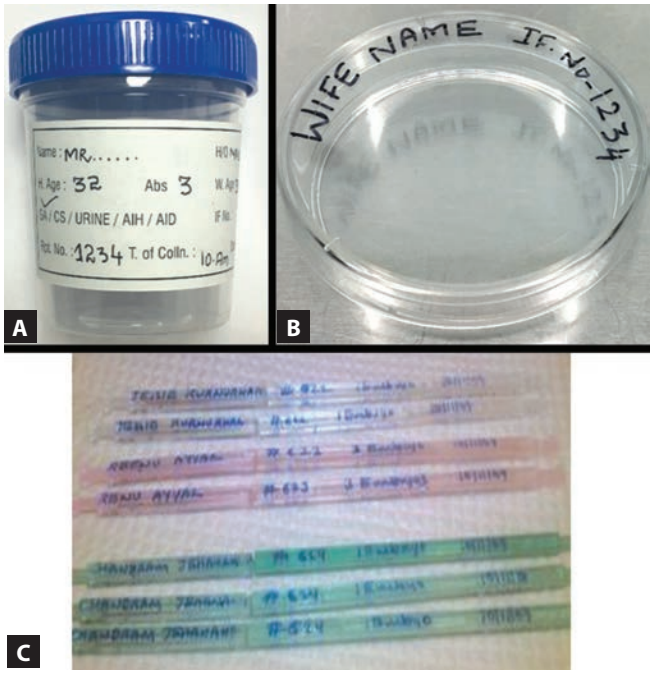

Figs. 14A to C: Verification of patient's identity.

- In cases of donor insemination, complete documentation including source and donor number should be done. Donors should be recruited only from the donor sperm banks which are accredited with the state.

Oocyte Retrieval

- An identity check before starting the procedure is mandatory.
- There should be efficient and quick handling and special attention to temperature and pH must be given. Appropriate equipment should be in place to maintain the temperature at 37°C. Flushing media, collection tubes, and dishes should be prewarmed. The egg retrieval room should be in close proximity to the laboratory and care must be taken to maintain temperature and pH during transportation.
- The time between oocyte retrieval and culture of washed oocytes should be kept at minimum and prolonged exposure of oocytes to follicular fluid is not recommended.

- Operator, timing of retrieval, and the number of collected oocytes must be documented.
- Written SOPs for egg search and identification, media used for aspiration, temperature, pH, and rapidity for evaluation must be available and documented for each procedure.
- Written protocols for description of stages of oocyte quality and maturity, magnification used, and remedies to be used for immature oocytes should be available. The morphological condition of all oocytes should be documented.

Insemination of Oocytes

- A double check of the identity of gametes before starting insemination is mandatory.
- Written procedures for insemination should be available.
- Proper documentation for each sample, time of insemination, and relevant observation at the time of insemination should be maintained.
- During insemination of each dish, temperature, humidity, and pH of the media should be controlled appropriately.

Embryo Culture and Transfer

- Appropriate measures to maintain adequate temperature and pH during culture and handling of embryos should be taken.
- Proper records on embryo quality assessment should be maintained which include the operator, date and time of assessment, and embryo morphological characteristics.
- A double identity check of the patient, the patient's file, and the culture dish(es) **(Fig. 14B)** are a must immediately before the transfer.
- For the transfer procedure, patient records should be maintained regarding:
  - Date and time of embryo transfer
  - Name of the operator
  - Name of the clinician performing the transfer
  - Number, developmental stage, and quality of embryos transferred
  - Type of catheter used
  - Fate of extra embryos and details about the procedure should be documented.

Cryopreservation

- A double check of the patient's identity is mandatory during the following steps:
  - Transfer of samples during labeled cryodish
  - Loading of labeled device **(Fig. 14C)**
  - Deposition in the cryobank
  - Removal from the cryobank
- At cryopreservation, proper documentation should be done on:
  - Device labeling
  - Cryopreservation method
  - Date and time of cryopreservation
  - Operator
  - Embryo quality and stage of development
  - Number of oocytes or embryos per device
  - Number of devices stored per patient
  - Location of stored samples (tank, canister)
- Cryodevices should be clearly and permanently labeled with patient details and unique identification code **(Fig. 14C)**.
- At the time of thawing, documentation should be done on
  - Thawing method
  - Date and time of thawing
  - Operator
  - Post-thawing sample quality
- A periodic check of the contents of cryobank should be done.
- During storage and handling of cryopreserved material, adequate and safe conditions should be maintained. Temperatures should never rise above –130°C. Liquid nitrogen levels should be checked and maintained.

In Vitro Fertilization Laboratory Cleanliness

- Proper cleaning and disinfection of the IVF laboratory are mandatory. These should be done daily after the day's work is over.
- The disinfectant should be nontoxic and odorless.
- Benzyl-alkyldimethyl chloride (Oosafe) or 70% alcohol (usually methanol) is used as disinfectant. Methanol is preferred over ethanol because of its lower vitality index and thus releasing lesser fumes in the laboratory environment.
- The use of halogens such as bleach solutions (chlorine) or betadine (iodine) is contraindicated because they are gamete and embryo toxic.

Protective Measures

The purpose of the protective measures is also to ensure personal safety and prevention of cross contamination and aseptic conditions for gametes and embryos:

- Use of nontoxic (nonpowdered) gloves and masks
- Use of vertical laminar-flow benches
- Use of mechanical pipetting devices
- Use of disposable materials: These must be discarded immediately after use in the proper waste containers. Potential infectious materials must be disposed of in a manner that protects laboratory workers and maintenance, service, and housekeeping staff from exposure to infectious materials in the course of their work.
- Needles and other sharps should be handled with extreme caution and discarded in special containers.

Special containers are used to discard used broken glassware and Pasteur pipettes.
- Use of cosmetics should be minimized and use of perfumes should be avoided.
- Vaccination of all personnel against hepatitis B
- Screening of all patients against infectious diseases
- Staff must be informed when a viral-positive patient has to be treated.

Laboratory Records and Documentation

Good documentation is an essential part of any QMS. The process and equipment validation and laboratory SOPs should be correctly and completely documented.

A document describing a method or process used in a laboratory is known as SOP. It should outline the competence demands on embryologists performing the process.

Records can be in the form of:
- *Paper records:*
  - Conventional method
  - Analysis not possible
- *Electronic records:*
  - Records in spreadsheets/database
  - Analysis possible immediately
  - Also ensures data backup.

It includes the following:
- Patients record in detail
- List of all instruments and their maintenance records
- Logbook of all disposable and culture media in the laboratory for day-to-day work, name of the suppliers, lot numbers, usage date, date of experiment
- Logbook record of all procedures done in the laboratory
- Records of grading the oocyte, embryo, and blastocyst and subsequent stages of development
- Log of laboratory incidents and milestones for future upgradation and modification
- Record of daily QC of equipment
- Record of all consent forms or legal papers regarding third-party reproduction
- Personnel records including educational credentials, continued education, and training
- Record of all publications and research programs essential for further progress of any ART center
- Records of license and registration
- Laboratory meeting minutes and documentation of the next objective

Advantages
- Available for review in future
- Helps in analysis later, when problems arise or improvements are desired
- Helps in determining corrective actions (QA) in future
- Helps to associate the maintained values with patient outcomes.

The records and documentation should be reviewed periodically by laboratory director or supervisory personnel:
- To confirm that the data were collected
- To confirm that corrective actions were taken when needed
- The corrective actions rectified the problem.

Key Performance Indicators

Performance indicators (PIs) are objective measures for evaluating critical healthcare domains (patient safety, effectiveness, equity, patient centeredness, timeliness, and efficiency). Key performance indicators (KPIs) are indicators deemed essential for evaluating the introduction of a technique or process, establishing minimum standards for proficiency, monitoring ongoing performance within a QMS for internal QC, external QA, benchmarking, and quality improvement. The best benchmarking for KPIs is done against an in-house-determined "gold standard." KPIs should be monitored for the whole laboratory **(Table 6)** and for each embryologist and doctor to maintain the principle of confidentiality and not ignoring the stress and decreased self-confidence it can lead to. The KPIs for ART laboratory have been proposed in Vienna Consensus.[49] The KPIs for cryopreservation have been proposed in alpha consensus.[50] These indicators typically assess cryosurvival being evaluated through return of apparently normal function or morphological development and implantation rate post embryo transfer. These are the most common indicators of cryosurvival for oocytes, zygotes, cleavage stage embryos, and blastocyst cryopreserved using either slow freezing or vitrification.

Audits

Clinical audit has been defined as a quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change. Thus, an audit, be it of the IVF laboratory or the clinic, is an impartial and objective assessment. Done properly, it is a strong framework to objectively, dispassionately, and systematically improve patient care in an ongoing manner. It provides a unique opportunity to not only prove competence but also improve quality of care which will finally determine the success of the clinic. It is discussed in Chapter 91.

EMERGENCY PLAN IN IN VITRO FERTILIZATION LABORATORY

- Emergency planning aims to describe the actions to be taken for (in the order of importance):
  - Safety of personnel and patients
  - Protection of all fresh and cryopreserved human material

TABLE 6: Key performance indicators for the ART laboratory.[51]

Key performance indicator	*Calculation*	*Benchmark value (%)*
1. ICSI damage rate	$\frac{\text{No. of damaged or degenerated}}{\text{All oocytes injected}} \times 100$	≤5
2. ICSI normal fertilization rate	$\frac{\text{No. of oocytes with 2PN and 2PB}}{\text{No. of MII oocytes injected}} \times 100$	≥80
3. IVF normal fertilization rate	$\frac{\text{No. of oocytes with 2PN and 2PB}}{\text{No. of COCs inseminated}} \times 100$	≥75
4. Failed fertilization rate (IVF)	$\frac{\text{No. of cycles with no evidence of fertilization}}{\text{No. of stimulated IVF cycles}} \times 100$	<5
5. Cleavage rate	$\frac{\text{No. of cleaved embryos on day 2}}{\text{No. of 2PN/2PB oocytes on day 1}} \times 100$	≥99
6. D2 embryo development rate	$\frac{\text{No. of 4 – cell embryos on day 2}}{\text{No. of normally fertilized oocytes}^a} \times 100$	≥80
7. D3 embryo development rate	$\frac{\text{No. of eight cell embryos on day 3}}{\text{No. of normally fertilized oocytes}^a} \times 100$	≥70
8. Blastocyst development rate	$\frac{\text{No. of blastocysts day 5}}{\text{No. of normally fertilized oocytes}^a} \times 100$	≥60
9. Successful biopsy rate	$\frac{\text{No. of biopsies with DNA detected}}{\text{No. of biopsies performed}} \times 100$	≥95
10. Blastocyst cryosurvival rate	$\frac{\text{No. of blastocysts appearing intact}}{\text{No. of blastocyst warmed}} \times 100$	≥99
11. Implantation rate (cleavage stage)[b]	$\frac{\text{No. of sacs seen on ultrasound}}{\text{No. of embryos transferred}} \times 100$	≥35
12. Implantation rate (blastocyst stage)[b]	$\frac{\text{No. of sacs seen on ultrasound}}{\text{No. of blastocysts transferred}} \times 100$	≥60

[a]Defined as oocytes with 2PN and 2PB on Day 1
[b]Based on total no. of embryos transferred to all patients in the reference group, not just those for whom an implantation occurred (ART: assisted reproductive technique; ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization)

  - Limitation of damage to equipment and medical records
- Communication measures in emergency situations should be clear for all personnel.
- Facilities:
  - Loss of electrical power should be compensated by generators or uninterrupted power supply (UPS) systems.
  - In case of failure of automatic supply lines of liquid N_2, tanks should be filled manually. A fully filled reserve tank should be kept as a backup.
- Equipment:
  - In case of power failure, critical equipment should be prioritized.
  - A backup of all critical equipment should be available which should be fully validated and ready for use.
  - Back-up cooled freezers and refrigerators should be available.
  - Cryopreservation vessels: It may be necessary to move tanks to another location.

TABLE 7: Checklist in in-vitro fertilization laboratory.[52-55]

Daily checklist	1. CO_2 incubator (temperature, CO_2, and humidity) 2. CO_2 cylinder (before and after procedure) 3. Temperature of Petri dish warmer 4. Temperature of heating stage, dry bath, and heating block 5. Bubbles in Teflon tubes of micromanipulator 6. Microscopes 7. Refrigerator 8. Media and consumable stocks 9. Overall cleaning 10. Daily disposable of waste materials is mandatory
Weekly checklist	1. Interiors of incubator—soiling and water level 2. Liquid nitrogen levels 3. pH meter check of the culture media 4. Circulating fan of the incubator
Monthly checklist	1. Stock of all disposables 2. Changing liquid paraffin of micromanipulator tubes 3. Checking uninterrupted power supply, alarm or call break system
Quarterly checklist	1. Servicing and calibration of incubator 2. Servicing of microscopes 3. Fumigation of laboratory
Half yearly checklist	1. Change of filter of laminar airflow 2. Change of filter of Coda tower
Annual checklist	1. Overall laboratory complex 2. Record keeping and maintenance

TABLE 8: Benefits and drawbacks of quality management system.

Benefits	***Drawbacks***
• *For patients:* Consistency, reproducibility, and highest quality of all diagnostic and therapeutic procedures • *For health insurance companies:* Highest quality care for their clients • *For IVF laboratory:* Trouble-shooting, maintenance of equipment and milieu, improved and standardized care • *For IVF clinic management:* – Optimization of working processes – Active risk management – Powerful mechanism for internal and external controls and decision making (saving costs) • Documented improvement of pregnancy rate	• Increased workload for management • Time consuming • Not always easy to motivate all the staff (increased competence, but also responsibility) • Expensive • Direct investments • Audits • Not easy to explain to patients

(IVF: in vitro fertilization)

- Medical records to identify the ownership of human tissue should be kept on a secure Web server.
- Regular revision of the emergency plan is necessary.
- Third-party arrangements should be in place with another IVF laboratory for emergency transfer of gametes and embryos (fresh and cryopreserved).

CHECKLIST IN IN VITRO FERTILIZATION LABORATORY

A regular monitoring of laboratory on daily, weekly, monthly, quarterly, half yearly, or yearly basis is mandatory to ensure QC and optimum results **(Table 7)**.

BENEFITS AND DRAWBACKS OF QUALITY MANAGEMENT SYSTEM

Quality management is not a task that can be performed alongside regular work. It comes with its own advantages and disadvantages **(Table 8)**.

CONCLUSION

Quality management is an ongoing process and is crucial for future follow up. At the beginning it appears to be endless, immense, time consuming, expensive, requiring lot of commitment, communication, cooperation and motivation, but once completed, it helps in standardization, reproducibility, traceability, transparency with increased efficiency and better results. It also helps in gaining trust and satisfaction of the patients. It is a never ending commitment and the only way by which we can promise safe and efficient IVF treatment for all patients.

KEY POINTS

- Quality management is an ongoing process and is crucial for future follow-up. At the beginning, it appears to be endless, immense, time consuming, expensive, requiring lot of commitment, communication, cooperation, and motivation but once completed, it helps in standardization, reproducibility, traceability, transparency with increased efficiency, and better results.
- It also helps in gaining trust and satisfaction of the patients.
- The QC should be at each level; laboratory personnel, equipment, consumables, procedures, record keeping and documentation, and also while doing audits.
- A proper plan including a backup plan and an emergency plan should always be ready.
- It is a never-ending commitment and the only way by which we can promise safe and efficient IVF treatment for all patients.

CHAPTER 91

Auditing of Clinical Outcomes

Arati R Rao

INTRODUCTION

Clinical audit has been defined as a quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change.

Aspects of the structures, processes, and outcomes of care are selected and systematically evaluated against explicit criteria. Where indicated, changes are implemented at individual, team, or service level and further monitoring is used to confirm improvement to healthcare delivery [National Institute for Health and Care Excellence (NICE) Guidelines, 2002].

The very first clinical audit was carried out by Miss Florence Nightingale during the Crimean War (1853–1855) where she meticulously demonstrated a significant reduction in mortality rates in the hospital wards by applying strict sanitary routines and standards of hygiene. Gradually, over the years conducting regular clinical audits has become quite the norm in many countries, but this unfortunately is not yet well accepted in India.

In fact, a study conducted by CMC Vellore in 2012 suggested that the root cause of noncompliance with audit was simply because it was not a priority in the busy schedules of practicing clinicians.[1] And, this was very likely due to a basic lack of understanding of the audit process.

BENEFITS OF AUDIT (BOX 1)

The benefits of a properly conducted audit are multifold—affecting not only the patients but also their caregivers (clinical staff) and the management too.

To the patient, regular audits will ensure quality, consistency, and efficacy of care.

To the staff, audits bring about significant professional development. They provide knowledge about newer developments in the field, current and established guidelines, and more importantly identifies the need for training. Data collection, an integral part of the audit, provides opportunities to publish.

BOX 1: Benefits of audit.

To the patient:
- Quality of care
- Consistency of care
- Effectiveness of care
- Patient satisfaction

To the staff:
- Professional development
- Awareness of current treatment guidelines and protocols
- Opportunities to publish
- Identifies training needs
- Improves clinical efficacy
- Improves communication

To the management:
- Strengthens self-regulation
- Improves cost effectiveness
- Reduces complaints and litigation
- Identifies the need for organizational change

All in all, *audits improve clinical effectiveness.*
They also help to improve communication—both interpersonal as well as intradepartmental.

To the management, audits will not only improve cost effectiveness, but will also reduce the risk of litigation and complaints. It also self-regulates and identifies the need for organizational change.

A properly conducted audit allows for an objective assessment of the quality of care with a focus on "how to improve". Transparency and accountability lead to high standards of care.

Who Should be Present at Audit Meetings?

Typically an audit meeting should have the primary caregivers—clinicians, nurses, andrologists, and embryologists—the persons who will implement the proposed changes; management representatives who will authorize any changes and whenever possible, the clinical audit team to regulate the entire process.

THE AUDIT CYCLE (FLOWCHART 1)

The audit cycle is a series of steps that are involved in a complete audit.

This cycle is closely interlinked with the reaudit cycle which is used to audit the changes that were suggested in the first audit—a sort of closing the loop process.

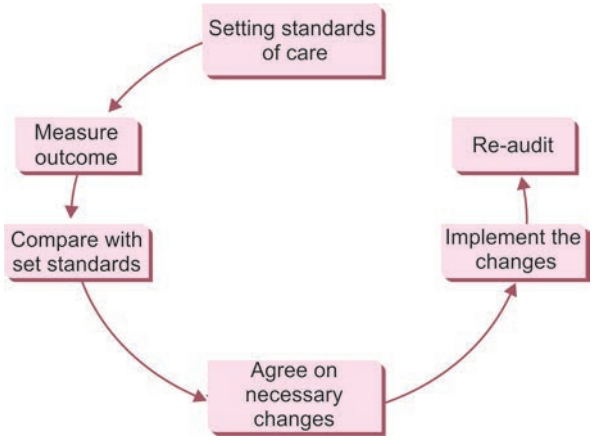
As is evident the audit is focused on quality of patient care. It is neither a research nor a process to collect and analyze data. Neither is it a criticism of clinical practices or technical competence **(Boxes 2 to 4)**.

SECTIONS TO BE AUDITED

Sections audited [International Organization for Standardization (ISO) 9001–2000]:

- Document control
- Record control
- Quality policy
- Quality objectives
- *Job description:* Responsibility and authority
- Provision of resources, infrastructure, and work environment
- *Human resources:* Competence, awareness, and training
- *Planning of product realization:* Process maps, documents, and records
- *Customer-related processes:* Consent, flow sheets, and communications
- Purchase
- *Service provision:* Procedures, validation, etc.
- Monitoring and measuring devices.

Flowchart 1: The audit cycle.



BOX 2: Differences between audit, research, and clinical service evaluation.[2]

- *Clinical audit:* Measures current practice against evidence-based clinical standards
- *Research:* Investigates the effects of new or existing treatment or technique on patients/carers
- *Service evaluation:* Evaluates the effectiveness or efficacy of current practice/services

An audit, be it of the in vitro fertilization (IVF) laboratory or the clinic is an impartial and objective assessment.

Done properly, it is a strong framework to objectively, dispassionately, and systematically improve patient care in an ongoing manner. It provides a unique opportunity to not only prove competence but to improve quality of care which will finally determine the success of the clinic.

SETTING STANDARDS

Audit is a process where actual practice is compared to established standards of good practice.

A standard is an explicit statement describing the area of care that is being measured.

The recommendations of standards are usually from international bodies such as the Royal College of Obstetricians and Gynaecologists (RCOG), American Society for Reproductive Medicine (ASRM), European Society of Human Reproduction and Embryology (ESHRE), etc.[3,4] Local consensus of expected practice norms may also be used.

BOX 3: Types of audit: horizontal, vertical and examination.

- *Horizontal audit:* Horizontal audit takes place within an organization and is often referred to as a "peer audit". This is used to evaluate the effectiveness of a process of one group as compared to another group within the same organization. An example of this type of audit is evaluation of pregnancy rates following frozen embryo transfer from two branches of the same clinic with the same quality management standards. A horizontal audit can be used to evaluate the shortcomings of a vertical audit
- *Vertical audit:* Vertical audits on the other hand dig deep. They focus on a single process or procedure. It may involve direct questioning of the operator, verification of related documents, and details of instrument calibration. This is easy to follow and can be used regularly. However, as it focuses on a single process, all aspects of the clinic may not be covered every time
- *Examination audit:* This is a type of vertical audit. It involves auditing of a procedure as it is being performed. It is used to ensure that the person has a good understanding of the procedure and adheres to the standard protocols set for this purpose. An example of this would be an audit of a clinician performing an embryo transfer

BOX 4: Types of audit: internal and external.

- *Internal audit:* Internal audits are conducted by the Internal Audit Committee composed of staff members/employees trained in the audit process. The management usually selects personnel who are familiar with the standards as well as the processes/activities performed. The audits may be conducted monthly or once in every 3 months (quarterly)
- *External audit:* External audits are conducted by outside organizations which are regulated by the International Organization for Standardization (ISO). Once a year (annual) along with a complete audit once in 3 years is recommended

In an IVF unit setting standards or benchmarking is used to compare services and results against the best in the field **(Box 5)**.

Obviously, the target of setting standards is to achieve 100% compliance with the set standards **(Boxes 6 and 7)**.[5]

SELECTING TOPICS FOR AUDIT

SMART forms the basis of selecting topics for an audit. Any area or process that is to be audited should basically fit the SMART criteria **(Box 8)**.

IN VITRO FERTILIZATION PROGRAM PERFORMANCE INDICATORS

For a patient, pregnancy and implantation rates are the most important indicators of a successfully run program. Cost and location of the clinic are also important.

While these indicators indicate the success of the IVF program as a whole, it must be remembered that standardizing performance indicators becomes difficult because of the multiple variables in this field. It is recommended that each program sets its own benchmarks for that particular function.

Listed here are the some examples of performance indicators **(Box 9)**.

BOX 5: Types of benchmarking.

- *Internal:* Comparison between centers within a group. In an ideal world, each center within a group should have the same results anywhere in the world. This not only depends on the clinicians but on operational uniformity
- *Competitive:* Comparison with direct competitors
- *Functional:* Comparison with the best in the field. This will influence the stimulation protocols, drugs used, and technologies applied. For any of this to be successful, a strong internal quality management systems initiative is essential to maintain uniformity of practice

BOX 6: Classification of standards.

- *Structure:* What do you need?
- *Process:* What do you do?
- *Outcome of care:* What do you expect?

BOX 7: Tips for setting standards.

- Evidence-based
- Reflect current practice; not what was done 2 years ago
- It should be achievable and realistic
- It should have measurable parameters to allow for comparison

BOX 8: SMART criteria for selecting an audit topic.

S—specific
M—measurable
A—achievable
R—related
T—time bound

It must be remembered that program performance indicators should be further classified based on the patient's age and the type of procedure used **(Boxes 10 to 14)**.

BOX 9: Program performance indicators.

- *Pregnancy rates:*
  - Biochemical [beta-human chorionic gonadotropin (hCG) positive]
  - Clinical (identification of the gestational sac)
  - Ongoing (fetal heart pulsations visualized by ultrasound at 7 weeks)
- *Implantation rates:*
  - Overall implantation rates = total number of gestational sacs seen on ultrasound/total number of embryos transferred
  - Multiple implantation = proportion of pregnancies with more than one gestational sac on ultrasound

BOX 10: Laboratory performance indicators.

- Oocyte grade/maturity
- IVF fertilization rates (proportion of inseminated oocytes that have 2 PN the day after insemination)
- ICSI fertilization rates (proportion of injected oocytes that have 2 PN the day after insemination)
- Poor or failed fertilization rated (proportion of cycles in which <25% of inseminated oocytes were fertilized)
- ICSI damage rates (proportion of oocytes that disintegrated during or just after the ICSI procedure)
- Zygote grade
- Cleavage rates (proportion of zygotes that have cleaved to become embryos)
- Embryo development rate (proportion of cleaved embryos that become four cells 2 days after insemination; proportion of cleaved embryos that become eight cells 3 days after insemination; proportion of cleaved embryos that become blastocysts 5 days after insemination)
- Embryo fragmentation rate (proportion of eight cell embryos with <5% fragmentation)
- Embryo grade (proportion of day 3 embryos with the highest grade)
- Embryo utilization rate (proportion of embryos that were either transferred or cryopreserved)
- Embryo cryosurvival rates (proportion of embryos that survived freezing and thawing cycle)

BOX 11: Efficiency indicators.

- Number of cases handled by individual operators
- Time lag between enquiry and response
- Proportion of patient records which are complete
- Number of phone calls answered
- Number of voicemails received
- Average time between conduction of a test and communication of results to clinician and patient

BOX 12: Best practice indicators.

- Incident reports
- Treatment complications
- Incidence of ovarian hyperstimulation syndrome (OHSS)
- Infection rates
- Number of positive and negative comments received

BOX 13: Laboratory indicators.

- Number of IVF and ICSI procedures done each month
- Utilization of consumables
- *Equipment efficacy:* For example, volume of liquid nitrogen required for top-up each month

(ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization)

BOX 14: Financial considerations.

- Revenue each month
- Comparison of fee structuring with other centers
- Number of referrals each month

The importance of identifying reference populations cannot be undermined. Stratification based on population demographics allows for more robust statistical data.

SETTING OBJECTIVES

An objective is a specific statement that clearly defines which aspects of quality are going to be measured in order to show that the purpose (aim) of the audit has been met.

It should be unambiguous so that there is no confusion about the focus and purpose of the audit.

While a center may have multiple objectives—this often may be difficult to handle for the audit team.

It will be better to divide the objectives into smaller and more manageable segments. As the proverb goes "one thing at a time and that done well".

It is always better to complete one audit, implement the changes, wait for them to work, and then move on to the next objective.

DATA COLLECTION

There are no specific definitions as to the sample sizes needed for clinical audits. This will depend on what is being audited and how easy it is to get the required information.

Random sampling is generally the best way to get a representation of the population being studied.

It is crucial that the sample is collected very carefully as inaccurate data can skew the audit results and give false results.

While clinical audits do not need ethical clearance, they are still bound by the data protection act and should be conducted within an ethical framework.

DATA ANALYSIS

The aim of data analysis is to convert data into useful information—in this case to see if the audit standards are complied with.

Details of statistical analysis are out of the scope of this chapter.

WRITING AN AUDIT REPORT[6]

An audit report outlines the measures taken to complete the audit.

Cover Sheet

It should include the audit title, date, name of lead auditor, and all the team members.

Introduction

It is a brief paragraph on the service being audited and the target group. It should also mention why the audit was undertaken and which standards were applied.

Aim

It is the purpose of the audit.

Standards

It is a list of the expected practice standards against which the audit will compare the current practice standards.

Methodology

It is the methods and tools used to collect data.

Size and Scope

This section documents—who was involved in conducting the audit, the target group, sample size, and the time frame when the audit was conducted.

Results/Findings

Results of the analyzed data should be presented in an easy-to-read graphical or tabular form.

Areas for change are identified along with any findings that may help in implementation of the changes.

Conclusion/Summary

It summarizes the findings of the audit along with evidence taken from within the results.

The report will indicate whether the set standards have been met—compliance or noncompliance when the standards have not been met. Noncompliance may be critical or noncritical.

Critical noncompliance is synonymous with a complete failure to adhere to the set standards. In other words, it is a system failure. On the other hand, a noncritical noncompliance is a failure to meet the set standards to a level where there will not be a total system failure.

Recommendations

Realistic changes are based on the audit findings.

The reaudit report should, in addition to the earlier, clearly state the changes that were proposed in the original

BOX 15: The action plan.

- Define what needs to change
- Define the actions necessary to bring about that change
- Establish a timeline for these actions to be carried out
- Identify person or persons responsible for these actions
- Indicate the evidence needed to show that these actions/ recommendations have been implemented

BOX 16: Simplified audit report.

- Observations
- Recommendations for improvement
- Timelines for implementation of change

audit and an assessment of the actions taken. A comparison of the findings of the current audit to the previous one must be documented.

RECOMMENDATIONS FOR CHANGE

Once the audit report has been accepted, the proposed changes must be discussed to fully understand why they are needed and how they will make a difference.

The proposed changes following a properly conducted audit constitute the action plan **(Box 15)**.

This should include clearly defined recommendations for change. Who should do it (named person) and by when (appropriate date and time) to give a realistic timeline for implementation.

Sample of audit information sheet	
Audit number	Date
Center name and address	
Department audited	
Lead auditor name:	Auditor 2 name
Supervisor name.	Signature
Section audited	

SCOPE OF THE AUDIT

Name the documents/processes audited. If only part of a process or document was completed—describe the same.

AUDIT REPORT

The final report should be simple, easy to read, and understand **(Box 16)**.

BOX 17: Traits of competent certification bodies.

- Accreditation to certify medical institutions
- Experience in certifying in vitro fertilization (IVF) clinics
- IVF specialists (clinicians and embryologists) on team
- Adequate time (at least 2 days) allotted to each center

Some organizations believe that by finding no non-conformances, i.e., a perfect audit indicates a clinic with an outstanding performance. However, this is more likely to indicate a poorly conducted audit as even the best clinics will always have scope for improvement.

Hence, the importance of finding suitable auditors/ certification bodies **(Box 17)**.

KEY POINTS

- An audit, be it of the IVF laboratory or the clinic is an impartial and objective assessment. Done properly it is a strong framework to objectively, dispassionately, and systematically improve patient care in an ongoing manner.
- It provides a unique opportunity to not only prove competence but to improve quality of care which will finally determine the success of the clinic.

CHAPTER 92

Periconceptional Challenges and Modifiable Risk Factors: Evidence to Practice

Revathi S Rajan

INTRODUCTION

Adverse outcomes due to dysfunctional placentation should be mapped from the time of implantation which is the essence of an "extended inverted pyramid" of prenatal care.[1]

This emphasizes the need to identify the possible risk factors that could complicate pregnancy especially in those undergoing "assisted reproduction" periconceptionally to optimize perinatal outcomes. Many of these women have no previous obstetric experience posing a challenge to the clinicians to decide risk modulation protocols that are conventionally based on previous obstetric outcomes.

Hence, it is quintessential to identify modifiable risk factors periconceptionally influencing conception and beyond.

BACKGROUND

Understanding of the complex interaction at the maternal fetal interface is crucial both in terms of challenges and adaptive mechanisms as any imbalance in these could lead to adverse pregnancy outcomes. This emphasizes the need for anticipating clinical stress prior to its onset based on the factors that help effective prediction; the true essence of risk modulation.

Here are listed various challenges and their implications encountered during the periconceptional period. Though their implications have not been fully understood; identifying modifiable risk factors prior to conception can contribute to better fertility and pregnancy outcomes.

OXIDATIVE STRESS

A disequilibrium between reactive oxygen species and processes of detoxification and restoration leads to oxidative stress. Evidence has shown that presence of inflammation without an adequate oxidizing environment may trigger complications including early pregnancy losses, preeclampsia and fetal growth restriction. Prediction of the same using biomarkers of oxidative stress is still not yet standardized. Hence, interventions to counter oxidative stress and its implications are still being researched.[2]

IMMUNE REGULATION IN PREGNANCY (FIG. 1)

The "placenta" which forms the maternal fetal interface is a complex unit that is composed of regulatory factors that could influence continuation of pregnancy.

As the pregnancy progresses, the regulatory mechanisms controlling these factors change and the process is almost clearly defined.

The trophoblasts primarily invade the uterus facilitating an active gas exchange including provision of nutrients and also simultaneously allow disposal of waste at the maternal-fetal interface.

The placenta allows for immune tolerance facilitating pregnancy progression. Any impairment of this results in a disease state-specific to pregnancy.

Maternal adaptive responses also occur allowing placental and fetal development. These include a shift of the immune response from T helper 1 (Th1) to Th2 profile which

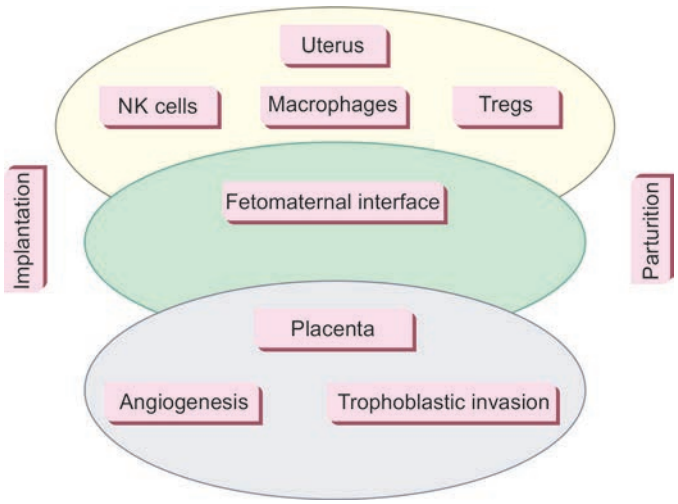

Fig. 1: Immune regulation pathway.
(NK: natural killer; Tregs: regulatory T cells)

is considered to be typical during pregnancy. The cluster of differentiation 4 (CD4) regulatory T cells (Tregs) which predominate in the latter half of the pregnancy modulate maternal immune responses directed toward the fetus and are triggered by paternal antigens.

The uterine natural killer (NK) cells ($CD56^{bright}$ and $CD16^{dim}$) have been recognized as the dominant cell type responsible for trophoblastic invasion.

"Implantation" is facilitated by the infiltration of the syncytiotrophoblasts into the endometrium and the differentiation of the trophectoderm into cytotrophoblasts for the embryo. The extravillous trophoblasts are those syncytiotrophoblasts in contact with the decidua and serve as an endocrine organ coordinating with maternal adaptive immune responses.

Fetus as an Allograft

"Pregnancy" is a complex regulatory mechanism involving both inflammatory and immunosuppressive responses leading to the acceptance of the fetal allograft. The immunoregulatory factors generated by the placenta help in establishing a state of immune tolerance and protects rejection of the developing fetus.

The trophoblastic invasion and angiogenesis are controlled by mechanisms involving both immune and vascular networks with maternal surveillance mechanisms in the fetus favoring progressive growth.

The trophoblasts are primarily important and crucial for the survival of the fetal allograft.

In a healthy pregnancy, these trophoblasts are resistant to "NK cells" and lymphocyte activated cells and define the fetoplacental interface. They also express NK cell type Fc-gamma receptor III (responsible for phagocytosis) and other immunosuppressive factors similar to transforming growth factor-beta (TGF-β).

Natural Killer Cells

Malfunction of the natural killer (NK) cells has been attributed to infertility and recurrent miscarriages.

Natural killer cells identified by CD56 predominantly inhabit the uterus especially at the implantation site. They are in close contact with the invading trophoblastic cells which are important for the remodeling of spiral arteries. There is defective trophoblastic invasion in conditions such as preeclampsia, fetal growth restriction, and recurrent abortions. The exact role of NK cells in the recognition of the trophoblasts and the consequence of this is yet to be established.

Peripheral NK cells are misassumed to be similar to uterine NK cells. They vary based on age, ethnicity, and sex. Though these NK cells are being measured and high values have been attributed for adverse fertility and pregnancy outcomes; they do not reflect the status or function of the uterine NK cells.

Hence therapies directed to suppress peripheral NK cells are not warranted. In fact, some of them have produced adverse effects to the mother and the fetus.[3]

Antinuclear Antibody Status

Antinuclear antibodies (ANA) are a group of antibodies that are directed against nuclear and nucleolar proteins of the biological cell. ANA is classically associated with systemic lupus erythematosus (SLE) but can be positive in other autoimmune disorders and some elderly individuals. Hence, clinical correlation with seropositivity is essential to make a working diagnosis.

Evidence has shown that ANA positivity could influence implantation. Implantation failures in in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI) cycles; especially those in the first treatment cycle have shown a positive correlation with ANA positivity. However, this did not influence cumulative pregnancy rate without treatment. Hence, it was concluded that medications directed for the treatment of seropositive status would favor better implantation rates especially to those in the first treatment cycle.[4]

Antinuclear antibody positivity has also been shown to be associated with unexplained recurrent pregnancy loss (RPL) and also predicted unfavorable obstetric outcomes. Antinuclear antibody is to be measured by the immunofluorescence technique. Though enzyme-linked immunosorbent assay (ELISA) offers a high degree of sensitivity but has low specificity and hence could be used only as a screening test.

Structured and bigger studies are needed to prove the influence of ANA positivity on fertility and pregnancy.

Mapping Inflammatory Markers: Role in Immunomodulation

Methods to establish the diagnosis of NK cell malfunction and also those seronegative ANA category of patients with adverse fertility or pregnancy outcomes have still not been standardized. Any inflammatory trigger in the body can initiate hostile autoimmune responses unfavorable for conception. It is a challenge to make an accurate diagnosis of autoimmune conditions that could complicate fertility and pregnancy.

Measuring specific biochemical parameters reflective of the various organ systems of the body to map inflammatory responses could be an indirect method to measure hostile autoimmune responses.

Derangement of basic blood profiles such as complete blood count (CBC), metabolic profiles (abnormal levels of transaminases), acute phase reactants [C-reactive protein (CRP)], etc., could suggest a diffuse inflammatory process triggered by autoimmune etiology.

Parameters like elevated erythrocyte sedimentation rate (ESR) could be nonspecific but could reflect disease intensity.

Normalization of this parameter could be appreciated only after a while following the resolution of the inflammatory process.

Step-up immunological studies/serologies/flow cytometry/human leukocyte antigen (HLA) typing, etc., may also yield inconclusive results for making a diagnosis. Hence, basic and advanced testing (if suspicious of a defined autoimmune condition), together with clinical suspicion would add value in making a comprehensive clinical diagnosis.[5]

C-reactive Protein

It is an immune protein generated in the body and participates in defense against provoked antigens by opsonization and triggering the complement system.

Hence, if CRP in the blood is high, it could reflect an exaggerated inflammatory response triggered by a hostile autoimmune process.

A value of CRP <0.2 mg/dL is considered to be normal and any value more than 1 mg/dL could imply inflammation in the general population.

C-reactive protein levels during pregnancy:

- First trimester—not established. However, a value of >5 mg/dL has been known to be associated with low birth weight babies and neonatal complications.
- Second trimester—0.4–20.3 mg/dL
- Third trimester—0.4–8.1 mg/dL.[6]

Prednisolone and hydroxychloroquine are drugs [both classified as Food and Drug Administration (FDA) category C] that have been used extensively for immunomodulation during the periconceptional period and beyond. It is recommended for the clinician to explain with clarity the benefits of immunomodulation as against the probable risks before drug administration.

It is a challenge to make an accurate laboratory diagnosis of autoimmune disease which continues to remain so even in the periconceptional period. A battery of tests including basic laboratory investigations, metabolic panel, and acute phase reactants may add value apart from advanced immunological studies, serologies, and HLA typing.

The sensitivity for diagnosis and negative predictive values of ANA, which is one of the most common investigations that is performed in the general population, is low for autoimmune diseases. For specific rheumatic diseases, ANA yields a high negative predictive value of 97%, though the positive predictive value is 11%. However, the sensitivity and the specificity of ANA for the same are 42 and 85%, respectively.[7]

Application of clinical criteria and qualifying a particular disease state prior to testing significantly increases the sensitivity for diagnosis of autoimmune diseases.

Thyroid Peroxidase Antibody

Recent research has shown significant association between thyroid antibodies with infertility and recurrent miscarriage.

Effects on Fertility

High levels of thyroid peroxidase (TPO) antibody and high thyroid-stimulating hormone (TSH) have negative effect on IVF and embryo transfer in terms of embryo quality and abortion rates.

There has been an increased association of TPO antibody positivity with endometriosis as the latter is known to coexist with other autoimmune conditions. There has also been a similar association of polycystic ovarian syndrome (PCOS). This has been attributable to the increased estrogen to progesterone ratio usually seen in females with PCOS.

Effects on Pregnancy

Thyroid hormone is considered essential for normal placentation. Evidence has shown that preeclampsia, preterm delivery, and fetal growth restriction could be attributable to defective early placentation.[8] These effects are worsened in women with TPO positivity with thyroid dysfunction. A recent study has also shown that TPO-positive hypothyroid women are also more prone to midtrimester abortions compared to those who are hypothyroid and TPO-negative.

Another recent prospective study performed at a tertiary center for fertility and high-risk pregnancy in South India between August 2013 and September 2015 where outcomes of pregnancy in women with TPO positivity were mapped after appropriate dose adjustments of thyroxin concluded that there was a trend toward decrease in midtrimester abortions in these women. About 76.5% of these women were subclinically hypothyroid and hence emphasized the need for appropriate surveillance and management of this cohort to avert adverse obstetric consequences.

A positive TPO antibody test was diagnosed when the levels were equal to or >35 IU/mL. A TSH level of ≥2.5 mIU/L at booking in the first trimester was included under the category of subclinical hypothyroidism and was started on thyroxin supplements. Overt hypothyroid pregnant women who were already on thyroxin supplements were also included. Dose adjustments were made aggressively once in 4–6 weeks in the range of 1–2 μg/kg body weight. Trimester specific ranges to guide supplementation were followed as described in **Table 1**.

Adverse outcomes in pregnant women with thyroid peroxidase (TPO) positivity have been enumerated in **Table 2**.

In this study, pregnant women with TPO antibody levels of >600 IU/mL were significantly associated with gestational hypertension and fetal growth restriction.

Significant associations were found between pregnant women aged 30 years and older who were also TPO positive

TABLE 1: Trimester specific ranges to guide supplementation.

Trimester	*Normal range of thyroid-stimulating hormone*
First	0.1–2.5 mIU/mL
Second	0.2–3 mIU/mL
Third	0.3–3 mIU/mL

TABLE 2: Adverse outcomes in pregnant women with thyroid peroxidase (TPO) positivity.

Adverse outcomes	*No. of patients (n = 115)*	*%*
Gestational glucose intolerance/ GDM	69	60
Hyperhomocysteinemia	50	43.5
Bad obstetric history/RPL	49	42.6
Threatened abortion	25	21.7
Gestational hypertension	17	14.8
Antinuclear antibody (ANA) positive status	17	14.8
Antiphospholipid antibody (APLA) positive status	14	12.2
Oligohydramnios	6	5.2
Second trimester abortion	6	5.2
Funneling of cervix	5	4.3
Premature rupture of membranes (PROM)	5	4.3
Missed abortion	5	4.3
Fetal growth restriction	4	3.5

(GDM: gestational diabetes mellitus; RPL: recurrent pregnancy loss)

with hyperhomocysteinemia, antiphospholipid antibody (APLA), bad obstetric history, and RPL.[9]

Adverse outcomes in pregnant women with thyroid peroxidase (TPO) positivity as per antibody levels have been enumerated in **Table 3**.

MICRONUTRIENTS AND METABOLIC FACTORS

Hyperhomocysteinemia

"Homocysteine" is a sulfur-containing amino acid synthesized in the body from an essential amino acid methionine. It is metabolized through two pathways: (1) remethylation and (2) transsulfuration. B_{12} and folic acid are essential for remethylation and B_6 is essential for transsulfuration **(Fig. 2)**.

Hyperhomocysteinemia is defined as levels ≥15 µmol/L.

Homocysteine levels decrease during pregnancy attributable to hemodilution, increased glomerular filtration along with increased utilization by the fetus apart from the hormonal changes during pregnancy.

Hyperhomocysteinemia in pregnancy is hence defined as any value >12 µmol/L.

It is more commonly due to combined deficiencies of B_6. B_{12} and folic acid in Southeast Asian countries unlike in the Caucasian population in whom genetic mutations in the enzymes involved in its metabolism are also common.[10]

The test is highly labile and needs standardization. A fasting ethylenediaminetetraacetic acid (EDTA) sample needs to be collected and centrifuged immediately. Values in early pregnancy are considered more reliable to predict adverse maternal and fetal outcomes.

TABLE 3: Adverse outcomes in pregnant women with thyroid peroxidase (TPO) positivity as per antibody levels.

Adverse outcomes	*No. of patients (n = 115)*	*TPO-AB levels*		*p-value*
		<600 (n = 100)	*>600 (n = 15)*	
Gestational glucose intolerance/GDM	69	61 (88.4%)	8 (11.6%)	0.572
Hyperhomocysteinemia	50	45 (90%)	5 (10%)	0.395
Bad obstetric history	49	45 (91.8%)	4 (8.2%)	0.181
Threatened abortion	25	23 (92%)	2 (8%)	0.518
Gestational hypertension	17	12 (70.6%)	5 (29.4%)	0.041
Antinuclear antibody (ANA) positive status	17	15 (88.2%)	2 (11.8%)	1.000
Antiphospholipid antibody (APLA) positive status	14	13 (92.9%)	1 (7.1%)	0.690
Oligohydramnios	6	4 (66.7%)	2 (33.3%)	0.175
Second trimester abortion	6	4 (66.7%)	2 (33.3%)	0.175
Cervical funneling	5	4 (80%)	1 (20%)	0.509
Premature rupture of membranes (PROM)	5	4 (80%)	1 (20%)	0.509
Missed abortion	5	5 (100%)	0 (0%)	1.000
Fetal growth restriction	4	2 (50%)	2 (50%)	0.082

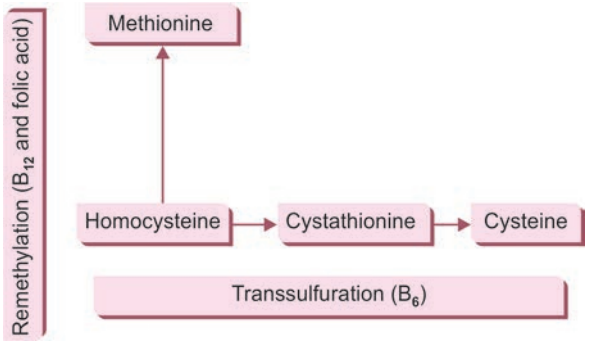

Fig. 2: Homocysteine metabolism.

Hyperhomocysteinemia could be attributable for adverse outcomes both during pregnancy and beyond. It has been established as independent causal factors for pregnancy complications. Suboptimal methylation could result in recurrent miscarriages, fetal structural defects, preeclampsia, fetal growth restriction/preterm labor, and intrauterine fetal demises. High levels of homocysteine could also adversely influence IVF outcomes. Attributable risks outside pregnancy include cardiovascular disease, vascular stroke, osteoporosis, and other neurodegenerative disorders.

Appropriate supplementation with B_6, B_{12}, and folic acid helps to control hyperhomocysteinemia in most of the Southeast Asian population where the cause of deficiency is nutritional.

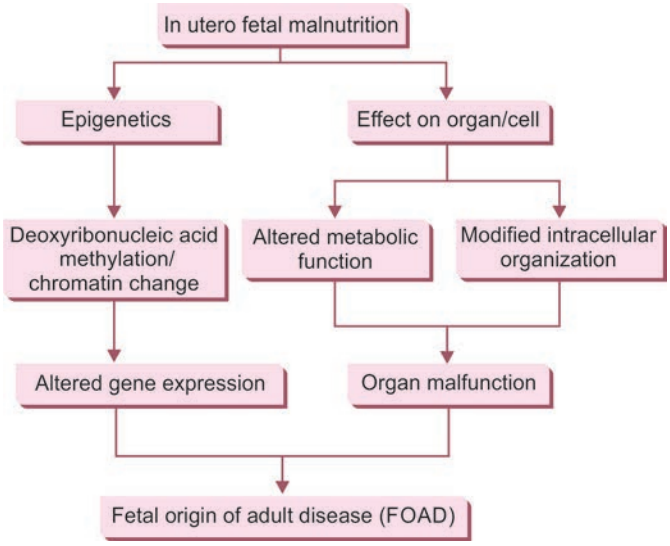
A study conducted by Pratip Chakraborty et al., Kolkata in 2013, has depicted "hyperhomocysteinemia" as a significant risk factor in predicting pregnancy salvage rates in women with PCOS as obesity and insulin resistance controlled with other confounding factors. Anticoagulation with low-molecular-weight heparin and Ecosprin conferred an additional advantage in averting pregnancy wastage in those with the hyperhomocysteinemia phenotype.[11]

Hyperhomocysteinemia which is a consequence of altered micronutrients such as folic acid and B_{12} which could result in the generation of reactive oxygen species causing oxidative stress.

Another prospective study conducted at a tertiary center for fertility and high-risk pregnancy in South India that enrolled 442 pregnant women who were screened universally for a year (September 2012 to August 2013) reported a high prevalence of 28%, of which 37% of the women were primigravidae. The mean age of these women was 32 and the mean homocysteine level was 12.6 µmol/L. There was a strong positive correlation with ANA positivity and a trend toward a positive correlation with subclinical hypothyroidism (Pilot data).

Watchful surveillance for hyperhomocysteinemia and targeted value based supplementation would help avert adverse maternal and fetal outcomes and also contribute to a healthy adult life beyond pregnancy.

Flowchart 1: In utero fetal programming.



Hemoglobin A1c as a Predictor for Risk Modulation

Evidence has shown that there is a significant risk of congenital malformations for a hemoglobin A1c (HbA1c) value of >10.4%. However, the risk for adverse perinatal outcomes increases with an HbA1c of >6.9%.

Most studies recommend a pre pregnancy HbA1c levels of <7% in women with type 1 diabetes mellitus which further stresses the need for targeted preconceptional risk modulation.[12]

In Utero Fetal Programming (Flowchart 1)

"In utero fetal programming" is a novel concept that seems to have essential implications to Maternal Fetal Medicine translates to the fact that adverse intrauterine environment for the fetus can lead to irreversible change in the developing fetus contributing to "fetal origins of adult disease". Fetal overnutrition can predispose to permanent adverse changes in the genome overall influencing the metabolic homeostasis and neuroendocrine function, thus responsible for epigenetic changes resulting in changes in gene expression without any structural changes in the genome.[13]

Hence, effective surveillance for the risk factors complicating pregnancy adds value in delivering a mature fetus not only at birth but also ensures a healthy adulthood.

POST-IVF PREGNANCIES: SURVEILLANCE PATTERNS AND RATIONALE

Recent studies have established that the possible difference in perinatal outcomes between pregnancies due to assisted reproduction techniques (ARTs) and spontaneous conceptions cannot be attributed to ART per se suggesting that the inherent characteristics of the infertile population

like high maternal age and low parity which could be a priori risk factors influencing poor perinatal outcomes.

Enumerating below a prospective matched case-control study comparing outcomes of IVF/ICSI pregnancies with non-IVF pregnancies **(Table 4)** between January 2009 and June 2010 under similar standards of maternal and fetal surveillance performed at a tertiary center for fertility and high-risk pregnancy in South India (Pilot data).

Majority of studies aimed at assessing ART outcomes have quoted a high incidence of preterm births and low birth weight babies. However, in this study, 35% of the IVF/ICSI group were born preterm as compared to 26.7% in the non-IVF/ICSI group. The mean pregnancy duration was 31.8 ± 10.31 weeks as compared to 32.92 ± 10.17 weeks in IVF/ICSI and non-IVF/ICSI pregnancies, respectively. As majority of the pregnancies have been delivered at or beyond 31 weeks, the incidence of low birth weight babies was 26.7% in the IVF/ICSI group as compared to 23.3% in the non-IVF/ICSI group. These rates were not statistically higher than the prevailing rates nationally during the time of the study. The increased rate of multiple pregnancies in both the groups could have contributed to increased incidence of preterm births in both the groups.

Though single embryo transfer has been advocated to check the rates of multiple pregnancies as a result of IVF/ICSI, iatrogenic multiple pregnancies will continue to occur provided strict guidelines for controlled ovarian stimulation are implemented even in ovulation induction-timed intercourse/intrauterine insemination (IUI) cycles.

To conclude, there were more elderly women and an increased number of plural pregnancies in the IVF/ICSI group as compared to the non-IVF/ICSI group. Hence, in vitro handling of gametes did not significantly affect perinatal outcomes which were probably influenced by the a priori maternal risk factors.

TABLE 4: Comparison of primary and secondary outcome variables between in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI) and non-IVF/ICSI pregnancies.

Variable	*IVF/ICSI (n = 60)*	*Non-IVF/ICSI (n = 60)*	*p-value*
Age in years; mean ± standard deviation (SD)	31.02 ± 4.12	30.05 ± 3.45	0.166
Nullipara, No. (%)	56 (93.3%)	51 (85.0%)	0.239
P1, No. (%)	4 (6.7%)	8 (13.3%)	
P2, No. (%)	0	1 (1.7%)	
Singleton, No. (%)	43 (71.7%)	51 (85.0%)	0.121
Multiple pregnancy, No. (%)	17 (28.3%)	9 (15.0%)	
Duration of pregnancy (weeks)	31.80	32.92	0.551
• First trimester	8 (13.3%)	8 (13.3%)	1.000
• Second trimester	2 (3.3%)	5 (8.3%)	0.439
• Third trimester	0	1 (1.7%)	1.000
Preterm contractions, No. (%)	10 (16.7%)	5 (8.3%)	0.168
Gestational HTN/PE, No. (%)	10 (16.7%)	7 (11.7%)	0.432
Mode of delivery, No. (%)			
• Full-term vaginal delivery (FTVD)	2 (3.3%)	4 (6.7%)	0.679
• Lower segment cesarean section (LSCS)	46 (76.7%)	46 (76.7%)	1.000
• Blighted ovum	0	3 (5.0%)	0.244
• Missed abortion	7 (11.7%)	3 (5.0%)	0.322
• Spontaneous abortion	2 (3.3%)	4 (6.7%)	0.679
• Termination of pregnancy	3 (5.0%)	0	0.244
Fetal outcome, No. (%)			
• Intrauterine death (IUD)/neonatal death (NND)	4 (6.7%)	1 (1.7%)	0.364
Birth weight			
• Not known	1 (1.7%)	0	1.000
• <2.5 kg	16 (26.7%)	14 (23.3%)	0.833
• >2.5 kg	47 (78.3%)	48 (80.0%)	1.000
Preterm birth	21 (35.0%)	16 (26.7%)	0.323

Hence, appropriate/close maternal and fetal surveillance is important to optimize perinatal outcomes in IVF pregnancies. This was similar to the study conducted by De Sutter et al. (2005), where outcomes of IVF and non-IVF pregnancies were studied retrospectively **(Table 4)**.[14]

Larger studies need to be performed to aid better clinical extrapolation of the results.

ROLE OF ART/THIRD-PARTY REPRODUCTION AND PREIMPLANTATION GENETIC TESTING FOR ANEUPLOIDY IN CASES WITH RECURRENT PREGNANCY LOSS

Recent evidence does not support ART in cases with RPL without secondary infertility. Third-party reproduction for cases with RPL should be highly individualized based on the recurrence risk supported with a management strategy based on the latest evidence along with appropriate and relevant counseling. The use of preimplantation genetic testing for aneuploidy (PGT-A) has been supported by current and growing evidence in cases with RPL for idiopathic reasons.[15]

KEY POINTS

Evidence translated into practice:

- Surveillance for adverse outcomes as a consequence of dysfunctional placentation should be initiated during the peri-implantation phase—extended inverted pyramid of prenatal care shifting the focus too much earlier to clinical pregnancy.
- Predicting oxidative stress using biomarkers is still being researched which could pave the way to institute effective risk modulation strategies improving pregnancy outcomes.
- Several mechanisms influence immune tolerance at the maternal-fetal interface which involves effective angiogenesis and trophoblastic invasion. "Placenta" facilitates immune tolerance.
- Natural killer cell malformations have been attributed to infertility and RPL. However, peripheral NK cells do not reflect the status of uterine NK cells which are assumed to influence pregnancy outcomes. Hence therapies to suppress NK cells have shown no proven benefit.
- Isolated ANA positivity could influence fertility and pregnancy outcomes. However, its exact role and implications need to be researched with bigger studies.
- Thyroid peroxidase antibody positivity is known to be associated with adverse pregnancy outcomes. High levels of the antibody and high levels of TSH could have a negative effect on IVF. Dose-based adjustments of thyroxin with periodic surveillance could help avert adverse outcomes.
- Mapping inflammatory responses could be indirect but specific methods of measuring hostile autoimmunity in the body.
- Hyperhomocysteinemia could be attributed to adverse obstetric and fertility outcomes. Appropriate dietary supplementation of B_6, B_{12}, and folic acid could be beneficial especially when initiated periconceptionally.
- An HbA1c level of <7% preconceptionally is preferred for better outcomes in type 1 diabetes mellitus.
- Effective surveillance initiated periconceptionally for the identification of the probable risk factors that could complicate pregnancy helps to avert adverse irreversible changes in the genome aiding good in utero fetal programming.
- The perinatal outcomes of ART pregnancies do not differ significantly from non-ART pregnancies and effective surveillance for risk factors in ART pregnancies could result in better perinatal outcomes.
- Assisted reproductive technology can be recommended in cases with RPL only if there is associated secondary infertility. Third-party reproduction in RPL cases can only be suggested after judiciously weighing the recurrence risks. PGT-A can add value in idiopathic RPL.

CHAPTER 93

Emergencies in Infertility

Arunima Halder

INTRODUCTION

With the rise in infertility, more and more patients have been approaching infertility clinics for treatment. There has been rise in ovarian stimulation in the form of ovulation induction or controlled ovarian stimulation. With this has risen the increased chance of emergent complications during intrauterine insemination (IUI) or in vitro fertilization (IVF). Enlarged multicystic ovaries may release excess vascular endothelial growth factors (VEGFs) leading to extravasation of fluid to third space and ovarian hyperstimulation syndrome (OHSS) or may be too large and undergo torsion. Patients may present with vague pain and a high index of suspicion helps in early diagnosis of such a mishap in patients undergoing ovarian stimulation. Intra-abdominal and retroperitoneal bleed, which may occur during oocyte retrieval, though rare, is not unseen and may require immediate action. Extrauterine pregnancy is another complication, which is on the rise and may present with acute abdominal pain in case of rupture. In this chapter, we delve into these emergencies, which a reproductive medicine expert should always anticipate and be prepared for.

OVARIAN HYPERSTIMULATION SYNDROME

Ovarian hyperstimulation syndrome is the least common but most life-threatening iatrogenic complication of ovulation induction or controlled ovarian stimulation, which is characterized by ovarian enlargement, overproduction of ovarian hormones, and transudation of protein-rich fluid from vascular compartment to the extravascular compartment.

According to the Royal College of Obstetricians and Gynecologists (RCOG), OHSS should be considered as a possibility in any patient who is undergoing ovarian stimulation. However, the incidence of moderate-to-severe OHSS is around 3–8%.[1]

Classification of OHSS

Various authors have given various classifications of OHSS. RCOG 2016 in their Green-top guidelines has classified OHSS as described in **Table 1**.

Depending on the time of onset, OHSS can be classified into early- and late-onset OHSS.[2-4] Early-onset OHSS is milder, occurs within 3–7 days of human chorionic gonadotropin (hCG) trigger, and occurs in response to gonadotropin stimulation. On the other hand, late-onset OHSS, occurs around 10 days after the hCG trigger, is pregnancy related due to endogenous hCG of pregnancy, and is severe in nature.

Pathophysiology (Fig. 1)

Vascular endothelial growth factor is implicated as the key player in the genesis of OHSS and its action is propagated by hCG.[5-10] The renin-angiotensin system of the ovary as well as proinflammatory factors have also been shown to play a role in development of OHSS **(Table 2)**.

TABLE 1: Classification of ovarian hyperstimulation syndrome.

Mild	*Moderate*	*Severe*	*Critical*
• Bloating of the abdomen • Mild abdominal pain • Ovarian size <8 mL	• Moderate abdominal pain • Signs of ascites on ultrasonography • Nausea + Vomiting • Ovarian size 8–12 mL	• Clinical ascites with or without hydrothorax • Hyponatremia (<135 mmol/L) • Hyperkalemia (>5 mmol/L) • Oliguria (<30 mL/h or 300 mL/day) • Hematocrit >0.45 • Albumin <35 g/L • Hypo-osmolality <282 mOsm/kg • Ovarian size >12 mL	• Tense ascites • Hydrothorax • Hematocrit >0.55 • Oliguria/anuria • WBC count >25,000/mL • Thromboembolism • Acute respiratory distress syndrome

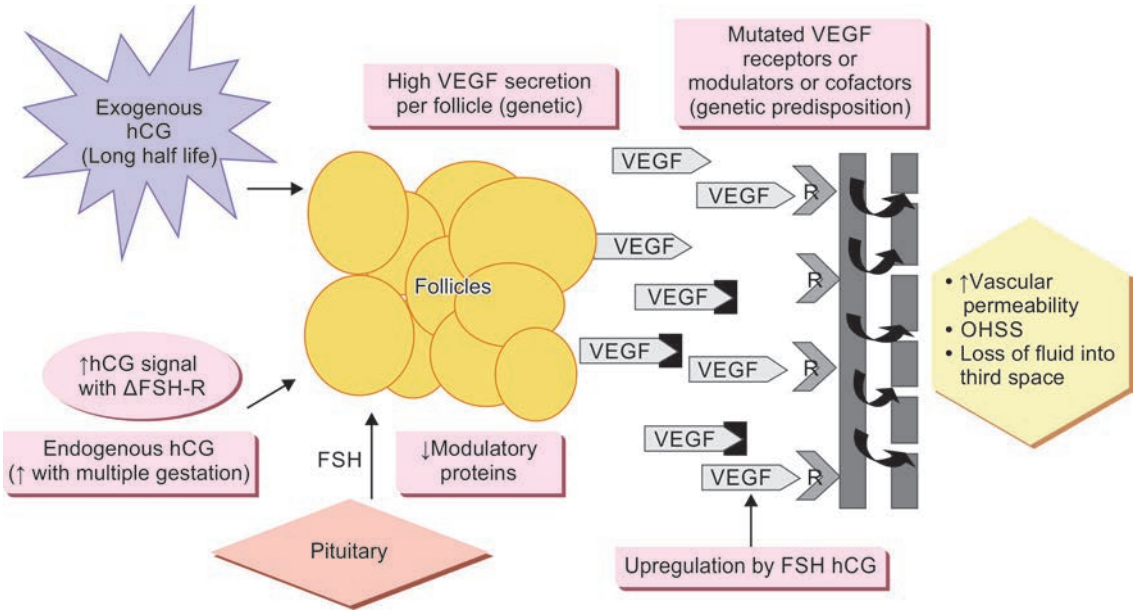

Fig. 1: Pathophysiology of ovarian hyperstimulation syndrome.
(hCG: human chorionic gonadotropin; VEGF: vascular endothelial growth factor; OHSS: ovarian hyperstimulation syndrome)

TABLE 2: Strategies for prevention of ovarian hyperstimulation syndrome.

Prevention	*Strategy*	*Advantage*	*Disadvantage*	*Evidence*
Primary	Chronic low dose step up protocol (decreasing the dose of gonadotropin)	• Decreasing the dose of gonadotropin • Decreases cost • Significantly decreases OHSS	Prolonged duration of stimulation	Orvieto et al.[11] with this protocol showed excellent safety profile
	GnRH antagonist protocol	• Significantly decreases • OHSS • Similar pregnancy rates as long protocol	Decreased flexibility of the protocol	Al Inany et al.[12] demonstrated that OHSS is decreased with GnRH antagonist protocol
	Metformin	• Reduces hyperinsulinemia and hyperandrogenism • Decreases number of follicles • Decreases OHSS		Tso et al.[13] suggested that metformin decreases the chance of OHSS (moderate quality evidence)
	Follitropin Delta	Provides statistically significant and clinically relevant decrease in incidence of OHSS without compromising live birth rates	May decrease the number of oocytes retrieved	Ishihara and Arce[14] (STORK group) suggested the use of Follitropin Delta for prevention of OHSS, which was reiterated by Yacoub et al., in his retrospective study.[15]
	Low Dose Aspirin	Well-known NSAID, inhibits the activity of COX1, preventing platelet aggregation thereby, preventing the pathological cascade of histamine, serotonin, PDGF, LPA thereby decreasing chance of OHSS	Minimal side effects	Guo et al., in their systematic review and network meta-analysis on the most appropriate pharmacological interventions for prevention of OHSS ranked low-dose aspirin as the Rank 1 choice of intervention. (Grade A evidence)[16]
Secondary	Agonist trigger	Elimination of OHSS	Luteolysis	Kol et al.,[17] suggested that GnRH-agonist is the key to prevention of OHSS. This was later supported by Cochrane meta-analysis by Youssef[18] in 2014 and Brown[19] in 2017. Several other studies have supported the same[20,21]
	Dopamine agonist	Reduces chance of moderate OHSS		Tang et al.,[22] proved in their Cochrane study that Cochrane decreases incidence of moderate OHSS

Contd…

Contd…

Prevention	*Strategy*	*Advantage*	*Disadvantage*	*Evidence*
Tertiary prevention	Freeze all strategy	Eliminates OHSS	Prolongs time to pregnancy	Blockeel et al.,[23] observed that one of the key strengths of freeze all protocol is prevention of OHSS
	Letrozole	Aromatase inhibitor decreases estrogen levels	Can be used only in oocyte donors and freeze all cases	Akman et al.,[24] found that letrozole reduces VEGF expression in OHSS and thus controls its occurrence
	Calcium gluconate	Decreases cAMP dependent rennin secretion decreasing VEGF synthesis	Monitoring required during calcium infusion	Naredi et al.,[25] demonstrated calcium gluconate to be extremely effective in prevention of OHSS
	Albumin/hetastarch	Borderline statistical decrease in OHSS	Heterogeneity of studies	Youssef et al.,[26] in their Cochrane analysis showed that plasma expanders were effective in prevention of moderate to severe OHSS
	Glucocorticoids	Affects VEGF gene expression	Insufficient evidence	Tan et al.,[27;] conflicting evidence available

(cAMP: cyclic adenosine monophosphate; GnRH: gonadotropin-releasing hormone; OHSS: ovarian hyperstimulation syndrome; VEGF: vascular endothelial growth factor)

TABLE 3: Evaluation of a patient with ovarian hyperstimulation syndrome (RCOG).

History	*Symptoms*	*Signs*	*Initial investigations*	*Subsequent tests*
• History of PCOS • Number of follicles at trigger • Drug used for trigger • Duration between trigger and onset of symptoms • Total number of oocytes retrieved • If embryo transfer was done or not	• Abdominal bloating or pain • Nausea and vomiting • Pedal edema • Vulval edema • Breathlessness • Reduced urine output • Other comorbidities like thrombosis	• Increase in weight • Tachycardia, tachypnea • Edema • Dehydration • Ascites, palpable abdominal mass • Peritonism • Signs of pleural effusion or pulmonary edema or pneumonia	• Complete blood count (CBC), Hematocrit (Hct), • Urea and electrolytes, osmolality, C-reactive protein (CRP), thrombophilia profile, liver function tests (LFT), ultrasound abdomen (USG) pelvis and thorax	• Electrocardiogram (ECG), chest X-ray, D-dimer • Arterial blood gas (ABG) • Ventilation perfusion scan

The concept of OHSS-free clinic was given by Devroey et al., where he emphasized the importance of segmentation of IVF.[28]

Evaluation of a Patient with OHSS

In the backdrop of ovarian stimulation, suspicion of OHSS should arise when a patient arrives with abdominal distension or pain. The symptoms for OHSS are vague and there are no particular investigations that pinpoint toward OHSS. Primary diagnosis of OHSS remains clinical.

RCOG[1] recommends the following evaluation in a patient with suspected OHSS **(Table 3)**.

Based on the initial assessment of the patient **(Table 3)**, and severity of OHSS **(Table 1)**, they can be treated as outpatient or inpatient.

Outpatient Treatment

Outpatient treatment can be offered to patients with mild or moderate OHSS and some patients with severe OHSS. All patients who are treated on an outpatient basis should comply with follow-up on a regular basis every 2–3 days.

- Verbal and written information should be given to the patient about their condition.
- Drink fluid as per thirst. Fluid intake should not be less than 1 L/day.
- Input output chart to be monitored. Urine output of less than 1,000 mL/day or a positive water deficit of more than 1,000 mL/day should imply immediate notification at the hospital.
- Low-molecular weight heparin (LMWH) should be given for thromboprophylaxis especially in cases of severe OHSS.
- Paracetamol or opioids for pain relief. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided as it can deteriorate renal function.
- Paracentesis, if required should be carried out transvaginally. Transabdominal paracentesis is preferred in a nonobese patient in whom large amount of ascitic fluid has to be drained (as it is feasible to put an indwelling catheter in this case).[1]

- Urgent reporting to hospital in case of worsening symptoms. Otherwise, a visit to the hospital every 2–3 days should be made.
- Hematocrit is a good tool to know the amount of hemoconcentration.

Need for Admission

- Inability to achieve adequate pain relief
- Inability to maintain required fluid intake due to nausea despite antiemetics
- Inability to follow-up routinely
- Worsening symptoms of OHSS despite outpatient interventions
- Critical OHSS.

Inpatient Treatment

Treatment of critical and severe OHSS should have a multidisciplinary approach and needs intensive care **(Figs. 2 and 3)**.

Several complications like thromboembolism **(Flowchart 1A)**, pleural effusion, adult respiratory distress syndrome (ARDS) **(Flowchart 1B)**, renal failure **(Flowchart 1C)**, and ascites **(Flowchart 1D)**, and should be looked out for and treated at the first suspicion.

Surgery in OHSS may be needed in cases of ovarian torsion, ovarian rupture, or ectopic pregnancy.

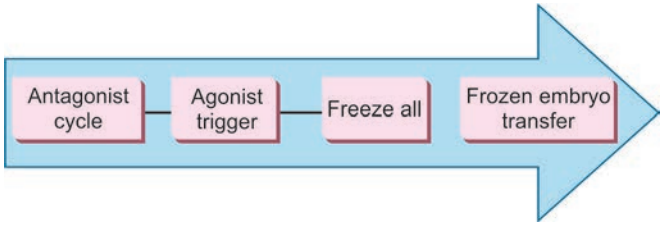

Fig. 2: Ovarian hyperstimulation syndrome-free clinic.

A. Daily checks
- Body weight
- Abdominal girth
- Intake/output
- Vitals
- Complete blood count
- Hematocrit
- Serum electrolytes
- Osmolality
- Liver function test

What may be required?
- Arterial blood gas
- Chest X-ray
- Electrocardiogram
- Ultrasonography
- C-reactive protein

B. Keys to fluid management
- Oral fluid replacement guided by thirst
- In case of inability to intake oral fluid, initial treatment by crystalloids (in presence of anesthetist)
- IV colloids: Albumin 25% 50–100 g over 4 hours every 4–12 hourly
- Intake output chart
- In case of oliguria, paracentesis may be tried
- Multidisciplinary approach at all decision points
- Renal dose of dopamine has been tried in some trials

C. Signals of recovery
- Diuresis
- Normalization of hematocrit
- Normalization of body weight and abdominal girth

Fig. 3: Inpatient treatment.

ADNEXAL TORSION

Adnexal torsion may be defined as a complete or partial rotation of the ovarian pedicle along its own axis leading to an obstruction to the inflow and the outflow of blood eventually leading to ovarian ischemia and eventual demise, if left untreated.[29] In the general population, the incidence of ovarian torsion is around 2.7% and majority of these occur in the reproductive age group.[30] The incidence of ovarian torsion in women undergoing IVF–intracytoplasmic sperm injection (ICSI) is 0.08–0.13%,[31] the incidence may increase to 7.5% in case of OHSS.[32]

Adnexal torsion is a gynecological emergency needing immediate diagnosis and intervention. Diagnosing a case of adnexal torsion may not be easy and may involve high risk of suspicion.[33]

Anatomy of the Adnexa (Fig. 4)

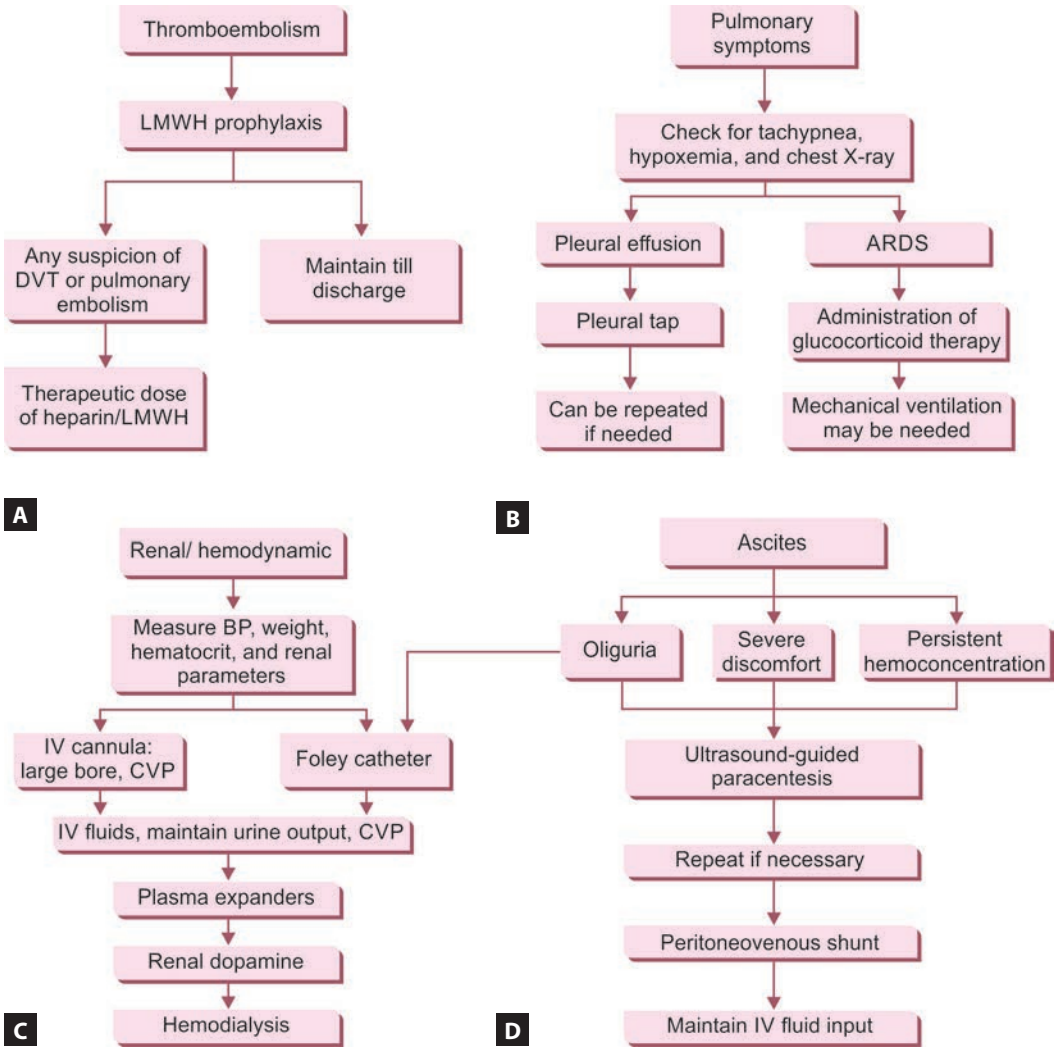
The ovary lies in a hammock made by the infundibulopelvic ligament on one side and the utero-ovarian ligament on the other side. The infundibulopelvic ligament is a loose structure which connects the ovary to the lateral pelvic wall. It houses the ovarian artery and the vein. The utero-ovarian ligament is a fibromuscular band, which embodies the ovarian branches of the uterine vessels.[34]

Once the ovary gets twisted, there is an initial compression of the venous and lymphatic outflow. Since the arterial walls are muscular and less collapsible the arterial flow is maintained. Following this the ovary starts to become edematous. In due course, the diffuse ovarian stroma develops, increasing the intraovarian pressure, and stretching the ovarian capsule. This ultimately compresses the arteries leading to ischemia and necrosis.[35]

- *Normal ovary:* Torsion may occur in the normal ovary especially in young girls who are prepubertal because of the loose, mobile ovarian ligaments.[36,37] With the advent of puberty, the ligaments become shorter and sturdier decreasing the chance of ovarian torsion.[29]

  Torsion may also occur when one undergoes strenuous exercise with a stimulated ovary.[37,38] Littman et al.,[37] reported a case where a 38-year-old patient with secondary infertility had undergone gonadotropin stimulation with IUI, which had failed. Following this, in view of two cysts she had taken recess from treatment during which she resumed her normal activities. During an exercise session, she developed acute abdominal pain and was rushed to the emergency department. Hence, one must be careful to advise the patient to avoid any form of strenuous activity until the cysts following ovarian stimulation are resolved **(Table 4)**.
- *Ovarian cysts and tumors:* It has been seen that ovarian torsions are most often found with benign tumors as compared to malignant tumors.[29,39-42] The reason behind this discrepancy could be the fact that malignancies

Flowcharts 1A to D: Complications in inpatient treatment.



(ARDS: acute respiratory distress syndrome; CVP: central venous pressure; DVT: deep vein thrombosis; LMWH: low molecular weight heparin)

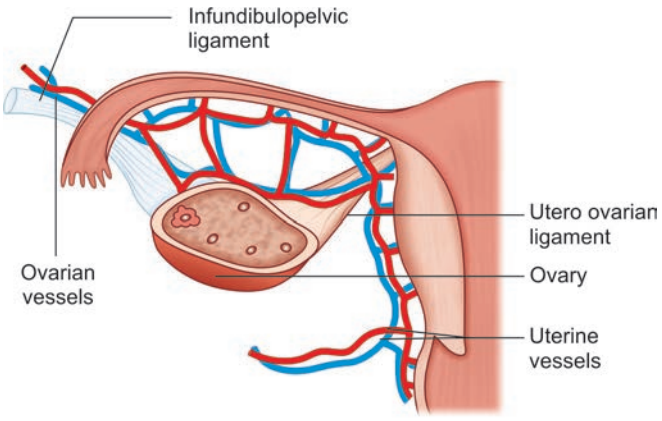


Fig. 4: Anatomy of adnexa.

are associated with adhesions, which decrease the incidence of the ovaries getting rotated around their axes. Of the benign tumors, benign cystic teratoma has been shown to be most commonly associated with ovarian torsion.[43,44]

TABLE 4: Predisposing factors to adnexal torsion.

Sl. No.	*Predisposing factor*	*Probable reason*
1.	Normal ovary	• Excessively mobile fallopian tubes and ovarian ligaments[33,34] • Long pelvic ligaments • Spasm of the tubes • Strenuous exercise[35] • Sudden changes in intra-abdominal pressure
2.	Ovarian tumors	• Benign ovarian tumors • Larger tumors >5 cm
3.	IVF	Larger ovaries due to multiple cysts
4.	Pregnancy	Physiological cysts
5.	Right side	Presence of sigmoid colon on the left side

- *In vitro fertilization:* According to Gelbaya et al.,[45] women who undergo assisted reproduction have 11-fold higher risk of ovarian torsion. Whether this is because of

increase in size of ovaries or increase in ascitic fluid in the abdomen which increases the mobility of the ovaries is still unknown.[46]

- *Pregnancy:* There have been several reports of ovarian torsion during pregnancy.[47] This is more in cases where conception has occurred following ovarian stimulation. Ovarian torsion is most common in the first trimester with decreasing trends in the second and third trimester.[29]

Diagnosis of Adnexal Torsion

The clinical presentation of adnexal torsion may be non-specific **(Flowchart 2)**. It may present as an acute stabbing pain in the lower abdomen radiating to the groin. Sometimes, the patient may experience intermittent episodes of pain exhibiting an acute on chronic phenomenon.[48] Nausea and vomiting may be associated in 70–85% of cases. In undiagnosed cases, where necrosis of the ovary has set in, fever could also be a presenting symptom.[49] History of ovarian stimulation should be elicited. Pain may typically start following strenuous exertion[38] or straining at stools. Signs of abdominal tenderness, localized guarding, or rebound tenderness, tachycardia, and pyrexia may be noted. Cervical motion tenderness may be present.

Huchon et al.,[50] devised a predictive score for the pre-operative diagnosis of adnexal torsion. According to this score, five criteria were included, which were given individual scores. Total score of less than 40 had a 3.7% risk of adnexal torsion, 40–60 had a 20% risk of adnexal torsion, and more than 60 had a 69% risk of adnexal torsion **(Table 5)**.

All said and done, a high index of suspicion is of utmost importance in diagnosing adnexal torsion especially in IVF patients.

Flowchart 2: Pathophysiology of adnexal torsion.

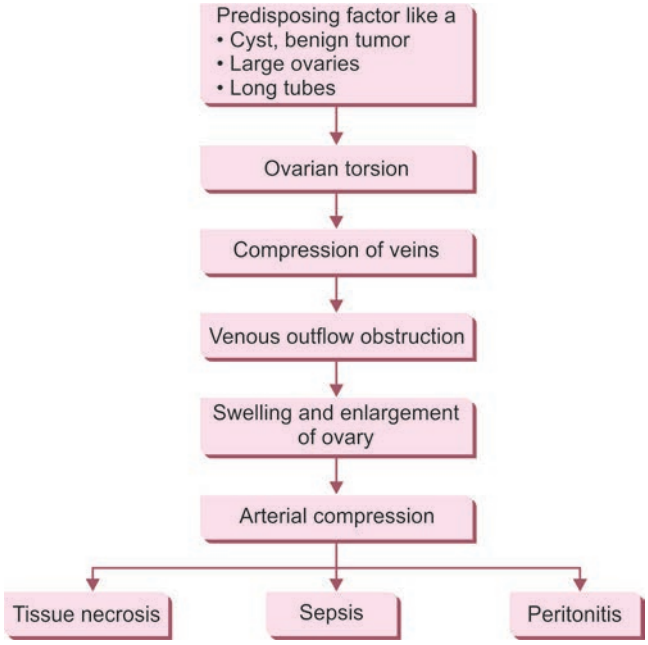

TABLE 5: Score for adnexal torsion.[50]

Sl. No.	*Parameter*	*Score*
1.	Spontaneous one-sided abdominal or lumbar pain	15
2.	Pain lasting <8 hours	20
3.	Vomiting	20
4.	Cyst >5 cm in the ovary on ultrasonography	25
5.	Absence of leukorrhea or metrorrhagia	25

Low risk: score <40, high risk : score >60

Laboratory Evaluation

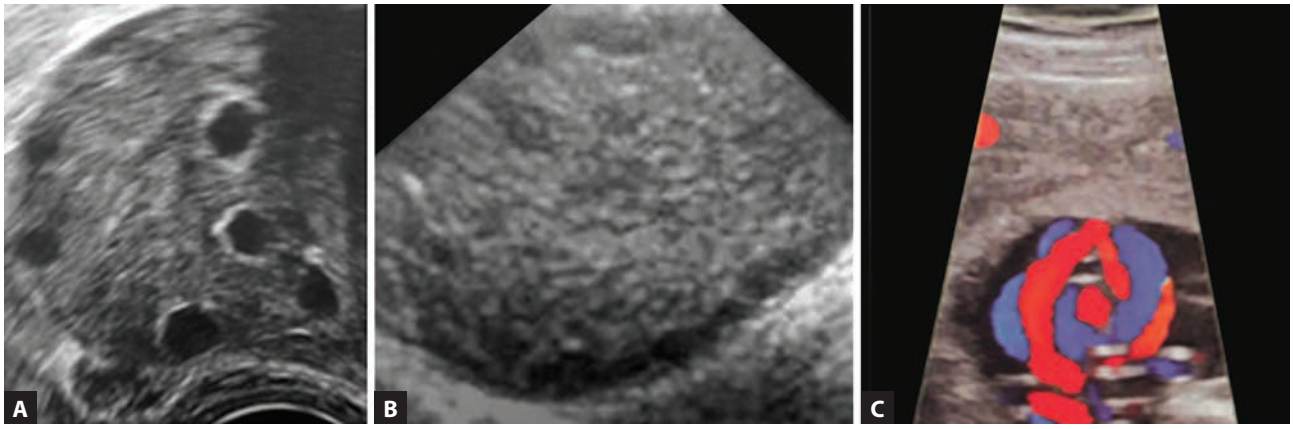
No specific laboratory parameters have been seen to be associated with ovarian torsion. Torsion leads to ischemia followed by ischemia–reperfusion injury. This eventually leads to rise in acute phase proteins that seem to be elevated in this condition. Patient may present with leukocytosis and raised C-reactive protein.[51,52] According to Cohen et al., preoperative elevation of interleukin 6 and not TNF-alpha pointed to the diagnosis of ovarian torsion in a case of acute abdomen.[53] Aran et al., in their experimental study on rats demonstrated that a rise in ischemia-modified albumin was associated with ovarian torsion model and this could emerge as an early serum biomarker of ovarian torsion in humans.[54]

Imaging

Ultrasonography (Gray Scale)

When a woman in her reproductive age comes with an acute abdomen, the primary method of evaluation is an ultrasonography (USG). In a series by Graif et al.,[55] USG for adnexal torsion was found to have a positive predictive value of 87.5% and a specificity of 93%.

The earliest ultrasonographic feature associated with ovarian torsion is follicular ring sign which occurs when there is obstruction to the venous and lymphatic flow **(Fig. 5A)**. Ovary may be unilaterally enlarged.[56] Once twisted, the ovary may acquire a more central location almost close to the fundus of the uterus.[57] Ovarian size may be greater than 4 cm as compared to the normal appearing contralateral ovary. The stroma may appear hypoechoic with follicles being peripherally arranged **(Fig. 5B)**.[58] This may also be a feature in young women with polycystic ovary syndrome (PCOS) but in the setting of acute abdominal pain and associated clinical and sonographic findings, one must think of adnexal torsion. A cyst that may be present on the ovary may become hyperechoic due to hemorrhage.[58] Small follicles may be seen having a echogenic rim due to acoustic enhancement.[51] Hematosalpinx may be visible.[52]



Figs. 5A to C: "Follicular ring sign", stromal edema on gray scale and whirlpool sign on Doppler.

TABLE 6: Summary of diagnosis of ovarian torsion.

Sl. No.	*Parameters*	*Findings*
1.	Symptoms	Sharp, stabbing pain radiating to the loin or thigh, vomiting, nausea, fever, history of strenuous exercise, or increased abdominal pressure
2.	Signs	Tachycardia, pyrexia, tenderness, and guarding of the affected side, rebound tenderness
3.	Gray scale ultrasound	• Unilateral ovarian enlargement • Hypoechoic stroma with peripherally arranged follicles • Hemorrhage within a cyst • Echogenic rim around follicles • Centrally located ovary • Twisted blood vessels at the pedicle • Free fluid in the pouch of Douglas
4.	Doppler	• Presence or absence of arterial blood flow depending on the progression of the disease • Whirlpool sign
5.	Serum markers	• Leukocytosis • C-reactive protein • Interleukin 6
6.	CT/MRI	• Ovary twisted to the contralateral side • Uterus deviated to the ipsilateral side • Thickened tubal walls • Fluid in pouch of Douglas

Free fluid may be visible, which may be hemorrhagic or nonhemorrhagic.[55] Twisted pedicle may be visible, which becomes enhanced on usage of color Doppler.[58]

On Doppler, blood flows may or may not be seen. The pathophysiology of ovarian torsion is a dynamic process. When only venous obstruction has occurred and the arterial blood flow is still maintained, ovarian blood flow may be visible. This however, does not rule out torsion.[53] The typical "whirlpool appearance" due to twisting of blood vessels may be seen **(Fig. 5C)**.[55]

Features on CT scan are mostly vague with the affected ovary rotated to the contralateral side. The uterus may appear shifted to the affected side. Ovary may also appear edematous with free fluid in the abdomen.[51,57,] On enhanced CT, the tubes may appear thickened.[57] MRI may not be of much help except in second and third trimesters where diagnosis by ultrasound is ambiguous **(Table 6)**.[58]

Management

Treatment for ovarian torsion is surgical. While deciding regarding the management, one should consider the progression of the condition, age of the patient, the desire for fertility, and presence of existing ovarian pathology **(Fig. 6 and Table 7)**. Traditionally, for such cases oophorectomy or salpingo-oophorectomy had been tried.[48]

However, recent studies emphasize the benefits of conservative surgery over radical surgery.[59–63] Despite the ovary appearing edematous and black, once detorted, it may still regain color and be viable. According to Chen et al.,[64] pain lasting for more than 48 hours may not correlate well with the successful outcome of the surgery. Recurrent torsion may implicate detorsion followed by oophoropexy.[65] If a leading point like a cyst has been identified it might be advisable to go ahead with cystectomy. This may however be risky as the tissues are friable.[53]

Fig. 6: Laparoscopic picture of ovarian torsion.

EMERGENCIES DURING OOCYTE RETRIEVAL

Bleeding

Vaginal bleeding during oocyte retrieval is common and occurs in up to 18% of the cases.[66] In most of the cases, this stops spontaneously. If it does not, pressure with sponge forceps or vaginal packing.

Intraperitoneal or retroperitoneal bleeding can occur with an incidence of around 1%.[67] Intraperitoneal bleed may be detected soon after the procedure. However, retroperitoneal bleed may have an indolent course.

Caution to be maintained, if such a bleed is suspected. Close monitoring of vitals should be done. Ultrasound may

TABLE 7: Management of ectopic pregnancy.

	Mode of treatment	***Indications***	***Regimen/method***	***Advantages***	***Disadvantages***	***Evidences***
Expectant	Close monitoring of BhCG	• Hemodynamically stable patient • Ectopic pregnancy detected on USG, falling BhCG level or initial level less than discriminatory zone	Close monitoring of clinical symptoms and BhCG until it reaches less than 15 IU/L	No side effects of methotrexate, no surgical or anesthesia related risks. No tubal damage as spontaneous regression occurs. Good fertility outcome	• Close monitoring required. • Risk of worsening leading to conversion to medical or surgical treatment	• *METEX trial*[91,92] by Mello et al., 60% of women with expectant management had an uneventful clinical course • *Cochrane 2007*[93] has not been able to adequately evaluate expectant management yet
Medical management	Single dose MTX	• Hemodynamically stable • Minimal or no symptoms • BhCG <5,000 IU/L • Size: <3.5 cm • No embryonic cardiac activity • Confirmed diagnosis of ectopic pregnancy • Compliance for follow-up	• 50 mg/m^2 MTX given in D1 • BhCG on D4 and D7 • Expected drop in BhCG >15% • Follow-up till BhCG <5	Decreased side effects of MTX	Increased chance of requirement of a second dose of MTX	• *Cochrane 2007:*[93] Methotrexate was less effective than laparoscopic salpingotomy. However, RCOG 2016[90] suggests that methotrexate and laparoscopic surgery can be equally effective in tubal ectopic pregnancies • Elito et al.,[94] provided a score >5 entailed 97% success rate with single dose
	Two dose MTX		Two doses of MTX on D1 and D4 with no leucovorin rescue. Look for >15% fall in BhCG	• Lower number of days for BhCG to decrease as compared to single dose • Better balance between convenience and efficacy[95]		• *Barnhart et al.*:[95] Two dose regimen minimizes number of injections and decreases surveillance visits • *Song et al.*:[96] no overall difference in single and two dose. In subgroup with BhCG >5,000 two dose was better
	Multiple dose MTX		• MTX 1 mg/kg on D1, 3, 5, and 7 • Leucovorin rescue 0.1 mg/kg on D2, 4, 6, and 8 • A fall in BhCG >15% calls for stoppage of treatment and start of follow-up	Less chance of failure of treatment	Increased side effects of MTX like gastritis, stomatitis, leucopenia, hair fall	According to *ASRM: Practice committee guidelines 2013,*[97-99] multiple-dose regimen has a success rate significantly higher than single dose regimen

	Mode of treatment	*Indications*	*Regimen/method*	*Advantages*	*Disadvantages*	*Evidences*
Surgical management	Salpingotomy	• Only one patent tube Future pregnancy desired Patient hemodynamically stable • Contralateral abnormal tube • Unruptured ectopic of <5 cm	Longitudinal incision over the most bulged part with minimal usage of cautery followed by hydrodissection and removal of conceptus in to	Maintenance of fertility	Chance of persistent trophoblastic disease	• *ESEP trial:100* salpingotomy did not significantly improve fertility prospects as compared to salpingectomy. • *DEMETER trial:101* No significant difference in 2 years fertility for active ectopic pregnancy while comparing conservative versus radical surgery
	Salpingectomy	• Tube is severely damaged • Uncontrolled bleeding • Recurrent ectopic pregnancy in the same tube • Large tubal pregnancy of >5 cm • Woman has completed her family	Coagulation near the cornua followed by division and removal of the tube	Complete removal of trophoblastic tissue	Fertility not preserved. Theoretical chance of damage to ovarian blood supply	
Persistent trophoblastic disease	Single dose methotrexate		50 mg/m^2 single dose			Level 1: evidence. (RCOG)[90]

(MTX: methotrexate; BhCG: Beta-human chorionic gonadotropin)

not reveal a bleed especially in retroperitoneal bleed. Fall in hemoglobin is the best diagnostic tool.

Once diagnosed, urgent laparotomy with blood transfusion, if needed, should be done.[68]

Pelvic Infection[68]

There may be inadvertent insertion of cervicovaginal flora during oocyte pick-up (OPU) or accidental puncture of hydrosalpinx or endometriotic cyst. This can lead to pelvic infection. Pelvic inflammatory disease following OPU is rare. Patients may present with fever, offensive vaginal discharge, lower abdominal pain, or painful micturition.

Intravenous antibiotics are the treatment of choice in these cases.

EMERGENCY AFTER EMBRYO TRANSFER

Ectopic Pregnancy

Presence of a pregnancy other than within the uterine cavity is known as ectopic or extrauterine pregnancy. In the normal population, incidence of ectopic pregnancy is 1–3%.[69] Rise of assisted-reproductive technology (ART) has seen a corresponding rise in ectopic pregnancy and accounts for around 2–8.5% of all pregnancies, which may be even higher when tubal factor is the cause of ectopic.[70]

Various Sites of Ectopic Pregnancy

Sites of ectopic pregnancy have been described in **Figure 7**.

Pathophysiology[71]

The exact pathophysiology of ectopic pregnancy in IVF is not known. Various theories have been put forward **(Flowchart 3)**.

Risk Factors

Maternal age: Evidence is conflicting regarding the role of maternal age in the incidence of ectopic pregnancy. Patil et al.[72] and Rana et al.,[73] showed an increase in ectopic pregnancy with increasing maternal age. This could be because of genetically incompetent embryos or due age-related changes in the tubal physiology. However, studies by Malak et al.[74] and Li et al.[75] have not found an association between the two.

Tubal factor: Any factor that alters the tubal functionality can be implicated in causing ectopic pregnancy. The presence of pelvic inflammatory disease (PID), especially, Chlamydia trachomatis antibodies has been implicated in causing ectopic pregnancy.[75] Other causes associated could be, the presence of endometriosis, previous history of ectopic pregnancy, and previous tubal

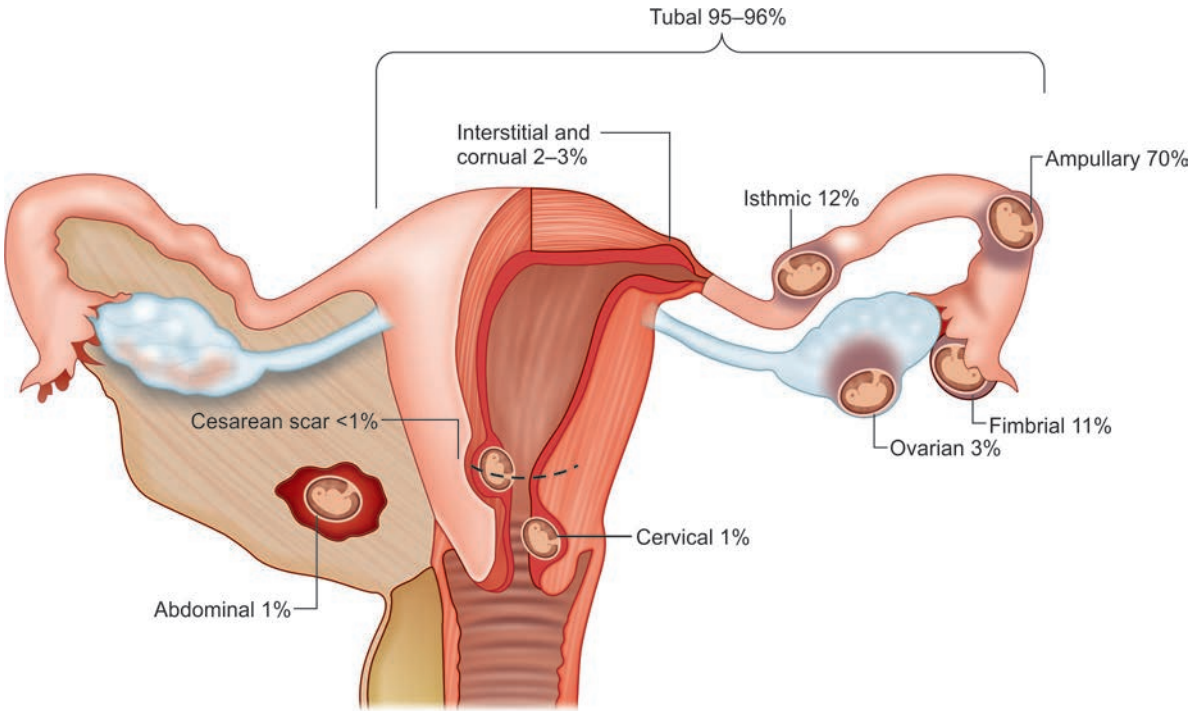

Fig. 7: Sites of ectopic pregnancy.

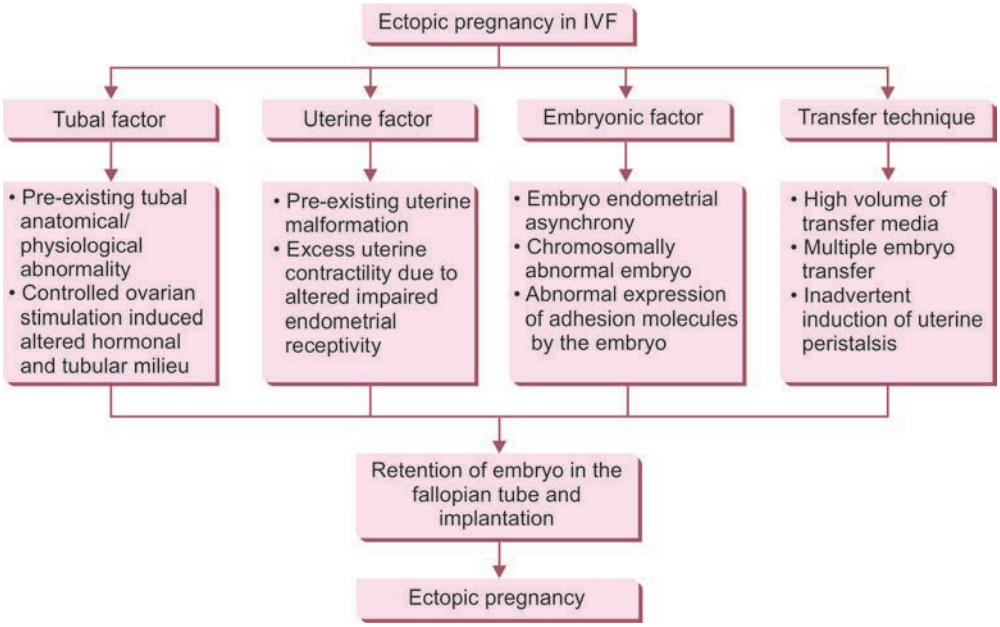
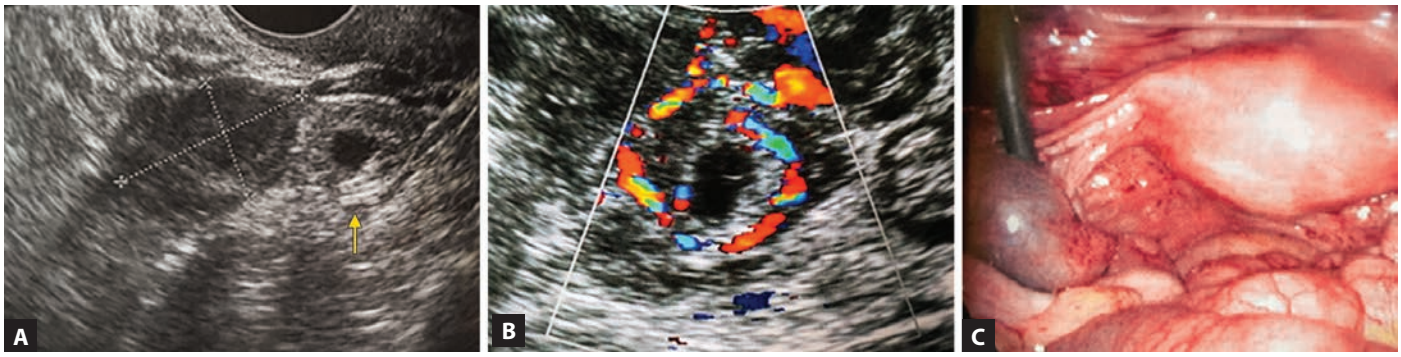
Flowchart 3: Pathophysiology of ectopic pregnancy in in vitro fertilization (IVF).



surgery. Cigarette smoking has been also associated with ectopic pregnancy especially because it decreases tubal and uterine motility.[76]

Uterine factors: Londra et al.,[77] suggested that there was an increase in incidence of ectopic pregnancy in fresh embryo transfer as compared to frozen embryo transfer. This could be because of the supraphysiological estrogen levels following ovarian stimulation rendering the uterus nonquiescent and nonreceptive. The same authors further went ahead to suggest that this risk was more with antagonist cycles as compared to agonist cycles.[78] Li et al.[79] corroborated the same by showing that there was significant reduction in ectopic pregnancy rates when frozen blastocyst was used for transfer. Effects of uterine abnormalities on ectopic pregnancy have not been adequately studied.[71,80]



Figs. 8A to C: Diagnosis of ectopic pregnancy.

Embryonic Factors

Initially, it was theorized that assisted hatching may be associated with increased chance of ectopic pregnancy however in a recent study by Hageman et al.,[81] it was shown that assisted hatching neither improved pregnancy rates nor increased ectopic pregnancy rates. Tong et al.[82] demonstrated that there was a significant decrease in ectopic pregnancy rates with day 5 or day 6 embryo transfers. Job-Spira et al.,[83] suggested that chromosomal abnormalities increased ectopic pregnancy rates.

Transfer Techniques

Marcus et al., noted that patients with ectopic pregnancy were transferred larger volumes of culture media as compared to those with intrauterine pregnancy.[84] Knutzen et al.[85] also demonstrated that there was increased risk for tubal pregnancy to occur with larger volumes of culture media. Several authors have demonstrated that inadvertent touching of the uterine fundus caused onset of uterine peristalsis, which lead to ectopic pregnancy.[86-88] Also multiple embryo transfers were shown to be associated with ectopic pregnancy.[89]

Diagnosis of Ectopic Pregnancy

Beta-human chorionic gonadotropin (BhCG) alone does not have any role in diagnosing ectopic pregnancy.[90] It should be used along with ultrasound for the complete diagnosis of ectopic pregnancy. Serial quantitative BhCG measurements are better parameters in diagnosing ectopic pregnancy.[71] Transvaginal ultrasonography can effectively determine the presence of an intrauterine or ectopic sac at the level of a discriminatory zone of BhCG 2000 IU/L **(Fig. 8A)**. The features on ultrasonography may be presence of a pseudo sac without the presence of double decidual sign. An adnexal mass may be seen moving separately from the ovary. On Doppler, a ring of fire appearance **(Fig. 8B)** around the ectopic pregnancy may be seen with low-peak systolic velocity (PSV).[58] Ectopic pregnancy is usually ipsilateral to a corpus luteum cyst. The diagnosis of a heterotopic pregnancy remains elusive and one should be careful to look at the adnexa even after seeing a viable intrauterine pregnancy **(Fig. 8C)**.

KEY POINTS

- Assisted-reproductive technology is more or less a nonemergency field. However, emergencies may arise when least expected. One has to be vigilant to diagnose the pathological condition early.
- OHSS in its severe form needs a multidisciplinary and meticulous approach.
- Adnexal torsion on the other hand needs a high index of suspicion and needs urgent laparoscopy. Increased risk of ectopic pregnancy in COS has been attributed to the process of ovarian stimulation and embryo transfer and requires careful monitoring, medical or surgical treatment, and close follow-up. Overall, one has to be cautious of the complications that might be encountered during stimulation, retrieval, and post-transfer.

CHAPTER 94

Fetal Reduction

Revathi S Rajan

INTRODUCTION

"Assisted reproductive technologies (ARTs)" have revolutionized obstetric practice. Although many infertile couples have benefited by begetting children, some of them are also faced with challenges such as multifetal pregnancies, fetal reduction, prenatal diagnostic procedures, etc.

Twenty six percent of all pregnancies after in vitro fertilization (IVF) are reported to be twins and about 1.3% of them are higher order multiple pregnancies.

Maternal and neonatal complications in higher order multiple pregnancies include an increase in the risk of preterm deliveries, hypertension including preeclampsia, gestational diabetes and postpartum hemorrhage. The neonates born as a consequence of higher order multiple pregnancies are encountered with issues such as prematurity, low birth weight, delayed milestones, cerebral palsy and learning disabilities.

Fetal reduction involves the elimination of one or more of the fetuses in the multiple pregnancy (which is usually a consequence of assisted reproduction), iatrogenically, in order to improve the perinatal outcome of the surviving fetuses.

BACKGROUND

Assisted reproductive technologies usually carry the risk of implantation of multiple embryos, resulting in multifetal pregnancies. This commonly includes quadruplets, triplets and twin pregnancies. "Fetal reduction" was an approach developed by the genetic researchers who were actively involved in the "Human Genome Project," which involves an ultrasound-guided termination of the most accessible fetus using pharmacological agents (potassium chloride) which is instilled intracardially into the fetus by a needle stab ensuring complete cessation of cardiac activity of the targeted fetus either through trans abdominal or transvaginal routes.

MEDICOLEGAL ISSUES AND PSYCHOLOGICAL IMPACT

The logic behind this technique is best described by Berkowitz[1] and colleagues as; "the medical justification for performing multifetal pregnancy reduction is philosophically similar to the "lifeboat analogy", where it is justifiable to sacrifice some "innocent" fetal lives to increase the chances of survival or decrease the risk of serious morbidity in the survivors of the procedure."

The ethical justification of this procedure has been described by Chevernak and colleagues,[2] who have expressed it in terms of these goals:

- Achieving a pregnancy that results in a live birth of one or more infants with minimal neonatal morbidity and mortality
- Achieving a pregnancy that results in the birth of one or more infants without anomalies.

Although an "informed consent" is procured from the couple before the procedure, it has been observed that a "true choice" is not made by them and is usually a decision made due to depression and fear prevailing in their minds. There is significant psychological distress reported due to the coercive choice made by the couple who have already been through enough stress during evaluation and treatment for infertility, which pressurizes them to make this decision hoping for a better perinatal outcome.

Ethical Issues

Decisions involving fetal reduction must be entirely autonomous. The pregnant mother should entirely make decisions for or against fetal reduction totally free of any stress or compulsion and must do it as per the directions of her thought processes after weighing the pros and cons completely.[3]

Principles of "Beneficence" and "Nonmaleficence" need to be incorporated while making decisions for fetal reduction. Fetal reduction is a procedure undertaken to

protect and promote the welfare of any multiple pregnancy (Principle of Beneficence) while inflicting less harm to the surviving fetuses (Principle of nonmaleficence).

Less harm involves reduction in complications such as preeclampsia and gestational diabetes and also decreasing the possibility of preterm birth and prematurity. It has been observed that the incidence of higher order multiples and multifetal pregnancy reduction is low in those countries where infertility has been granted an insurance cover thereby allowing the woman to access better treatments such as IVF as compared to controlled ovarian hyperstimulation. Limiting the autonomy of the physician by strictly limiting the number of embryos transferred may be another solution to reduce multiple pregnancies. Both these concepts involve the "Principle of Justice''.

Patient counseling needs to be nondirective; explaining the procedure of fetal reduction which is to be adopted as a salvage procedure including the option and consequences of no treatment. She could base her decision together with her spouse; after consultation with the maternal fetal medicine specialist, mental health specialist and the perinatologists. There should be no element of coercion in her mind while making the decision which could be based on her psychological make-up, religious beliefs and also her socioeconomic status. If the pregnant mother opts out of the procedure, the clinician needs to be supportive of her stand and must direct her to a facility with the necessary backup which could handle surveillance and delivery of higher order multiples. The exercised preferences and the necessary counseling details need to be correctly documented in the "informed consent" which is to be taken by the maternal fetal medicine specialist from the pregnant mother.

Reduction to a singleton is generally not preferred, although it may be offered in certain patients after weighing her circumstances in terms of medical risks and her socioeconomic status.

There have been several studies aimed to study the psychological impact of fetal reduction on the couple involved. Schreiner-Engel[4] and colleagues reported that 20% of those who participated in the follow-up, (postreduction) experience long-term "dysphoria". Garel and colleagues reported a 44% refusal rate for the interview.

Among those who attended the interview (post-reduction), most of them experienced "persistent depressive symptoms" mainly sadness and guilt, which was related to the procedure per se. The other participants made medical and rational comments experiencing no emotion. However, there is no research on the long-term consequences of the parental distress on the physiological development of the surviving children. The dynamics of "postabortion survivor syndrome" has still not been studied.

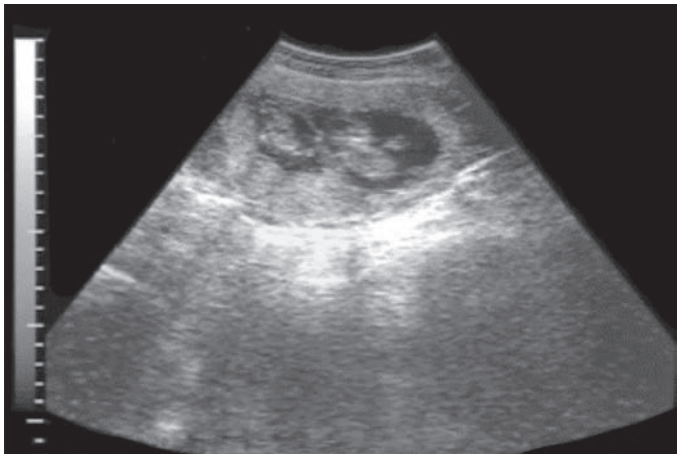

Fig. 1: Fetal reduction being attempted on a multiple pregnancy.

PROCEDURE

Timing of the Procedure

Ideally, fetal reduction is usually scheduled between 11 and 12 weeks of pregnancy, as by this time spontaneous fetal demises, if they should occur, would have already occurred. Another justification for performing this procedure at this period of gestation is that by the end 11–12 weeks, a nuchal translucency (NT) scan is also complete whereby an early scrutiny of the fetus to rule out anomalies is also done. This also enables the operator to choose the abnormal fetus (if any), for reduction which is referred to as "selective fetal reduction" **(Fig. 1)**.

METHODS

Multifetal pregnancy reduction can be performed using several techniques which are always ultrasound guided. It can be done either by transabdominal, transvaginal or transcervical aspiration, and also by intrathoracic injection of potassium chloride which can be performed by transabdominal or by transvaginal routes.

PREREQUISITES

Informed Consent

A detailed informed consent is to be obtained by the "maternal fetal medicine specialist" from the patient after explaining the pros and cons of the procedure. It must be emphasized to the couple that in the process of continuing a higher order multifetal pregnancy, there is an increased chance of losing all the fetuses due to a mid-trimester abortion or preterm delivery. Thus, fetal reduction must be offered to the couple as a salvage measure to improve the chances of survival of the remaining fetuses.

Antibiotics and Tocolysis

Prophylactic antibiotics usually a single dose of injectable cephalosporin or amoxicillin and clavulanic acid

combination is recommended just before the procedure. Some centers also recommend progesterone depot injections (postprocedure) along with prophylactic tocolysis, in spite of the fact that the role of progesterone in preventing uterine irritability after the procedure is not proven.

Preoperative Ultrasonography

Preoperative ultrasonography is important for the following:

- Assessment of the total number of fetuses
- Assessment of the chorionicity of the fetuses, as identifying a monochorionic pair could influence the operator to reduce the same, as monochorionic twins are associated with a poor perinatal outcome. Instilling potassium chloride to one twin of the monochorionic pair would result in the demise of both the monochorionic fetuses, as they share a common placenta
- Marking the topography
- Detection of the fetal anomalies and selective termination of a specific anomalous fetus.

TECHNIQUE

Transcervical Aspiration

It was described by Martene Duplan in the early 1980s. During this procedure, the patient is placed in lithotomy position and the procedure is performed under ultrasound guidance using an abdominal probe. The cervix is exposed using a Sims' speculum and the vagina is gently cleansed with antiseptic solution. The cervix is then gently grasped using a tenaculum and progressively dilated using Hegar's dilators. A Karman's cannula which is connected to a 20 mL syringe is then inserted through the cervical canal and is subsequently brought into contact with the embryo located next to the internal os.

The embryo is then aspirated with one brisk suction operated manually. The procedure is again repeated in the same fashion, if many embryos have to be reduced.

Disadvantages of the Procedures

- This procedure can be easily performed at an early gestation (about 9 weeks), but unfortunately screening for fetal abnormalities is not possible at this gestational age.
- The rate of abortion is generally higher when compared to other methods.
- This procedure involves dilatation of the cervix which can result in significant bleeding per vaginum.

Transabdominal Needling

In this procedure, a 20-gauge needle is inserted through the mother's abdomen into the thorax of the fetus. Earlier, fetal demise was achieved by injecting air or saline. Mechanical trauma was also used to cause fetal demise. These methods are always not successful, as these methods were associated with several drawbacks (for example, injecting air could alter the overall quality of the sonographic image). Thus, transabdominal fetal reduction is presently performed by injecting potassium chloride intracardially using ultrasound guidance. Fundally placed embryos are technically easier to needle when compared to low lying ones.

Under ultrasound guidance, with full aseptic precautions and under local anesthesia a 20-gauge needle (after removing the stiletto) is inserted through the mother's abdomen into the thorax of the fetus. After confirming the position of the needle a 2 mL syringe is attached to the needle and 1–2 mL of potassium chloride is injected through the syringe gently into the fetal cardia, ensuring that the fetus is not pushed away from the needle tip by the pressure of the fluid injected.

Occasionally, fluid injected into the fetus can be visualized as a transonic image in the fetal mediastinum and pleural cavity. If the needle has been inserted correctly into the fetal cardia, an asystole is obtained followed by complete cessation of the fetal heart within a few seconds. Fetal demise has to be confirmed again by a check scan preferably on the following day to avoid missing a failed attempt.

Transvaginal Needling

In this procedure, a 20-gauge needle is inserted through a guide attached to the vaginal probe which is advanced through the vagina into the uterus targeting the fetus concerned. After ensuring the correct placement of the needle into the fetal cardia, 1–2 mL of potassium chloride is instilled using a syringe, until complete cessation of fetal heart is confirmed.

OTHER METHODS

Mechanical trauma can also be used to bring about embryo reduction very early in gestation (by 7–8 weeks). This is usually accomplished by the transvaginal route.

In this method, the tip of a 25 cm long needle (with an external diameter of 1.6 mm) is connected through a catheter to a 20 mL syringe which is placed in contact with the embryo to be reduced. A brief suction is applied to effect complete cessation of cardiac activity of the embryo. It has several advantages such as:

- Performing the reduction procedure very early, in gestation, could prove to be psychologically more acceptable to most couples
- The rate of losing the entire pregnancy as a consequence of reduction is significantly lower when this procedure is performed at an early gestational age.

But, this procedure is associated with a disadvantage that the anomalous fetus, if any, cannot be chosen for reduction as scrutiny for anomalies at this gestational age is technically very difficult.

Potassium Chloride

It is the pharmacological agent which is commonly used in fetal reduction. It causes fetal demise by causing asystole followed by slowing and complete cessation of fetal heart. Although it is commonly used for fetal reduction, the efficacy of this agent has been questioned. The following issues have been debated:

- Stimulation of prostaglandin release along with release of cytokines which occurs as a consequence of the inflammatory response to the remnant fetoplacental tissue that is undergoing autolysis (postprocedure) has been attributed to be the cause for initiating preterm labor and pregnancy loss.[5]
- Rare case of anencephaly and fetal limb amputation following the use of potassium chloride has been reported
- The entire pregnancy could be lost if potassium chloride accidentally percolates into the nontargeted sacs.
- It has also been reported that potassium chloride induces the release of tissue plasminogen activators, matrix metalloproteinases and matrix degrading enzymes within the uterus, which could be attributed to rupture of membranes.

Complications

- The risk of complete pregnancy loss could be 1–2% in experienced hands. This could be a result of preterm premature rupture of membranes, accidental entry of potassium chloride into nontargeted sacs or preterm labor (due to uterine irritation as a consequence of the procedure).
- Risk of preterm premature rupture of membranes and threatened abortion, sometimes progressing to abortion also exists.

Some patients may also present with leaking or bleeding per vaginum which may be self-limiting.

FAILED REDUCTION

It is not uncommon to have a failed attempt of fetal reduction. Hence, careful mapping of the fetus (to be reduced) is crucial, as the surviving fetus after a failed attempt of reduction can have sequelae. Thus, all attempts to complete the procedure in a single sitting are preferred.

SELECTIVE REDUCTION

When multifetal pregnancy reduction is attempted, the fetus that is targeted to be reduced is the one that is easily accessible by the operator. But in some situations, selective fetal reduction is performed in which a particular fetus is chosen to be reduced probably due to a congenital anomaly associated with it which could have been detected by ultrasound or any other prenatal diagnostic procedure. In some cases, a fetus whose growth is significantly lesser than the other fetuses is chosen to be reduced.

STUDIES ON FETAL REDUCTION

- According to a meta-analysis by Dodd J and Crowther C, multifetal pregnancy reduction to twins compared to expectant management of higher order pregnancy seems to be an effective treatment option for any woman with a higher order pregnancy. This suggests that multifetal pregnancy reduction of higher order pregnancy to twins is medically justified.[6] Studies have shown no significant difference in mean gestational age at birth, birth weights and perinatal mortality rates between reduced and nonreduced twins.
- A comparative study conducted by Jung Ryoel Lee and his colleagues that compared the outcomes of different methods of multifetal pregnancy reduction involved 148 patients with multiple pregnancies from assisted reproduction programs who underwent multifetal pregnancy reduction. The patients were divided into potassium chloride and non-potassium chloride groups based on the agent used for fetal reduction. They were also divided into the early (<8 weeks of gestation) and the late groups (>8 weeks of gestation), based on the period of gestation at which fetal reduction was performed. They concluded that the early non-potassium chloride method (which involved cardiac puncture and aspiration of amniotic fluid with the fetus) showed a lower immediate loss (<4 weeks of the procedure) and preterm premature rupture of membranes. The take home baby rates as a result of this procedure were also more when compared to those pregnancies where the late potassium chloride method was used for fetal reduction.[7]
- Evans et al. in a collaborative study involving more than thousand cases observed that transabdominal multifetal pregnancy reduction was increasingly associated with a poor outcome compared to transvaginal or transcervical methods which subsequently improved as the expertise of the operator increased.[8] Transvaginal method is technically simpler when compared to transabdominal method and is similar to ovum aspiration.
- Recently, there has been a trend in which multifetal pregnancy reduction is performed in all cases of higher order pregnancies to singletons instead of twins to improve the perinatal outcome.[9] Further studies need to be performed to establish whether there is a definitive advantage conferred by this. Recent studies have also suggested that selective termination after 20 weeks of gestation does not increase the risk of fetal loss compared to procedures before 20 weeks of gestation. Cord coagulation, which is a new technique, is aimed at selective termination in monochorionic twins and is associated with high rates of morbidity and mortality.
- Pregnancy loss rates due to fetal reduction depend upon:
  - The experience of the operator
  - Number of fetuses at the start and also at the end of the procedure.

A multicenter experience[10] with over 3,500 completed reductions reported the following rates of fetal loss corresponding to the number of fetuses at the beginning and at the end of the procedure. The results were as follows:

Number of fetuses (at start)	Fetal loss (%)
6	15.4
5	11.4
4	7.3
3	4.5

Number of fetuses (at the end)	Fetal loss (%)
3	18.4
2	6
1	6.7

A single center[11] experience involving 1,000 consecutive multifetal pregnancy reductions showed the following results:

- Complete fetal loss was 5.9%
- Loss rate was lowest for a starting number of 2 fetuses
- Loss rate remained stable for reductions with a starting number of 3, 4 or 5 fetuses
- Loss rate increased to 12.9% for 6 or more fetuses at start
- The final number of fetuses also influenced the perinatal outcome.

Number of fetuses (at the end)	Fetal loss (%)
1	3.5
2	5.5
3	16.7

The mean gestational age of delivery varied (as indicated here) and was similar to unreduced pregnancies with a similar number of fetuses.

Number of fetuses (at start)	Gestational age at delivery (weeks)
1	37.9
2	35.3
3	33.5

KEY POINTS

- Multifetal pregnancy reduction is a procedure which is performed to achieve a pregnancy resulting in the live birth of one or more healthy infants with very minimal neonatal morbidity and mortality.
- Long-term consequences such as "postabortion survivor syndrome" which reflects the psychological impact of fetal reduction needs to be studied.
- Decisions for fetal reduction could be based on the "Principles of Beneficence, Nonmaleficence and Justice." The final decision needs to be completely autonomous which is to be made by the pregnant mother after weighing the pros and cons.
- No significant differences in perinatal outcome were observed between reduced and nonreduced twins.
- Transabdominal multifetal pregnancy reduction was associated with a poor outcome when compared to transvaginal or transcervical methods which gradually improved with the operator's experience.
- Pregnancy loss rates greatly depend upon the experience of the operator and the number of fetuses at start and at the end of the procedure.
- Optimizing assisted reproductive techniques is the best solution to reduce the need for invasive procedures such as fetal reduction.

ACKNOWLEDGMENTS

This chapter was first published in the textbook "An Introduction to Genetics and Fetal Medicine (Second edition)" by Dr Deepika Deka and Dr Narendra Malhotra. It has been further edited including concepts such as "Ethical Issues" involving fetal reduction which play a pivotal role influencing decision making.

CHAPTER 95

COVID-19 and Pregnancy

Varsha Patil, Chandana C

INTRODUCTION

Coronavirus disease 2019 (COVID-19) is a pandemic of the 21st century of global concern caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Novel corona SARS-CoV-2, which is the etiological agent of COVID-19, was first detected in Wuhan city of China in December 2019.[1] Since then, it has spread worldwide and has become one of the public health emergencies to mankind. Common cold (HCoV-229E, NL63, OC43, and HKU1), Middle East respiratory syndrome coronavirus (MERS-CoV), and SARS-CoV are the different types of coronavirus infections.[2] On March 11, 2020, COVID-19 was identified as a global pandemic by World Health Organization (WHO).[3]

ETIOLOGY

Coronavirus disease 2019 virus is a single-stranded ribonucleic acid (RNA) under the family of *Betacoronavirus* and subfamily *Sarbecovirus*. COVID-19 virus is made up of membrane glycoprotein (M), envelop protein (E), nucleocapsid protein (N), and spike protein (S) **(Fig. 1)**.[4,5]

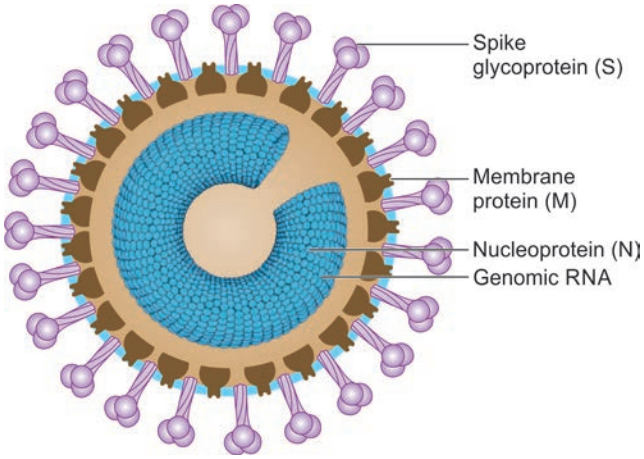

Fig. 1: Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). (RNA: ribonucleic acid)

In December 2021, WHO declared the five important variants of COVID-19 that are of global concern: The Alpha variant identified in London, the Beta variant identified in South Africa, the Gamma variant of Brazil, the Delta variant of India, and the Omicron variant.[6-8]

Transmission of COVID-19 is by respiratory secretions, feces, and fomites with mean incubation period of 5–7 days with a duration of disease varying from 5 days to chronic infection.

PATHOPHYSIOLOGY

The respiratory system is commonly affected by coronavirus disease because the virus binds to surface of type 2 alveolar cells of lungs at angiotensin-converting enzyme 2 receptors with the help of spike protein present on the surface of coronavirus.[9]

Coronavirus disease is a systemic hyperinflammation syndrome with elevated levels of interleukin 2, 5, and 6, protein 10 of gamma-induced protein, granulocyte-macrophage colony-stimulating factor, monocyte chemoattractant protein 1, macrophage inflammatory protein-1 alpha, and tumor necrosis factor alpha. Coronavirus disease with acute respiratory distress syndrome (ARDS) has classical elevated blood values of C-reactive protein (CRP), lactate dehydrogenase (LDH), D-dimer, and ferritin.[10,11]

CORONAVIRUS DISEASE 2019 AND PREGNANCY

The incidence of coronavirus disease is similar in pregnant and nonpregnant women, but the severity is more in pregnant women, especially in the last trimester because of the following three reasons:[12]

1. Altered body immune system during pregnancy.
2. Reduction in total lung capacity and inability to clear the secretions.
3. Pregnancy is a hypercoagulable state, with a high level of circulating coagulation and thrombogenic factors.

Majority of infected pregnant women do not require hospitalization.

Risk factors of severe disease and critical illness during pregnancy include age >35 years, obesity, preexisting hypertension, diabetes mellitus (DM), asthma, chronic kidney disease, cardiopulmonary disease, malignancy, and immunocompromised status.

CLINICAL PRESENTATION OF CORONAVIRUS DISEASE IN PREGNANCY

Clinical features are cold, cough, fever, myalgia, headache, vomiting, nausea, diarrhea, breathing difficulty, and loss of smell and taste; few cases will be asymptomatic.[13]

Among the symptomatic cases, 81% of patients develop mild to moderate infection with mild pneumonia, 14% will be having severe infection, and 5% will develop features of critical illness; one-third of infected persons will be asymptomatic.[14-17]

EFFECTS OF CORONAVIRUS DISEASE ON PREGNANCY

- Coronavirus disease 2019 will not add to the risk of miscarriage or pregnancy loss according to the available evidence. COVID-19 infection is not an indication for medical termination of pregnancy (MTP).
- Current evidence suggests of no vertical transmission, no risk of teratogenicity, and no possible congenital anomalies.[18]
- Current evidence suggests that vaginal secretions and breast milk are negative for COVID-19 virus.
- Incidence of preterm birth is increased in pregnancy with COVID-19, but it is not clearly understood whether it is because of spontaneous onset of preterm or iatrogenic induced.
- Studies have shown that COVID-19 adds to the risk of peripartum depression, anxiety, and domestic violence.[18]
- Current evidence suggests that the majority of babies of COVID-19 infected mothers usually do not show any symptoms; neonatal mortality rate is similar in both infected and noninfected COVID-19 infected newborns.[19]

Coronavirus disease 2019 infection is not an indication for lower segment cesarean section (LSCS). Mode of delivery should depend on obstetrics/fetal indications but should not be dependent on COVID-19 positivity. Cesarean section is only indicated in cases of refractory hypoxemic respiratory failure or worsening critical illness.[20]

SYMPTOMS AND CLASSIFICATION OF SEVERITY OF CORONAVIRUS DISEASE 2019

Clinical features of coronavirus disease in pregnancy are cold, cough, pyrexia, myalgia, headache, vomiting, nausea, diarrhea, shortness of breath, loss of smell and taste, or asymptomatic.[21]

Classification

- *Asymptomatic:* Without symptoms but tested COVID positive on the screening test.
- *Mild disease:* Mild clinical features of cold, cough, pyrexia, body aches, mild breathing difficulty, or positive findings on chest imaging.
- *Moderate disease:* Associated with bronchopneumonia, respiratory acidosis, and pyrexia not relieved by antipyretics but maintaining peripheral oxygen saturation (SpO_2) level of >95%.
- *Severe disease:* Respiratory distress with respiratory rate (RR) of >30/min, with SpO_2 of <95%, and with >50% lung involvement on chest computed tomography (CT) or X-ray.
- *Critical disease:* End-organ dysfunction involving renal, cardiac, and pulmonary systems with circulatory collapse shock requiring artificial ventilation.

PREVENTIVE MEASURES TO BE TAKEN BY PREGNANT WOMEN TO AVOID CORONAVIRUS DISEASE 2019 (FIG. 2)

- Vaccination
- Staying indoors
- Wearing an N95 mask
- Avoid crowded places
- Social distance of at least 1 meter from others
- Work from home
- Hand hygiene with soap and water or sanitizer
- Avoid touching the eyes, nose, or mouth with unwashed hands[22]
- Disinfection of surfaces with 1% hypochlorite solution
- Avoiding unnecessary travels
- Reduce the number of people visiting the mother and the baby after delivery.

INDICATIONS FOR CORONAVIRUS DISEASE 2019 TESTING DURING PREGNANCY

- Symptomatic pregnant women
- Hospitalized pregnant women who are in labor or near full term
- Pregnant women hospitalized for other reasons
- Newborns having acute pulmonary infections or sepsis.

Centers for Disease Control and Prevention (CDC) and Indian Council of Medical Research (ICMR) recommend reverse transcription-polymerase chain reaction (RT-PCR) of nasopharyngeal swab to detect COVID-19 infection.[23] Patients having productive cough and sputum should be tested for COVID-19.

Fig. 2: Precautions for coronavirus.

Reverse transcription-polymerase chain reaction test should be conducted in the centers recognized by the central or state government. False negative rate is about 10–30%. Gold standard test to identify coronavirus disease is nucleic acid amplification test (NAAT).

Other investigations include complete blood count (CBC), renal function tests, liver function tests, coagulation profile, D-dimer, LDH, procalcitonin, and serum ferritin level.

Chest imaging such as CT scan/X-ray should be done only if indicated after the consent from pregnant patient and her attender with proper abdominal shielding.

COMPUTED TOMOGRAPHY SCAN FINDINGS OF CORONAVIRUS DISEASE 2019

Mild and early infection: Bilateral multilobar ground glass opacities which have nonsymmetrical, posterior, and peripheral distribution.

Advanced and severe infection: We can see crazy paving of subpleural dominance associated with consolidation.

Peripheral ground glass opacities without pleural effusion are the diagnostic findings of CT chest of COVID-19 patients.[24]

ANTENATAL CARE

Government of India recommends at least four antenatal visits along with one ultrasound scan in the second and third trimesters.

1. *First visit/registration:* Pregnant women should get registered with a healthcare provider as soon as pregnancy is recognized preferably within 3 months.
2. *Second visit:* Between 14 and 26 weeks.
3. *Third visit:* Between 28 and 34 weeks.
4. *Fourth visit:* Between 36 weeks and term.

At least one ultrasound in the second and third trimesters.

We are aiming to decrease the exposure of healthy pregnant women to new infections and exposure of healthcare workers to infected pregnant women and asymptomatic carriers by decreasing the number of visits.

Detailed history of pregnant women to be taken considering: coming from hot spot area, immunocompromised conditions, travel history, and history of exposure.

Duration and number of antenatal visits should be reduced during antenatal visits of pregnant women.

Antenatal Care and Care of Infected Pregnant Women During Coronavirus Disease

- Pregnant women with mild infections and asymptomatic carriers do not require any extra tests.
- Growth scans, routine antenatal tests, and visits are delayed until the patient completes the period of isolation.
- Pregnant women are made aware about the warning signs of COVID-19 and pregnancy.
- Pregnant women should be taught about the self-monitoring of oxygen saturation, temperature, pulse, and respiration (TPR) charting, and self-isolation.

Antenatal Follow-up After Coronavirus Disease 2019 Infection

- *Recovery from infection in first trimester:* Consider one obstetric ultrasound during pregnancy between 18 and 22 weeks of pregnancy as part of routine antenatal care.
- *Recovery from infection in the latter half of pregnancy:* Consider sonographic assessment of fetal growth 2 weeks after infection.

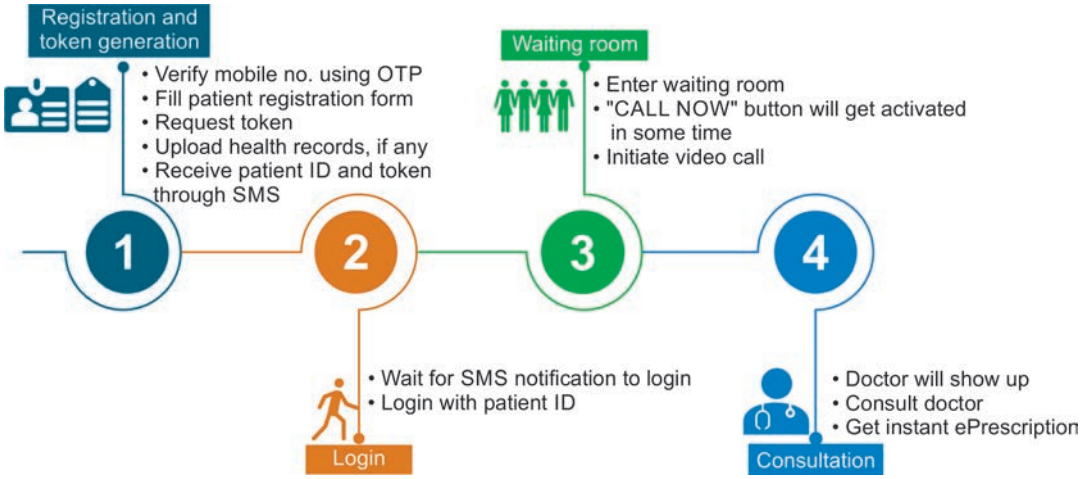

Fig. 3: e-Sanjeevani online outpatient department (OPD) consultation process.

eSanjeevani

eSanjeevani is a telemedicine for maternal–fetal health services during the COVID pandemic by the Ministry of Health and Family Welfare (MoHFW) of India for doctors and patients. In eSanjeevani, two types of telemedicine services are available:

1. Doctor-to-doctor at Ayushman Bharat-Health and Wellness Centres (AB-HWCs)
2. Patient-to-doctor eSanjeevani outpatient department (OPD) teleconsultations **(Fig. 3)**
   a. *eSanjeevani AB-HWC:*
      i. It is a doctor-to-doctor telemedicine platform made available at majority of the health and wellness centers across India in hub and spoke model under the Ayushman Bharat scheme of Government of India.
      ii. "Hubs" are medical college hospitals and district hospitals. "Spokes" are primary and secondary and community health centers.
   b. *eSanjeevani OPD:*
      i. Nationwide online OPD service which helps patients to consult doctors by video consultations.
      ii. Every video consultation generates an e-prescription which allows patients to get medicines or go for diagnostic investigations as advised.

TRIAGING

- Triaging is an important screening method that should be adopted at a healthcare facility to avoid/minimize exposure between COVID-19 infected and noninfected pregnant women.
- A checklist is used in triaging to separate pregnant women into three groups: (1) COVID positive, (2) COVID suspect, and (3) screen negative **(Box 1)**.
- Triaging should be done near the main entrance of the hospital and the place should be spacious enough to maintain social distance between pregnant women and healthcare workers.

BOX 1: Checklist for triaging.

Name: _____ *W/O:* _____

Age: _____ *Gestational age:* _____

Phone no.: _____ *Address:* _____

Q1. Does the PW present with the following?
- Fever with cough—Yes/No
- Fever with shortness of breath—Yes/No
- Past history of fever with cough or shortness of breath—Yes/No
- History of contact with COVID positive—Yes/No
- The patient is a healthcare worker—Yes/No

Q2. Is the PW asymptomatic but a high-risk contact:
- Living in the same household with COVID positive—Yes/No
- Heath care worker providing care to COVID positive—Yes/No
- Traveling with COVID positive—Yes/No

Q3. Does the PW belong to hot spots/clusters/large migration gatherings/evacuee centers and presenting symptoms such as fever/cough/sore throat/runny nose—(Yes/No)

If answer to any of the above is *Yes*, PW to be sent to suspect ward and sample sent for testing or referred to higher centers, if all answers are *No*, patient to be sent to LR.

(LR: labor room; PW: pregnant woman)

- Triage area should have a fully equipped trolly with separate examination room.
- Proper referral services should be available in case any woman needs to be referred.
- Management of screen-negative patients should be done as per routine and standard protocol.
- COVID-suspect pregnant women should be isolated in a suspect area, and sample for testing should be sent **(Flowchart 1)**.
- Pregnant women who are in labor or having obstetric emergencies should be managed in septic labor ward.

Drawbacks of Triaging

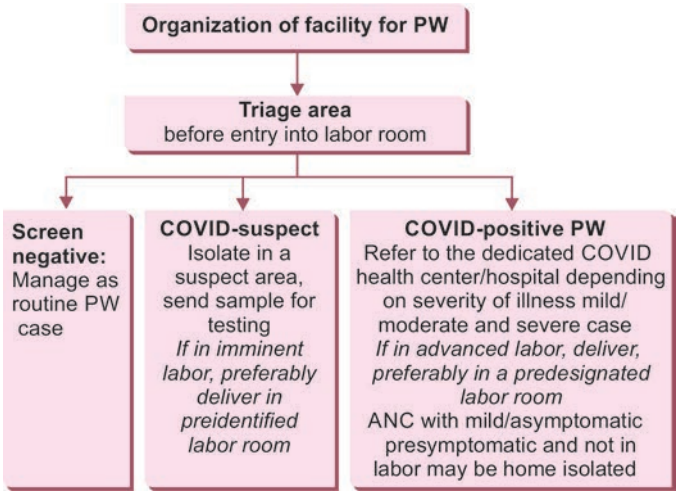
- Healthy pregnant women are at a risk of getting exposed to asymptomatic carriers.
- Patients might not reveal the history of exposure to travel and clinical features.

MANAGEMENT OF MILD OR ASYMPTOMATIC CORONAVIRUS DISEASE 2019 INFECTION DURING PREGNANCY

Guidelines for Home Isolation

- *Isolation place:*
  - A separate adequately ventilated room with attached bathroom
  - Avoid sharing of personal items with other people in the household
  - 1% hypochlorite solution should be used to clean the surfaces which are touched frequently.
- *Respiratory and hand hygiene:*
  - Use three-layered medical masks or N95 masks
  - Dispose the worn masks after 8 hours of usage
  - Follow respiratory etiquettes
  - Practice hand hygiene by washing hands with soap and water for 20 seconds or with alcohol-based sanitizer
  - Healthy diet, adequate rest, and good water intake should be followed
  - Coryza, cough, and fever should be treated
  - Steam inhalation and lukewarm water gargles will help
  - Tablet paracetamol 650 mg QID is used to treat fever. In case of persistent fever, consider naproxen 250 mg twice a day.

Flowchart 1: Facility for COVID-suspect PW.



(ANC: antenatal care; COVID: coronavirus disease; PW: pregnant woman)

- Persistent cough for >5 days should be treated with inhalational budecort.
- Ivermectin and doxycycline are contraindicated in pregnancy.[25]
- Home monitoring of pulse, temperature, RR, and oxygen saturation using the below chart every 4th hourly **(Table 1)**.

INDICATIONS FOR INPATIENT MANAGEMENT

- High-risk patients having poorly controlled DM, hypertension, chronic renal disorders, cardiorespiratory disorders, cancer, immune-compromised conditions.
- Patients who are unable of getting home quarantined and having risks for fetomaternal condition.
- Appearance of below warning signs during self-isolation will mandate hospitalization **(Table 2)**.

TREATMENT OF MODERATE TO SEVERE CORONAVIRUS DISEASE 2019 INFECTION IN PREGNANCY

Patients with moderate to severe infection need hospitalization with a multidisciplinary approach with specialists and intensive care unit (ICU) unit.

- *Investigations:*
  - CBC, differential count, renal and liver function tests: Every 1–2 days.
  - CRP, procalcitonin levels, LDH, interleukin 6 levels, serum ferritin, and D-dimer values: Every 2–3 days.
  - General random blood sugar (GRBS) monitoring in women receiving corticosteroids.

TABLE 2: Warning signs mandating hospital admission.

Clinical features:	
• Breathing difficulty	• Tachypnea
• Inadequate oral intake of fluids and medicines	• Uncontrolled fever
• Pleuritic chest pain	• SpO_2 below 95% at rest or on exertion
• Delirium and lethargy	• Peripheral cyanosis
• Associated obstetrical conditions such as preterm, antepartum hemorrhage, and reduced fetal movements	

(SpO_2: peripheral oxygen saturation)

TABLE 1: Home monitoring for coronavirus disease 2019.

Day of illness	*Temperature*	*Pulse rate*	*Oxygen saturation*	*Symptomatic assessment (better/same/worse)*	*Respiratory rate*	*Remarks*
7:00 AM						
11:00 AM						
3:00 PM						
7:00 PM						

- Chest imaging with CT scan/X-ray should be done only if indicated with abdominal shielding after consent with the pregnant mother and her attendant.

- *Medications:*
  - *Oxygen therapy:* Oxygen saturation should be maintained ≥95% by using a nonrebreather mask and high-flow nasal cannula.
  - Inhalational budesonide with metered-dose inhaler (MDI) spacer 800 µg twice a day for 7 days.
  - *Corticosteroids:* Methylprednisolone 0.5–1 mg/kg in two divided doses for 5–10 days. Methylprednisolone is preferred as it does not cross the placenta.
    - *Indications for corticosteroids:*
      - Patients with high RRs and poor oxygen saturation
      - Patients with pneumonia
      - Patients with cytokine storm.

Dexamethasone or betamethasone should be used for fetal lung maturity, followed by steroids in the form of methylprednisolone or hydrocortisone if indicated in the management of COVID-19 patients.

- Antibiotics are administered to prevent secondary bacterial infections and fever persisting for more than 6 days.
- *Anticoagulants:*
  - Low-molecular-weight heparin in a prophylactic dose used in a pregnant woman with mild COVID-19 with comorbidities
  - Low-molecular heparin is used in therapeutic dose twice daily in moderate to severe COVID-19 cases.
    - *Antepartum:* Continue thromboprophylaxis for 10 days after hospital discharge, longer duration if persistent morbidity
    - *Postpartum:* If the woman had a cesarean section and limited ambulation, stop anticoagulant when she is planned for discharge and home isolation.

MANAGEMENT OF CRITICALLY ILL AND SEVERE HYPOXIC CORONAVIRUS DISEASE 2019 PREGNANT PATIENTS

Indications of Intensive Care Unit Admission

- Falling trend of SpO_2 levels and poor oxygenation in spite of oxygen supplementation
- Persistent hypotension in spite of adequate fluid management
- Features of multi-organ failure.

Indications for Endotracheal Intubation

In the following situations, when oxygen requirements rise above 15 L/min by nasal cannulas, 40–50 L/min by high flow nasal cannulas, >60% of FiO_2 by Venturi mask, and Glasgow Coma Scale <8 these are the conditions which need oxygen saturation to be maintained above 94% and are the conditions that require endotracheal intubation.

MANAGEMENT OF CORONAVIRUS DISEASE 2019 PREGNANT WOMEN IN LABOR

Management of COVID-19 pregnant women in labor is shown in **Box 2**.

POSTNATAL CARE OF CORONAVIRUS DISEASE 2019 PATIENT

The healthcare providers should discuss with the mother about the temporary separation of mother and neonate.[26]

The neonate is kept in separate isolation room with an adequate caretaker, if the mother accepts.

If the mother desires for rooming in the same room/hospital with limited facility for isolation, adequate steps to be taken to reduce the cross infection from infected mother to the baby.

Breastfeeding

Mother and baby in temporary isolation: Expressed breast milk should be fed to the baby by a healthy caretaker.

Mothers should use a dedicated and properly sterilized breast pump with good hand hygiene practices.

COVID-positive lactating mother who opted for rooming in: Breastfeeding should be done after wearing a triple-layered mask and adequate hand hygiene practice before and after the feed.[27]

Discharge Advice

- Counsel regarding warning signs of COVID-19 infection during the postnatal period
- To follow preventive measures at home to reduce COVID cross-infection
- Video consultation facility to be provided.

BOX 2: Management of COVID-19 pregnant women in labor.

- Severity of infection should be assessed and management should be done with multidisciplinary team approach in tertiary care unit
- TPR and SpO_2 charting should be done
- Ensure the onset of labor according to standard protocols
- Continuous fetal monitoring should be done by CTG
- Oxygen supplementation if SpO_2 falls below 94%
- COVID-19 infection with pregnancy is not any indication for LSCS. LSCS is only indicated in severely comprised respiratory status or for obstetric indications
- COVID-19 infection is not a contraindication for spinal or epidural anesthesia
- Instrumental delivery can be performed to cut short the second stage of labor
- Active management of third stage of labor should be done

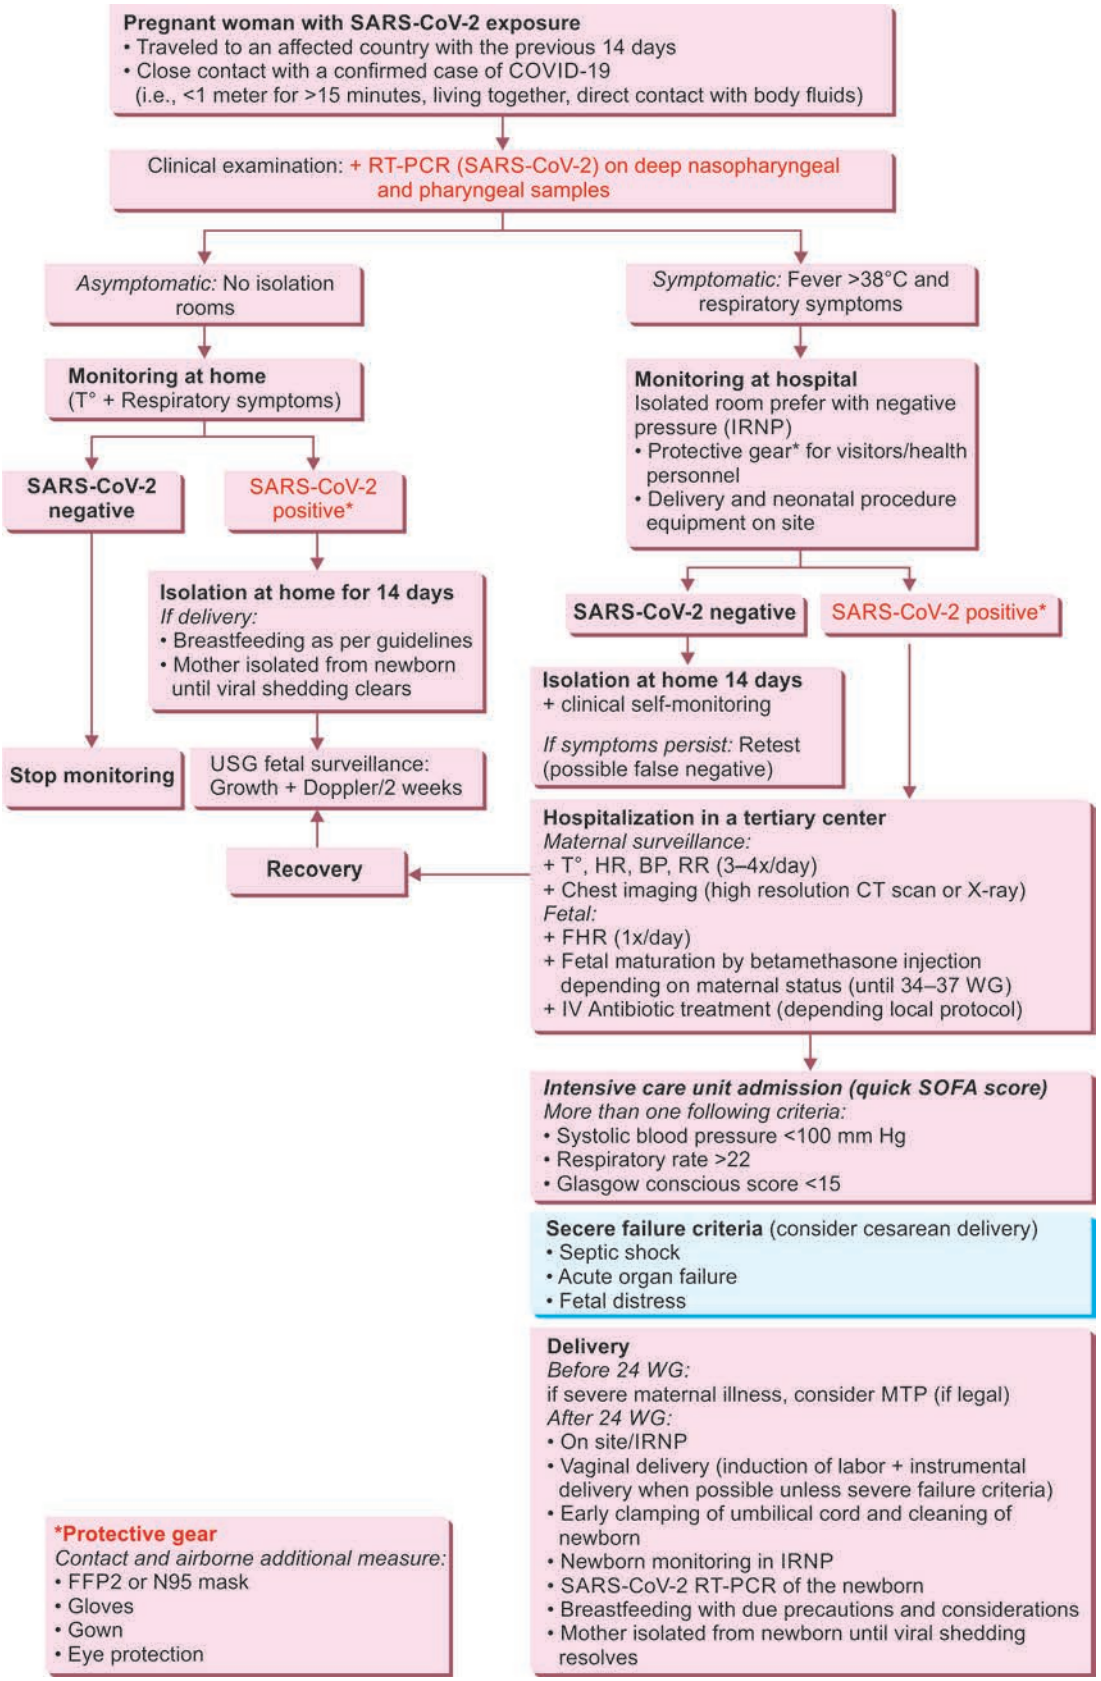
Coronavirus disease 2019 positive status is not an indication for medical termination of pregnancy (MTP)/induction of labor (IOL)/LSCS

(COVID-19: coronavirus disease 2019; CTG: cardiotocography; LSCS: lower segment cesarean section; SpO_2: peripheral oxygen saturation; TPR: temperature, pulse, respiration)

- Postnatal advice regarding iron, calcium supplementation, perineal hygiene, breastfeeding, and contraception should be given.

Management of COVID-19-positive pregnant woman is shown in **Flowchart 2.**

Flowchart 2: Management of COVID-19 positive pregnant woman.



Source: Adapted from Lancet, which is present in guidance for the management of pregnant women in COVID-19 pandemic by ICMR/NIRRH.[18]

BOX 3: Personal protection equipment (PPE) in the management of suspected/confirmed patient of coronavirus disease 2019.

Respiratory protection:
- Triple-layered surgical mask
- N95 facemasks

Eye protection: Goggles and face shield
Body protection: Water-resistant complete gown which covers head and shoes
Hand protection: Properly fitting gloves

BOX 4: Steps of donning of personal protection equipment (PPE).

- *Step 1:* Proper hand wash should be done before donning
- *Step 2:* Appropriately fitting respirator or mask should be owned
- *Step 3:* Face shield and eye protection goggles should be owned
- *Step 4:* Appropriate size of gloves should be worn

USE OF PERSONAL PROTECTION EQUIPMENT IN THE MANAGEMENT OF SUSPECTED/CONFIRMED PATIENT OF CORONAVIRUS 19 DISEASE

Use of personal protection equipment in the management of suspected/confirmed patient of COVID-19 disease is shown in **Box 3**.

HOW TO USE PERSONAL PROTECTIVE EQUIPMENT

Use of personal protective equipment is shown in **Boxes 4 and 5**.

CORONAVIRUS DISEASE 2019 VACCINATION IN PREGNANT WOMEN AND LACTATING WOMEN

Based on the recommendations from the National Technical Advisory Group on Immunization (NTAGI), MoHFW has approved vaccination of lactating and pregnant women against COVID-19 in 2021.

Pregnant women should be counseled regarding the benefits and side effects of COVID-19 vaccination and also the risk associated with COVID-19 infection in pregnancy.

Timing of Vaccination

A pregnant woman can take COVID vaccination in any trimester of pregnancy. If she has been infected with COVID-19 in the present pregnancy, she should take vaccination in the postnatal period.

Coronavirus disease 2019 vaccination will reduce the severity of coronavirus infection but will not prevent from infection, so in spite of vaccination, coronavirus appropriate behavior such as N95 masks, hand hygiene, social distancing, and proper respiratory etiquettes needs to be followed.

BOX 5: Steps of doffing of personal protection equipment (PPE).

- *Step 1:* Gloves are removed after disinfecting with alcohol-based hand sanitizer and to be disposed in biohazard bin
- *Step 2:* After wearing a pair of new gloves the gown should be doffed off
- *Step 3:* Goggles and face shield should be removed from the backside of the strap
- *Step 4:* Respirator/mask should be removed next
- *Step 5:* Removal of new pair of gloves after using alcohol-based sanitizer
- *Step 6:* Proper hand wash with soap and water

CONCLUSION

Coronavirus disease is a pandemic of 21st century of global concern which has caused public health emergency to mankind. Several variants of COVID-19 are of concern like Alpha, Beta, Gamma, Delta, Omicron and new Beta 7 variant recently. Even though respiratory system is the most commonly affected organ system, COVID-19 is a systemic hyperinflammation syndrome with elevated levels of many inflammatory mediators. Incidence of coronavirus disease is similar in pregnant and nonpregnant women, but the severity of infection is more in pregnant women. Vaccination is an effective way to reduce the severity of COVID-19 infection, but it will not prevent from a person getting infected. So let us all follow the effective preventive measures like social distancing, proper respiratory hygiene and hand hygiene etiquettes and fight against COVID-19.

KEY POINTS

- Coronavirus disease 2019 is global health emergency of 21st century, first got detected in Wuhan city of China in December 2019.
- COVID-19 virus is a single-stranded RNA virus, under family of beta corona virus and subfamily sarbecovirus.
- Transmission of COVID-19 is by respiratory secretions, feces and fomites with the mean incubation period of 5 to 7 days with duration of disease varies from 5 days to chronic infection.
- Clinical features are cold, cough, fever, myalgia, headache, vomiting, nausea, diarrhea, breathing difficulty, loss smell and taste or may be few cases will be asymptomatic.
- Current evidence suggests that COVID-19 will not add the risk for miscarriage or pregnancy loss, no vertical transmission, no risk of teratogenicity and no increase in neonatal mortality rate but incidence of preterm birth is increased in pregnant women with COVID-19, but it is not clearly understood that it is because of spontaneous onset of preterm or iatrogenic induced.
- All pregnant women must be made aware about the warning signs of both COVID-19 and pregnancy.
- *eSanjeevani:* A telemedicine platform for maternal fetal health services during COVID pandemic by ministry of health and family welfare of India for doctors and patients.

- Home quarantine with monitoring of vitals, inpatient management and ICU management depends on severity of infection.
- Corona virus infection is not an indication for termination of pregnancy or cesarean section
- Use of Personal Protection Equipment (PPE) in the Management of Suspected/Confirmed Patient of COVID-19 will protect healthcare providers from getting infected.

CHAPTER 96

Essentials of Statistics: A Clinician's Perspective

Gautham T Pranesh

DATA AND ITS TYPES

Data is a collection of facts and figures that are collected and analyzed as a part of a research initiative.

Data is the raw material of statistics. Data can be collected in many ways; it can be qualitative or quantitative, it can be recorded by hand or digitally, and it can be stored on paper or electronically.

There are many different types of data:

- *Quantitative data:* This is data that has been measured numerically or with some other quantity-based unit. Examples of quantitative data include parameters such as height, temperature, and weight.
- *Qualitative data:* This is data that has been measured qualitatively such as through a survey response or an open-ended question. Examples of qualitative data include gender, ethnicity, patient responses to a questionnaire on pain scales, etc.

Data in a research study is called a *data item* or *variable*, essentially a value that can vary from individual to individual. As described, the previously mentioned variables can be either quantitative or qualitative. A parameter is a characteristic that describes the distribution of a variable in one specific population compared to another population (i.e., the mean height for males in one country compared to the mean height for males in another country).

Measurements can be applied to data based on a set of rules or levels of measurement.[1] Variables can further be classified based on the levels of measurement as:

- *Nominal variables:* Categorical variables where there is no inherent natural order. For example, gender as a variable may be classified into male and female (or more categories). None of the categories are regarded as higher or lower than the other categories. Nominal variables may be summarized as percentages and are often represented as pie charts, column or bar chart.
- *Ordinal variables:* Categorical variables that have a natural ascending or descending order. The distance between two categories is however, not constant and may be abstract. For example, if we were to classify pregnancy status based on a beta-human chorionic gonadotropin (β-hCG) laboratory test as negative, indeterminate, and positive, each of the categories represent an incrementally higher value of β-hCG. Note that, the negative group may have a value of 0–5 mIU/mL, indeterminate 5–20 mIU/mL, and positive above 20 mIU/mL, i.e., distance between the two categories is unequal. Ordinal data is best summarized as frequencies and percentages and is best displayed as a column or bar chart.
- *Interval variables:* Interval variables are continuous variables that can be measured as a discrete nonzero number. The distance between two adjacent numbers on the scale is however constant. For example, measurements of body temperature follow a scale with discrete intervals. The difference between 37.3°C and 37.4°C is the same as 39.3°C and 39.4°C. The value 0°C does not represent the absence of temperature, but a very cold temperature. If you combine two objects with 20°C temperature, you do not get 40°C temperature! (unlike weight). The value of zero does not imply the absence of the characteristic being measured. Interval variables may be represented as histograms, bar or column charts of summaries or line graphs over time. Interval variables can be best summarized by means, medians, and standard deviations.
- *Ratio variables:* Ratio variables are similar to interval variables but include the value 0 indicating absence of the variable in measurement. An example of a ratio variable is the number of M2 oocytes that may be obtained in a procedure. This can have a value such as 4, 5, or 6 with the differences between values being 1 and cannot have a value in between these discrete numbers. A value of 0 indicates that no oocytes were obtained and is plausible in the data set. Ratio variables can also be best summarized by means, medians and standard deviations and may be represented as histograms, bar or column charts of summaries or line graphs over time.

Nominal and ordinal variables are often called categorical variables whereas interval and ratio variables are called continuous variables.

SUMMARIZING DATA

Once data is collected, variables need to be summarized for further analysis. Measures of central tendency, measures of dispersion and the distribution of data are common ways of summarizing data.[1]

Measures of central tendency are used to describe the "typical" or "central" value for a set of data.

The two most common measures of central tendency are the mean and the median. The arithmetic mean is the sum of all values divided by the number of values in a set. The median is the middle value in a set when ordered from lowest to highest. The mode represents the most repeated observation in a variable.

Measures of dispersion are used to measure the spread of data from an average.

The standard deviation is a measure that is used to quantify how much the data in a distribution deviate from the mean. The coefficient of variation is a measure that quantifies the relative dispersion of data in relation to its mean. The coefficient of variation is the ratio of standard deviation to the mean. To calculate the coefficient of variation, divide the standard deviation by the mean and then multiply by 100.

Statistical tests are often classified as parametric (where they assume that the shape of data distribution is well-defined such as a normal distribution) or nonparametric (where no such assumptions are made. The shape of a distribution can be visually determined by plotting a histogram or through plots like the box and whisker plots.

NORMAL DISTRIBUTION AND ITS PROPERTIES

Numerical clinical data such as laboratory test values, height, weight, etc., may follow a wide range of distributions. Many biological variables when plotted as a histogram with the observation values obtained in a sample on the X-axis against the frequency of such observations on the Y-axis result in a bell-shaped curve. This curve conventionally resembles the normal distribution or the Gaussian distribution.[2] The normal distribution curve is continuous, described by the mean, a measure of the central point and standard deviation, a measure of the width or spread of data. The curve is symmetric about its mean with an equal number of values distributed on either side. Data sets obtained in clinical research may be approximated to the normal distribution.

Such approximations of data can be extended to use the properties of the normal distribution to infer clinically relevant information. For example:

- 68.3% of values for a normal distribution lie within one standard deviation (1 SD) of the mean on either side
- 95.4% of values for a normal distribution lie within two standard deviations (2 SD) of the mean on either side
- 99.7% of values for a normal distribution lie within three standard deviations (3 SD) of the mean on either side **(Fig. 1)**.

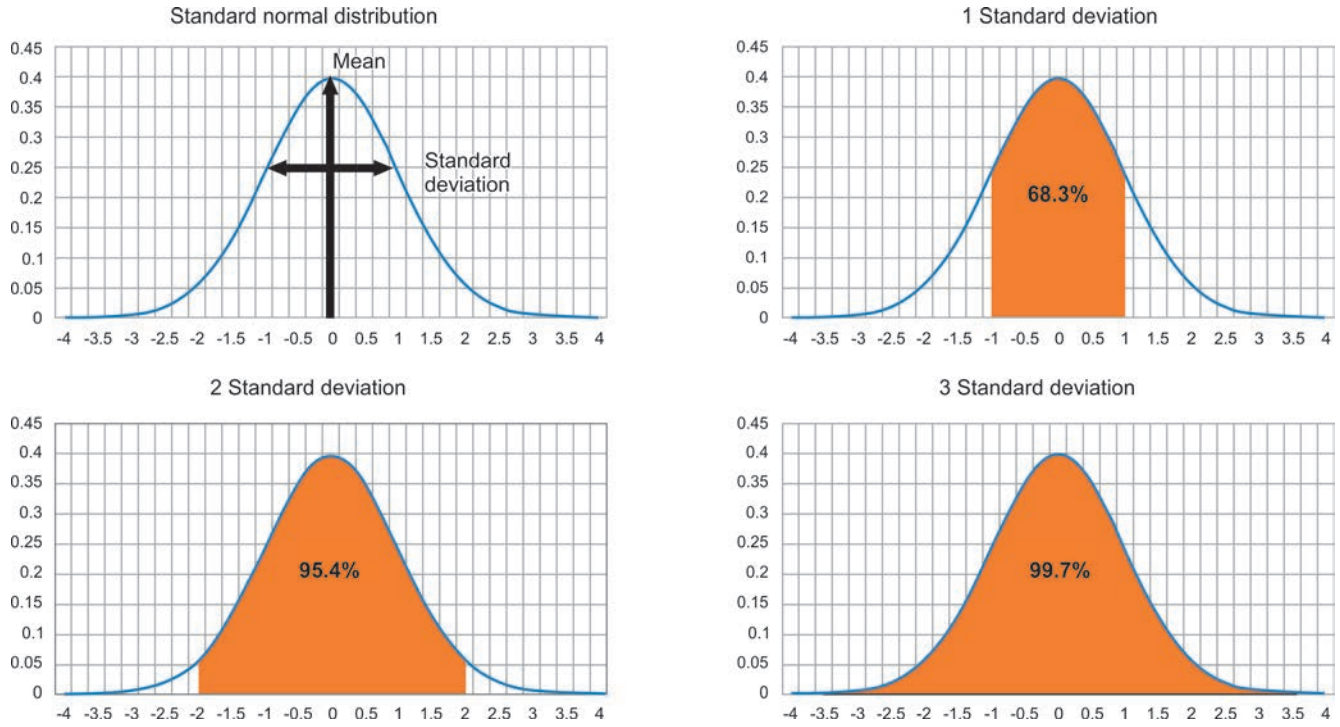

Fig. 1: Standard normal distribution and area under the curve (shaded area) at 1 standard deviation, 2 standard deviation, and 3 standard deviations.

If data in a clinical setting is approximated to a normal distribution, the mean ± 1.96 standard deviations cover 95% of the sample, a property which is often used to estimate reference ranges. The values of mean +1.96 SD and mean −1.96 SD provide the upper and lower cut-offs for such ranges.

If we take multiple random samples of size n from a population, we are likely to find a slightly different mean for every sample. If we plot a frequency histogram of the values of such means obtained across many samples-experiments, the resulting distribution of the sample means would approximate to a normal distribution. In other words, the sample means are distributed normally around the population mean with the variability being termed as the standard error of the mean (SEM). As the standard error of mean is normally distributed, for a sample with n observations, a mean of μ and a standard deviation σ, it can be calculated as

$$\text{SEM} = \sigma/\sqrt{n}$$

Furthermore, 95% of all possible sample means would lie within the limits $\mu \pm 1.96 \times \text{SEM}$.

The properties of the normal distribution enable us to develop a confidence interval, a measure of reliability by a range for estimates of an unknown variable such as a reference range or a range of possible means, at a designated confidence level (i.e., 95% of all values).

STATISTICAL TESTS AND THEIR APPLICATION

There are a wide variety of statistical tests that may be applied to data. Selection of the appropriate statistical tests depends on the purpose of analysis (comparison of means, establishing association, prediction of values, etc.), the level of measurement (type of data), number (two groups or more than two groups) and type of samples (independent samples versus paired samples). **Table 1** provides a brief example of commonly used statistical tests.

In most statistical analysis, the first step is to establish a "null hypothesis" (H_0).[6,7] The null hypothesis is a statistical statement implying that the differences observed across samples in an experiment is due to chance alone. Statistical tests evaluate the p-value, the probability of rejecting the null hypothesis when the null hypothesis is true. A low p-value, say a p-value of 0.001 indicates a 1 in 1,000 probability of rejecting the null hypothesis when the null hypothesis is true. By established convention, most medical research deems a p-value of <0.05 to be statistically significant.

Experiments done to infer from the real world and statistical tests therein have the possibility of two types of errors, type I and type II as shown in **Table 2**.

Type I errors or false positive results on experiments result in rejecting the null hypothesis due to a chance finding when the null hypothesis is the truth. The impact of this error would be a change in clinical practice when there is no benefit derived from the change. Type II errors indicate the failure of an experiment to reject the null hypothesis due to chance when the null hypothesis is true. The type I error or significance level is the probability of rejecting the null hypothesis when the null hypothesis is true, denoted by α (alpha). The type II error is denoted by β (beta) and provides

TABLE 1: Examples of commonly used statistical tests.

Parametric test	*Equivalent nonparametric test*	*Levels of measurement*	*Purpose*	*Examples*
Two sample (unpaired) t test	Mann–Whitney U test	Interval or ratio data	Comparison of two independent samples from the same population[3]	Comparison of peak estradiol values in patients with agonist versus antagonist protocol
One sample (paired) t test	Wilcoxon matched pairs test	Interval or ratio data	Compare two sets of observations from the same sample	Comparison of sperm motility before and after antioxidants in the same group of patients
One way analysis of variance	Kruskal–Wallis test	Interval or ratio data	Compare >2 sets of independent samples from the same population[4]	Comparison of sperm motility in patients receiving vitamin E, vitamin C or CoQ10
Chi-square test	Fisher's exact test	Nominal or ordinal data	Tests the null hypothesis that the distribution of two or more categorical variables is the same in two or more independent samples[5]	Comparison of pregnancy rates in patients with fresh versus frozen embryo transfers
Pearson's correlation	Spearman's rank correlation	Nominal, ordinal, interval, and ratio	Test linear strength of association between two variables[6]	What is the association between peak E2 and AFC in women undergoing antagonist protocol?
Regression by least squares	Nonparametric regression	Nominal, ordinal, interval, and ratio	Prediction of one variable based on the changes in another variable[6]	Prediction of MII oocytes obtained on retrieval based on estradiol values in patients

(AFC: antral follicle count; CoQ10: Coenzyme Q10; MII: metaphase II)

an estimate of the power of a test calculated as 1 – β. Thus, the power of a test is a measure of the ability to reject the null hypothesis correctly. By convention, most tests are powered between 80 and 95%.

STUDY DESIGNS AND STATISTICAL MEASURES

Clinical studies may be broadly categorized based on design into descriptive and analytical designs. Observational clinical studies can be further categorized into descriptive and analytical studies.

Observational Studies

Case Reports

Case reports are descriptive, observational studies where an investigator describes in detail observations such as signs, symptoms, diagnosis, treatment, and follow-up in an individual patient with a finding of interest. The detailed report usually contains the demographic details of patients and describes a unique or novel observation. The report may provide references to literature review where such observations were previously noted. Case reports provide early signals for design of studies to evaluate efficacy, adverse events, or impact on healthcare economics.

TABLE 2: Errors in experiments versus reality.

		Reality	
		H_0 is true	*H_0 is not true*
Experiment results	*Accept H_0*	Correct	Type II error
	Reject H_0	Type I error	Correct

Case reports—where is it used?

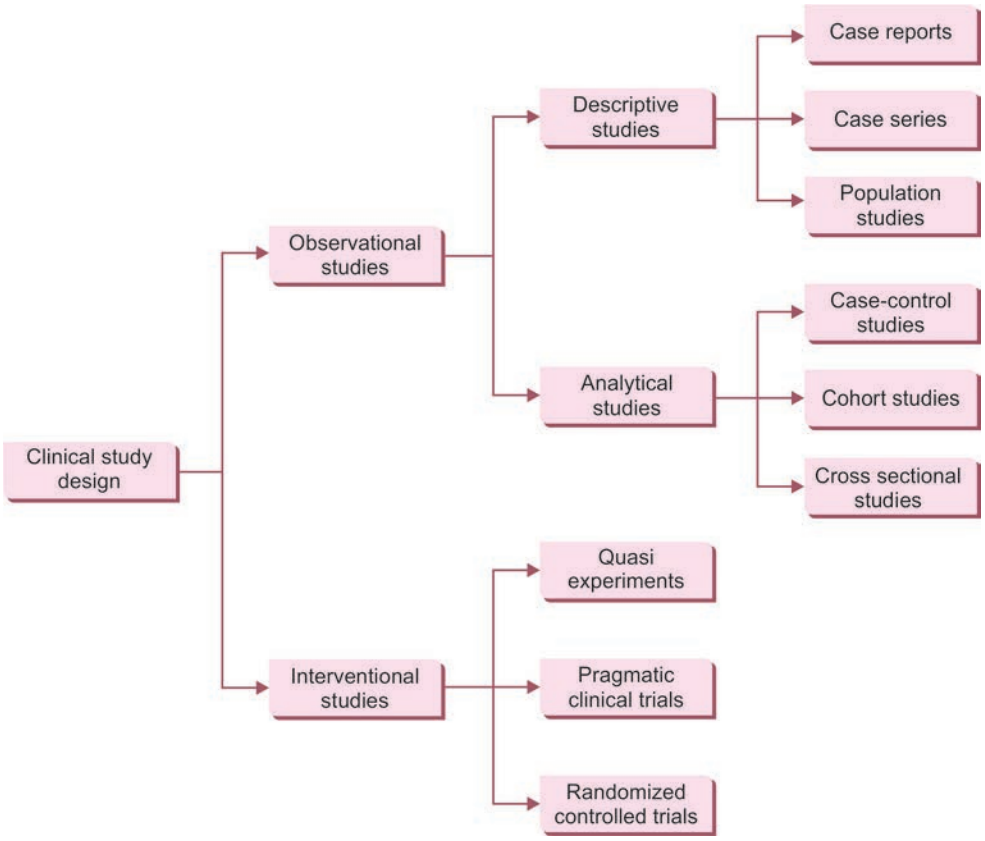
Case reports are used to describe unique clinical findings or observations by an investigator.

Case Series

Case series are descriptive observational studies that track subjects with a known exposure (a treatment, a symptom, exposure to a potential toxin etc.) involving four or more cases. The narrative on the report is experience based. Case series may be consecutive or nonconsecutive and are often vulnerable to selection bias. Other forms of bias that may impact a case series include the following:

- *Placebo effects*—when improvement in subjective symptoms is noted even when the patient receives a placebo or a nonactive treatment.
- *Hawthorne effects*—the propensity of subjects to modify their behavior when under observation in a study. For example, patients in a study may adopt a healthier lifestyle than usual when they are under observation **(Flowchart 1)**.

Flowchart 1: Research study design.



- *Rosenthal effects*—also termed as the Pygmalion effect. A subject's behavior can change or improve based on the high expectations of the investigator who is observing in specific areas. For examples studies have found that a teacher's expectation or impression of a student can influence the performance of the student.

Case series—where is it used?
Case series although low in terms of the level of evidence provide a subjective insight into early signals associated with a disease or event. This may be used as a basis for further evaluation in larger studies.

Population Studies

A population study is a descriptive observational study of a group of individuals taken from the general population who share a common characteristic, such as age, sex, or health condition. This group may be studied for different characteristics such as their response to a drug or risk of getting a disease. The study draws comparisons within the characteristic of interest in a descriptive manner. Such comparisons may include questions on "when the disease is occurring," "where the disease is occurring," "who is getting the disease," and the "number of events obtained."

Population studies—where is it used?
Population studies help in understanding broad associations and the underlying natural history of an event.

Case-control Studies

Case-control studies are a type of analytical observational study that compare patients with disease (or another outcome variable) and compare them across to suitable matched controls who serve as a comparison or reference group. The selection of controls is done based on them not having the disease or outcome of interest, without prior knowledge or in a manner that is independent of the exposure. The studies help investigators to identify the role of specific exposures and their association with an event or disease. Recall bias often has an impact on the data collected in this type of study design **(Fig. 2)**.

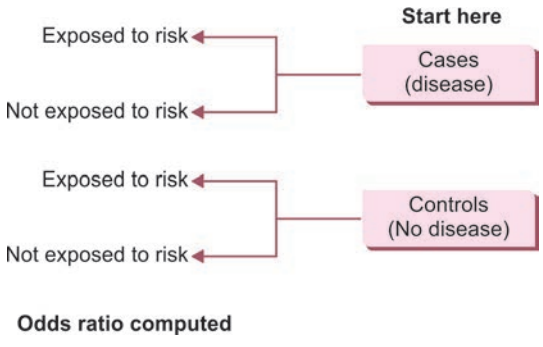


Fig. 2: Case control study design.

Case-control studies—where is it used?
Case-control studies are used as a relatively inexpensive study design to explore associations between risk factors and disease. The study design can be used in cases where the incidence of disease is low. The design also allows establishing an association where alternative designs involving active intervention may be impractical or unethical (for example, exposure to toxins, radiation, etc.).

Statistical measures in a case control study

- *Exposure rate:* Number of persons in the diseased (cases) or nondiseased (control) groups who have the history of a prior exposure.
- *Odds:* The odds of an event are calculated by dividing the number of times an event happens versus the number of times that an event does not happen. For example, the probability of rolling 1 on a fair dice is 1/6, the probability of not rolling 1 is 5/6. The odds of rolling a 1 are (1/6)/(5/6) or 1/5.

$$\text{Odds of event in exposed group} = \frac{\text{Probability of event in exposed group}}{\text{Probability of no event in exposed group}}$$

$$\text{Odds of event in nonexposed group} = \frac{\text{Probability of event in nonexposed group}}{\text{Probability of no event in nonexposed group}}$$

- *Odds ratio:* The odds ratio is the ratio of odds of disease having been exposed to the risk factor as compared to not being exposed to a risk factor. An odds ratio of 1 suggests that the risk of exposure is not associated with an event or a disease. An odds ratio of >1 indicates that the risk of exposure is associated with an increased risk of developing an event or disease. Similarly, an odds ratio of <1 indicates a higher probability of a disease or an event in the nonexposed group suggesting a protective effect.

$$\text{Odd ratio} = \frac{\text{Odds of event in exposed group}}{\text{Odds of event in nonexposed group}}$$

Examples of case-control studies: A 2014 study titled "Association of venous thromboembolism with hormonal contraception and thrombophilic genotypes" evaluates 948 cases of women in Sweden with a diagnosis of venous thromboembolism and 902 women who serve as controls from the same population (derived from the Swedish population register) to evaluate the risk of exposure to combined hormonal contraception.

Table 3 presents the data summarized from the study above.

- *Exposure rate* = No of cases with exposure/total no of cases × 100
- *Cases:* 311/948 × 100 = 32.8%

TABLE 3: Data summarized from the case-control studies.

	Cases	*Controls*	*Total*
CHC	311	107	418
No CHC	637	795	1.432
Total	948	902	1,850

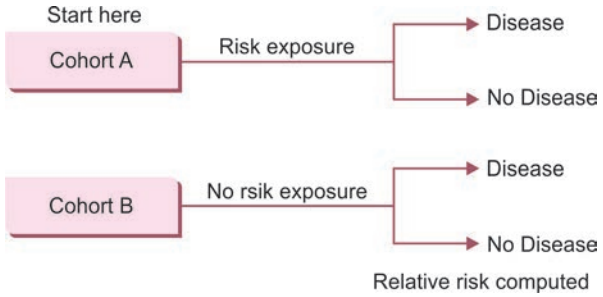

Fig. 3: Cohort study design.

- *Controls:* 107/902 × 100 = 11.9%
- Frequency of venous thromboembolism is higher in patients on combined hormonal contraception compared to those who are not
- Odds—chance of disease in exposed/chance of disease in not exposed
- Odds of venous thromboembolism in cases = (311/948)/(637/948) = 311/637 = 0.49
- Odds of venous thromboembolism in controls = (107/902)/(795/902) = 107/795 = 0.13
- Odds ratio = 0.49/0.13 = 3.8 (i.e., patients on combined hormonal contraception had 3.8 times higher risk of thromboembolism compared to controls).

Cohort Studies

A cohort is a group of people with similar characteristics. Cohort studies measure the risk of developing an event in the exposed group and similarly the risk of developing an event in those who are not exposed. Cohort studies can be designed either as prospective or retrospective studies (cohort details are obtained from medical records or insurance claims) **(Fig. 3)**.

Cohort studies—where is it used?

Cohort studies are used for epidemiological analysis on how risk factors affect the incidence of diseases. Cohort studies provide strength of association between a risk of exposure and a disease and may provide preclinical justification for the plausibility of protective factors (treatments/prevention). The design also allows to establish an association where alternative designs involving active intervention may be impractical or unethical (for example, exposure to toxins, radiation etc.).

Statistical measures in a cohort study

- *Incidence rate:* The incidence rate is a measure of the number of individuals developing a disease or having an event over a period. For example, if a study evaluating 2,000 intracytoplasmic sperm injection (ICSI) pregnancies found 40 birth defects over a period of one year, the incidence of birth defects in ICSI derived pregnancies would be 40/2,000 or 2% per year.
- *Estimation of risk:* Estimates of risks evaluate the probability of an event happening in a cohort who either have a risk of exposure or have no risk of exposure. A risk estimate can be calculated by dividing the number of subjects who had an event from the total number of subjects in the cohort. We can measure estimates of risk separately of the group with a risk of exposure and the group with no risk of exposure. The estimates of risks in the two groups are used to evaluate the relative risk or the risk ratio.
- *Risk ratio (relative risk):* The risk ratio describes the risk of developing the disease in the exposed group when compared to the nonexposed group as a ratio. A ratio of 1 indicates no difference in risks between the exposed and the nonexposed groups. A risk-ratio of >1 indicates a greater risk of an event in the exposed group as compared to the group without exposure.

TABLE 4: Data on acute ovarian failure (AOF) in this study.

	Developed AOF	*Did not develop AOF*	*Total*
Radiotherapy	162	670	832
No radiotherapy	53	2,505	2,558
Total	215	3,175	3,390

Examples of cohort studies: The "acute ovarian failure in childhood cancer survivor study" is an example of a cohort study. The study looked at 3,390 girls who were survivors of childhood cancers and evaluated the risk of acute ovarian failure (AOF) in those exposed or not exposed to radiotherapy (the cohorts).

The data on acute ovarian failure in this study can be summarized in **Table 4**.

- Incidence rate = no of patients who developed disease/total no patients with exposure × 100
- Incidence rate of AOF in patient exposed to RT = 162/832 × 100 = 19.5%
- Incidence rate of AOF in patients not exposed to RT = 53/2,558 × 100 = 2.1%
- Relative risk = incidence in exposed/incidence in not exposed = 19.5%/2.1% = 9.29 (i.e., girls exposed to radiotherapy are at 9.29 times higher risk to develop AOF)
- Attributable risk = (incidence in exposed-incidence in nonexposed)/incidence in exposed × 100
- Attributable risk = (19.5 – 2.1)/19.5 × 100 = 17.4/19.5 × 100 = 89.2% (i.e., exposure to radiation attributes to 89.2% of the increased risk in developing AOF).

Cross-sectional Studies

Cross-sectional studies are analytical, observational studies used in epidemiology to analyze cross-sectional data from a population, or a representative subset, at a specific point in time. Unlike the case control and cohort study designs which follow groups ahead or in the past in time, cross sectional studies provide a snapshot at a specific moment in time. This predisposes the studies to temporality, confounding, and measurement bias related problems.

Cross-sectional studies—where is it used?
Cross sectional studies are used to evaluate prevalence of a disease in a population. Such a design can also be used to evaluate correlation between two or more variables in the population.

Statistical measures in a cross-sectional study
- *Prevalence:* An estimate of the number of existing cases at a specific point of time within a population.
- *Correlation:* Correlation is a measure of linear statistical relationship between two variables. The strength of association is measured by the correlation coefficient. A correlation coefficient of 0 indicates that there is no association between the two variables. A coefficient of 1 suggests a strong positive correlation whereas a coefficient of –1 suggests a strong negative correlation. Pearson's correlation coefficient is used for parametric data and Spearman Rank correlation coefficient for nonparametric data.

Interventional Studies

Interventional studies evaluate the effect of an intervention (a drug, treatment etc.) as compared to a lack of the said intervention on specified outcome measures. A few key terms commonly used in interventional studies defined as per Good Clinical Practice (GCP) guidelines[8] include:
- *Blinding:* A procedure in which one or more parties to the trial are kept unaware of the treatment assignment(s). Single-blinding usually refers to the subject(s) being unaware, and double blinding usually refers to the subject(s), investigator(s), monitor, and, in some cases, data analyst(s) being unaware of the treatment assignment(s).
- *Clinical trial/clinical study:* Any investigation in human subjects intended to discover or verify the clinical, pharmacological and/or other pharmacodynamic effects of an investigational product(s), and/or to identify any adverse reactions to an investigational product(s), and/or to study absorption, distribution, metabolism, and excretion of an investigational product(s) with the object of ascertaining its safety and/or efficacy. The terms clinical trial and clinical study are synonymous.
- *Adverse event:* Any untoward medical occurrence in a patient or clinical investigation subject administered a pharmaceutical product and which does not necessarily have a causal relationship with this treatment. An AE can therefore be any unfavorable and unintended sign (including an abnormal laboratory finding), symptom, or disease temporally associated with the use of a medicinal (investigational) product, whether or not related to the medicinal (investigational) product.[8]
- *Good Clinical Practice (GCP):* A standard for the design, conduct, performance, monitoring, auditing, recording, analyses, and reporting of clinical trials that provides assurance that the data and reported results are credible and accurate, and that the rights, integrity, and confidentiality of trial subjects are protected.
- *Randomization:* The process of assigning trial subjects to treatment or control groups using an element of chance to determine the assignments in order to reduce bias.

Quasi Experiments

Quasi experiments are interventional studies that evaluate a cause-effect impact without randomization. Such studies often select patients from a population based on a set of inclusion or exclusion criteria and evaluate effects before and after an intervention. Quasi experiments are limited by internal validity as there is no true control group in the design.

Statistical measures in a quasi-experiment: Researchers often use tests such as paired-t test for parametric data or Wilcoxon matched pair test for nonparametric data for such studies.

Examples of a quasi-experiment: A study titled "intraovarian injection of autologous platelet rich plasma on ovarian reserve and IVF outcome parameters in women with primary ovarian insufficiency" evaluates the markers of ovarian reserve antral follicle count (AFC), anti-Müllerian Hormone (AMH) and follicle stimulating hormone (FSH) on day 2, before and after intraovarian injection of platelet rich plasma in women with primary ovarian insufficiency.

Adaptive Clinical Trials

An adaptive clinical trial is a clinical trial that is designed for flexible course correction based on the evaluation of an intervention (treatment or medical device) by observing participant outcomes (and possibly other measures, such as side-effects) on a prescribed schedule. Subsequent modifications such as escalation or de-escalation may be made to the dose of the drug, sample size, patient selection criteria, frequency of dosing, etc., based on the observed participant outcomes.

Pragmatic Clinical Trials

Pragmatic clinical trials or practical clinical trials are designed to evaluate the effects of an intervention in real world settings as opposed to an ideal setting in a randomized

controlled trial. Such an approach may involve a critical appraisal of inclusion exclusion criteria to match real world patients, cluster randomization for interventions across different centers based on standard healthcare operations to compare new treatments against standard conventions across centers. Patient recruitment and collection of data may be done from electronic health records in line with the standard healthcare operations in the real world. Such studies help in making evidence from trials practical and inclusive while ensuring engagement of the healthcare system for making relevant changes to policy.

Randomized Controlled Trials

Randomized controlled trials (RCTs) are clinical study designs which measure outcomes of interventions as compared to controls while avoiding bias through randomization. Subjects are selected into a randomized controlled trial based on a predefined set of inclusion-exclusion criteria. Subjects are then randomly allocated to the interventional or control arm and then followed to collect outcome measures **(Fig. 4)**.

Statistical measures in a randomized controlled trial

- Comparison of means (average number of oocytes in group A vs. B)
- Comparisons of proportions (e.g., pregnancy rates with group A vs. B)
- *Risk reduction:*
  - Relative risk reduction
  - Absolute risk reduction
- Number needed to harm/treat
  - 1/absolute risk difference
  - Answers usefulness of interventions.

Examples of calculation of number needed to treat in RCTs: A study titled "does varicocele repair improve male infertility? An evidence-based perspective from a Randomized Controlled Trial" evaluates pregnancy as an outcome in couples where the male partner was diagnosed to have a varicocele and was randomly allocated to undergo a surgical correction or managed conservatively. The summary of outcomes in this study is provided in **Table 5**.

- *Event:* Failure to conceive
- *Experimental event rate (EER):* 51/75 = 0.68
- *Control event rate (CER):* 65/75 = 0.86
- *Absolute risk reduction (ARR)* = 0.86–0.68 = 0.18
- *NNT* = 1/ARR = 1/0.18 = 5.5 (i.e., 1 additional pregnancy would be seen every 5.5 patients treated with varicocele surgery as compared to no treatment).

Fig. 4: Randomized controlled trial design.

OTHER APPLICATIONS OF STATISTICS IN A CLINICAL SETTING

Evaluating Research and Quality of Evidence for Evidence-based Practice Guidelines

Evidence-based medicine (EBM) is the conscientious, explicit, judicious, and reasonable use of modern, best evidence in making decisions about the care of individual patients. Clinical research is often subject to bias and other limitations. Hence, the strength of evidence generated by studies follow a hierarchy as depicted in **Figure 5**.

Critical appraisal of research must include evaluation of the certainty of evidence. Such an evaluation is likely to include the answers to questions including:

- What are the limitations of the study?
- Are the results consistent with previous studies?
- Are the results precise?
- How applicable are the results to the population?
- Are the interventions proposed, and outcomes measured in line with standard practices?
- Is this all the research that exists? Is this a one-off finding?
- Are there any statistical signals that increase confidence such as dose-response, large effect size, etc.

The translation of research into clinical practice often goes much beyond purely scientific and statistical considerations. Deliberations on the certainty of evidence, feasibility, risk versus benefit, resource availability, and equity play a critical role in the translation of scientific studies to guidelines for clinical practice.

TABLE 5: Pregnancy rates in patients with varicocele surgery as intervention.

	Varicocele surgery	***No surgery***	***Total***
Pregnancy	24	10	34
No pregnancy	51	65	116
Total	75	75	150

Fig. 5: Hierarchy of evidence.

Quality Control/Process Control

Quality control or process control is a critical part of the quality assurance program in the laboratory. Some of the commonly used approaches for quality control include checks based on correlation to ensure consistency in processes (for example peak E2 in an ovulation induction cycle would correlate with the number of oocytes retrieved), defining key performance indicators (cleavage rate, fertilization rate, blastocyst rate, etc., pregnancy rate etc.) based on historical and peer-group comparisons and the use of control charts for critical parameters such as temperature, gas pressures or pH as depicted in **Figures 6A and B**.

The chart in panel A represents a process that is in control for temperature where all values are in between mean ± 2 standard deviation. The process chart in panel B shows a trend toward failure starting on day 18 with the process failing to meet specifications between day 22 and day 25. The process appears to be corrected on day 25.

Control charts present data in a graphical manner which makes it easy to recognize changes in the process such as trends, shifts, and drifts from established thresholds.

Auditing Data and Data Quality

Statistics provides a good set of tools for evaluating practices during audits. Plotting data helps in visually identifying suspicious patterns such as irregularity or repeatability which may point toward systemic problems such as rounding-off values.

Figures 7A and B represent data from manual sperm counts obtained from a laboratory information management system compared to an automated system. Note that the data from the manual counts show drastic changes between patients with values that are even numbers or multiples of 5, suggesting rounding off data. Also, we see suspicious patterns in the manual data with over 10 patients having a value of 68 or 70 million sperms per mL but none at all with 69 million cells per mL!

Figure 8 highlights distinct peeks at multiples of 5 with disproportionately lower frequencies in the numbers in between which appear to be artifacts of rounding off numbers.

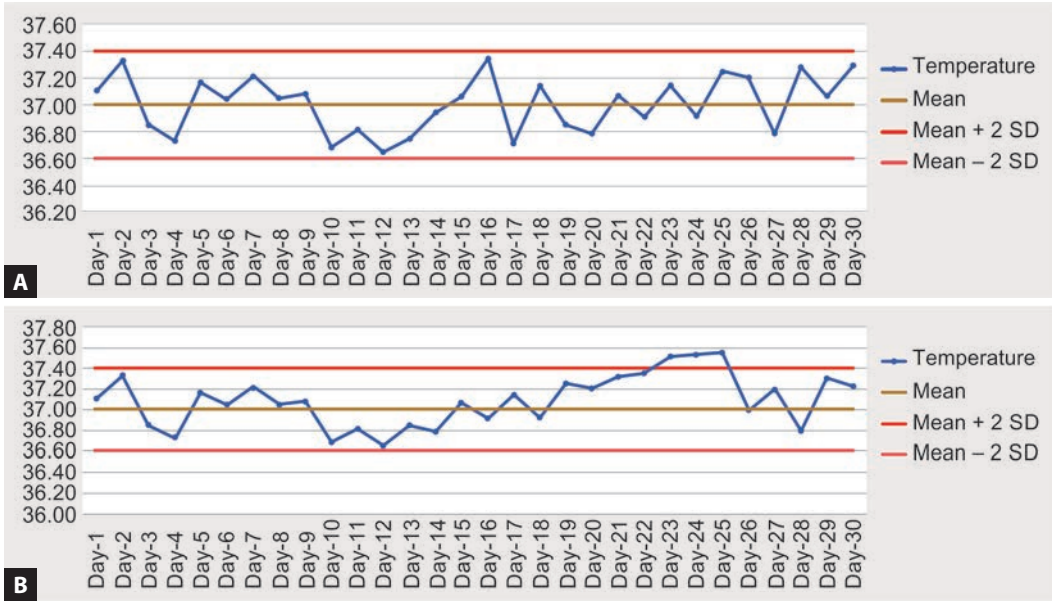
Analysis of Diagnostic Test Performance

Diagnostic tests aid a clinician with information that helps to rule-in or rule-out specific pathological or health conditions. To perform this task reliably, it is important for clinicians to understand the performance and limitations of performance of a diagnostic test. Test performance is evaluated against a gold-standard test using a case-control study. The measures obtained on test performance include the sensitivity and specificity of the test.

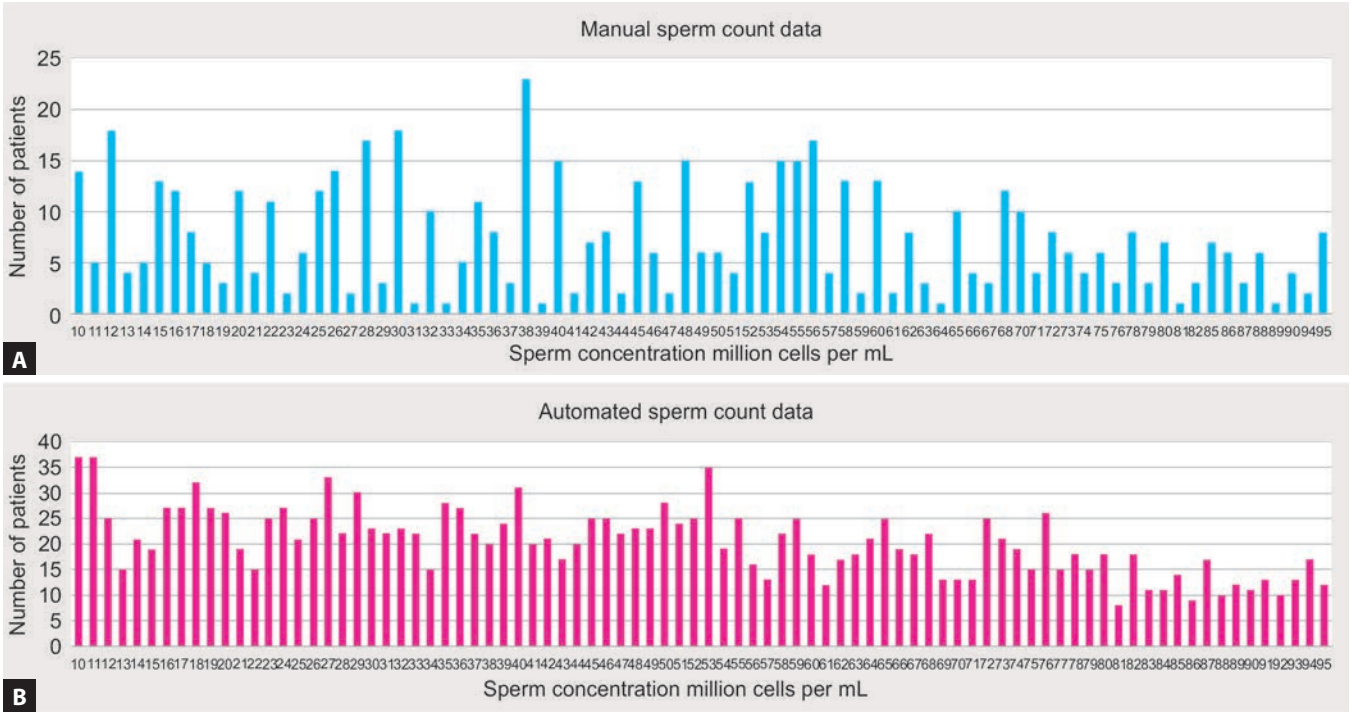
The sensitivity of the test is defined as the ability of a test to correctly identify patients with a specific disease whereas the specificity of a test is defined as the ability to correctly identify people who do not have the disease. As an example, sensitivity and specificity may be calculated as follows **(Table 6)**:

- Sensitivity = 231/258 = 0.90
- Specificity = 54/86 = 0.63.

In a clinical setting, many tests can give a positive result in not only people with the pathology of interest but also in some apparently healthy individuals. Although sensitivity and specificity provide details about the performance of the test, the metrics do not provide any insight on whether a



Figs. 6A and B: (A) Control chart—in control process; (B) Control chart—out of control process.



Figs. 7A and B: Data from manual sperm counts obtained from a laboratory information management system compared to an automated system.

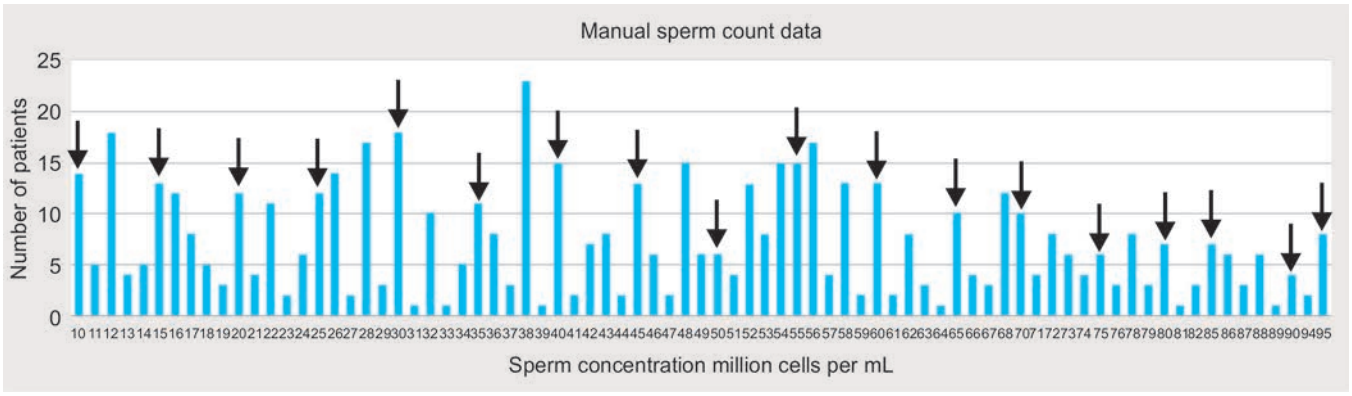


Fig. 8: Auditing data—automated versus manual semen analysis, suspicious regularity in data.

TABLE 6: Calculation for sensitivity and specificity.

		Gold standard		
		Positive	***Negative***	***Total***
Test	Positive	231	32	263
	Negative	27	54	81
	Total	258	86	344

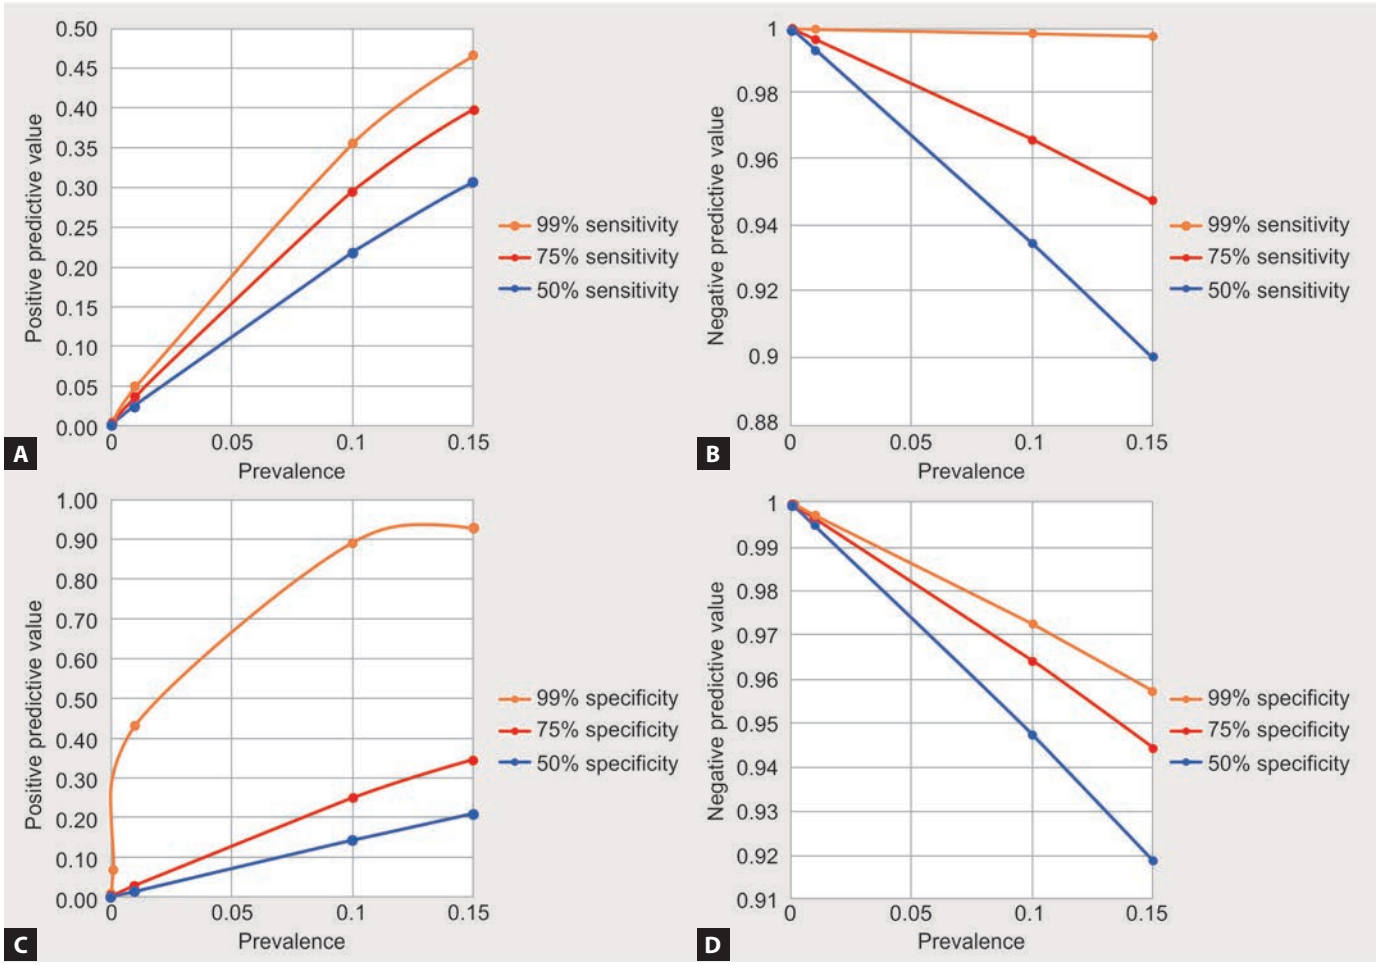
patient has a disease condition given that the test is positive or negative.

The positive predictive value of a test provides the true positives among all people who tested positive by the test. Similarly, a negative predictive value predicts the number of people who have no disease given that the test is negative.

- Positive predictive value = 231/263 = 87.3%
- Negative predictive value = 54/81 = 66.6%.

In a clinical situation where you have a choice of more than one testing strategy, knowledge of the prevalence of the disease and the performance of the test can help in the decision of using the correct test. The relationship between test sensitivity, specificity, disease prevalence, and positive and negative predictive values is illustrated in **Figures 9A to D**.

For example, the clinical objective in a test for a life altering condition such as a diagnosis for human immunodeficiency virus (HIV) would be to have a high positive predictive value. A test with high specificity provides a high increase in positive predictive values even when the prevalence is low. Thresholds for tests like HIV are established with a



Figs. 9A to D: Predictive values versus prevalence of disease.

preference to specificity versus sensitivity. Another example, a diagnosis of myocardial infarction may be regarded as a medical emergency warranting immediate intervention. A test with a high negative predictive value can confidently rule out such a diagnosis. A test with high sensitivity provides a good negative predictive value even when the prevalence of the disease is relatively low in the population.

Determining Optimal Cutoffs for Tests

Many tests like AFC generate results as numerical data. In order for these results to be meaningful, clinicians use a cut-off value to make decisions. Changes in cutoff values influence sensitivity, specificity, and predictive values. Selection of an appropriate cutoff hence becomes prudent in a clinical setting. The receiver-operator characteristic (RoC) curve[9] is a statistical tool that is used to determine cutoffs for numerical tests based on dichotomous or binary outcomes.

The receiver operator characteristic curve plots sensitivity (true positives) against 1-specificity (an estimate of false negatives) to obtain a curve. The point of inflection of the curve or the shortest distance from the upper left-hand corner provides the points for an optimal cutoff.

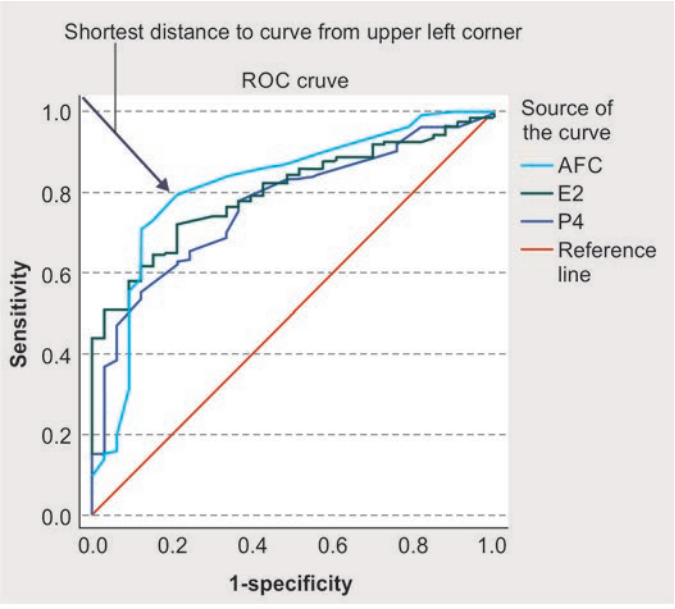


Fig. 10: Receiver operator characteristic curves.

As an illustrative example, **Figure 10** represents three receiver operator characteristic curves for numerical values of antral follicle count (AFC), peak estradiol (E2) and

progesterone (P4) on the day of trigger to predict if a patient would obtain five or lesser oocytes on pick-up. The values of these analytes on the curve having the shortest distance from the upper left corner represent the optimal cutoffs for determining patients who would obtain five or less oocytes on oocyte pickup. The area under the curves for AFC (0.818), E2 (0.800), and P4 (0.768) provide a guide for selection of the best test for this purpose. The AFC test with the highest area under the curve is likely to be the best test in this study to determine patients who would obtain five or less oocytes on retrieval.

CONCLUSION

Statistics serves as a tool to examine data generated within a clinic to implement evidence-based data driven decisions. The data driven statistical approach has value in several areas' day to day such as quality control, detection of non-conformities, evaluating diagnostic tests, and establishing cutoffs for diagnostics tests in addition to the applications in research. The principles of modern medicine have been built on a scientific basis established on shoulders of many clinicians and scientists in the past. It is the duty of a healthcare professional of the day to keep this scientific curiosity alive for newer learnings and better patient outcomes.

KEY POINTS

- Research studies often include the steps of asking a research question, designing an appropriate study to answer the research question, collecting data, analysis, summarizing and presenting data and drawing conclusions from the analysis.
- Evidence based medicine is the conscientious, explicit, judicious, and reasonable use of modern, best evidence in making decisions about the care of individual patients.
- Applications of statistical approaches beyond research and evidence-based medicine include areas such as quality control, detection of nonconformities, evaluating diagnostic tests, and establishing cutoffs for diagnostics tests.

CHAPTER 97

Semen Analysis in 21st Century Medicine: A Paradigm Shift

Fahim L Rajwate, Ashish S Reddy, Vasan SS

INTRODUCTION

Nearly 15% of couples are unable to conceive after a year of unprotected intercourse. A male factor is solely responsible in about 20% of infertile couples and contributory in another 30–40%[1] and another study by Hull et al.[2] suggested spermatozoal defects accounting for some 30–50% of cases of subfertility. Although the semen analysis is not a test of fertility, it is the most important single indicator of the functional status in the male reproductive tract. Clinical studies of infertile patients have established "limits of adequacy" below which the chance of initiating a pregnancy becomes more difficult. A minimum of two evaluations is recommended to establish a profile of the seminal parameters.

SEMEN ANALYSIS

Semen analysis is the cornerstone of the laboratory evaluation of the infertile male and helps to define the severity of the male factor. The first person to suggest that semen analysis should be a routine investigation in the evaluation of every case of infertility was Edward Martin.[3-5] Martin also demonstrated that there were two major causes of azoospermia and he was also the first to recognize the polymorphism of human sperm. John MacLeod then elevated semen analysis from being a simple observation into a science. He recognized that not only sperm numbers but sperm motility and morphology were also important in the evaluation of the potential fertility of semen.[6] He even tried to associate certain sperm shapes with specific clinical entities such as varicocele.[7] However, many clinicians and laboratory personnel did not follow MacLeod's lead in relation to semen analysis. In or around 1980s, it became clear that many laboratories worldwide were not even attempting to examine a number of variables within a semen sample that were important in the determination of fertility. Often only an estimation of the sperm concentration was being performed and no assessment of either motility or morphology was made by a number of pathology laboratories. Thus, information that could be obtained from the examination of semen was not being sought.[8]

By the early 1980s, however, Mortimer and colleagues were anxious to further advance the understanding of the inter-relationships between the different variables in a semen analysis[9] and also introduced the concept of quality assurance in relation to the analysis of semen.[10] It is now very clear that careful training in semen analysis, such as that set-up by the ESHRE Andrology Special Interest Group that includes both theoretical as well as practical training in semen analysis, is very effective in raising the skills of laboratory personnel in relation to semen analysis.[11]

However, it should be understood that semen analysis is a guide to fertility and not an absolute proof of fertility of an individual. Over the time it has become clear that the relationship between infertility and sperm numbers, sperm movement and sperm morphology is not a simple one. It has been known for a long time that reproductive pathology in the female partner reduces the potential fertility of a male with a normal sperm count[12] while a high sperm count such as that achieved using donated sperm can overcome female problems that could otherwise result in childlessness.[13] Thus the male-female interaction in infertility is immensely important to the outcome in relation to pregnancy, and this inter-relationship cannot in any way be incorporated into a semen analysis.

The literature in relation to the fate of the sperm once they enter the female genital tract in the human is very sparse. However, it is clear that, of the total number of sperm that enter this tract in a conception cycle, all but one is lost. Many of the sperm also drain out of the vagina after coitus in the phenomenon also known as flow back. What percentage of the ejaculate enters the cervical mucus is unclear but it is probably small. Of those sperms entering the cervical mucus, a proportion may become eliminated by their passage into the folds of the cervical epithelium and by their entry into the cervical glands.[14] Many sperms also loose or change their motility on entering the cervical mucus.[15]

The numbers of sperm that traverse the uterine cavity in the human and reach the uterotubal junctions in the human is unknown but probably only a few thousand sperm enter each Fallopian tube.[16] Those sperm that do succeed in entering the Fallopian tubes will therefore only make up a very small percentage of the total numbers seen in the whole ejaculate.

Due to the relatively vast surface area of the heaped-up epithelium of the Fallopian tubes (certainly vast in relation to the size of a spermatozoon); only a relatively small number of sperm will be able to access the oocyte. Not only must the sperm traverse the corona but they must also be able to exhibit hyperactivated movement and must not have undergone the acrosome reaction until they are close to the zona pellucida. It is thus also possible that human fertilization may depend frequently upon a sperm oocyte ratio that may be as low as 1:1.

THE AMERICAN UROLOGICAL ASSOCIATION BEST PRACTICE POLICY AND THE AMERICAN SOCIETY FOR REPRODUCTIVE MEDICINE PRACTICE COMMITTEE REPORT

An initial screening evaluation of the male partner of an infertile couple should be done if pregnancy has not occurred within 1 year of unprotected intercourse. An earlier evaluation may be warranted if a known male or female infertility risk factor exists or if a man questions his fertility potential. The initial evaluation for male factor infertility should include a reproductive history and two properly performed semen analyses. A full evaluation by an urologist/andrologist or other specialist in male reproduction should be done if the initial screening evaluation demonstrates an abnormal male reproductive history or an abnormal semen analysis. Further evaluation of the male partner should also be considered in couples with unexplained infertility and in couples in whom there is a treated female factor and persistent infertility.[3,4]

THE PROBABILISTIC NATURE OF HUMAN FERTILITY

The very term infertility is not helpful because it implies a complete incapacity to conceive, whereas most couples who fail to conceive within a year are capable of conception, just with a decreased probability of doing so in a given time. The clinician must decide which of these couples is likely to conceive in an acceptable time frame. It is no longer sensible to treat fertility as a binary categorical variable.

This differs from distinguishing between fertile and infertile populations because most (but not all) couples with a high chance of conception per cycle will conceive in the first year and never reach the clinic.

Among couples who stopped contraception and ultimately conceived, about 30% did so in the first cycle of unprotected intercourse. After 12 months, the conception rate per cycle had declined to 10%, and the average success rate per cycle in the second year of trying was about 5%. Consequently, among couples attending infertility clinics after 1 year of unprotected intercourse, even those likely to conceive will have an average spontaneous conception rate of only about 5% per cycle.

WHO Standardization of Semen Testing

With the aim in providing standardization worldwide, WHO has published its first manual in 1980 and subsequently five editions have been released over the last four decades. The latest 6th Edition was published in July 2021 with the aim of making semen analysis worldwide more robust via extensive research and by considering the criticism and drawbacks of previous versions, thereby making it efficient to practice in clinical andrology and reproductive medicine.

The Need for the New 6th Edition

The WHO 2010 5th Edition, aimed to facilitate the standardization of semen analysis procedures via a detailed step-by-step approach to various basic and optional semen tests. The percentile values proposed in the 5th Edition were derived from fertile men whose partners had a time to pregnancy ≤12 months (1,959 men from 8 countries representing 4 continents (Europe, Americas and Oceania).

The 5th Edition Received the Following Criticism

1. Inadequacy to represent the general population , this can be attributed to
   a. Over- and under-representation of some areas of the world and their respective population. (8 countries and 4 continents: Oceania, Americas, Europe were included)
   b. Percentile values which represented lowest limit of fertility could be used as a fertility cut-off and these men could be classified as infertile leading to a denial of proper male fertility evaluation and may be pushed to Assisted Reproductive Technology (ART).

WHO 6th Manual

1. Commended the importance of SA as a tool to:
   a. Assist fertility/infertility diagnosis,
   b. Assess male reproductive health and function to guide management
   c. Guide the choice of ART procedure
   d. Monitor response to treatment
   e. Measure the efficacy of male contraception.
2. Optimized SA procedures by including detailed steps and a methodological sequence for test execution.
3. Described new sperm tests for the assessment of Sperm DNA Fragmentation (SDF) and seminal Oxidative

Stress (OS), while abandoning obsolete tests such as human cervical mucus.
4. Addressed the drawback of the 5th Edition related to the demographic under-representation of some geographical regions.

The new 6th Edition served the following advantages/strengths:
1. Abandoned the "percentile values "which was construed as reference values of semen parameters.
   The 6th Edition clearly specified that the 5th centile values are only one way to interpret but not sufficient enough to diagnose male infertility and has introduced the concept of "Decision Limits".
2. The editors of the manual have been voluntarily removed the terms "Normozoospermia" "Asthenozoospermia", "Necrozoospermia", "Teratozoospermia" on the basis that reference thresholds alone are meaningless and that multiple criteria must be applied to establish a diagnosis of male infertility.
3. Combined data of the previous 5th Edition and additional new data of fertile men, whose partners had a time to pregnancy ≤12 months of last decade (2010–2020). Thus, the 6th Edition contains results of semen samples of 3,589 fertile men (1,800 subjects from 5th Edition and 1,789 new, total 3,589 subjects) providing greater statistical power to new reference range.
4. The newly added data was an analysis of semen samples of 3,589 participants, originating from 13 countries and 2 continents, two countries in Southern Europe, along with two countries from Asia and one country from Africa.
5. Recommended extended semen test namely, SDF, fluorescence in situ hybridization (FISH) in certain clinical scenarios.
6. Gives future scope to update guidelines for extended semen test namely, SDF, FISH
7. Provides scope to incorporate epigenetic and seminal OS into clinical practice.
8. More precise evaluation and reporting at low sperm concentration ($<2 \times 10^6$/mL)
9. Systematic based approach for Sperm morphology assessment with multiple and better-quality micrographs of spermatozoa from unprocessed semen samples that are considered normal, borderline, or abnormal (anomalies of the head, intermediate piece and tail) with detailed explanations, rendering the manual helpful.
10. The significance of recording the presence of large cytoplasmic droplets is emphasized.

Why the Need to Change?

Identifying a semen problem in the early stages of infertility can help begin an appropriate treatment program more expediently or if you discover that there is a serious untreatable sperm problem, you are apprised of this early on. Also tests and investigations and possible treatment directed at the cause can be developed.

The new guidelines from the WHO as per the 6th manual have redefined the new "Decision Limits" values for semen analysis which aids the clinician in understanding the significance of the male factor more accurately as a range.

TABLE 1: WHO 5th, 2010 and WHO 6th, 2021 edition of semen parameters.

Semen parameters	*WHO 2010*	*WHO 2021*
Volume (mL)	1.5 (1.4–1.7)	1.4 (1.3–1.5)
Total number (10^6/ejaculate)	39 (33–46)	39 (35–40)
Total motility (%)	40 (38–42)	42 (40–43)
Progressive motility (%)	32 (31–34)	30 (29–31)
Nonprogressive motility (%)	1	1 (1–1)
Immotile (%)	22	20 (19–20)
Vitality (%)	58 (55–63)	54 (50–56)
Normal forms (%)	4 (3–4)	4 (3.9–4)

(WHO: World Health Organization).

Comparison of the 5th and 6th WHO Manual

Thresholds of basic semen parameters used in the 5th Edition "reference values" and those described as "useful values" in the 6th Edition are shown in **Table 1.**

Important changes from the 5th manual:
1. The categorization of sperm motility has reverted to fast or rapid progressively motile, slow progressively motile, nonprogressively motile and immotile (grade a, b, c, or d, respectively)
2. The assessment of sperm vitality is recommended when total sperm motility is below 40%
3. The significance of recording the presence of large cytoplasmic droplets is emphasized
4. SDF testing "could represent an important addition in the work-up of male infertility.

MORPHOLOGY OF SPERMATOZOA

Morphologically normal: Now 4% (5th centile value).

Previously 15%, this value refers to the number of sperm with normal shape and structure, 4% is considered the new bottom line of normalcy although the average percentage of morphologically normal sperm in the best fertile group was over 9%. Morphology values between 0 and 4% denote greatly impaired fertility possibly requiring intracytoplasmic sperm injection (ICSI).[17,18]

Why the decline in morphology numbers over the years:
- The implementation of strict evaluation criteria with the unfortunate result that sperm morphology evaluation became overcritical with regard to normality

- The fact that over the years more criteria for sperm morphological abnormalities were identified and introduced into the evaluation system
- True decline because of negative environmental factors.

Other measures of sperm health include: viscosity, fructose levels, pH to determine the level of acidity/alkalinity and tests for agglutination, antisperm antibodies, sperm penetration and "round cells" which can indicate infection.

What are We Trying to Achieve?

The new 6th manual injects science and probability chance into reporting instead of reporting a single binary number as was done for years and also provides clarity to the physician.

During the examination of an infertile couple, the underlying problem should be diagnosed so that it can be corrected or appropriate tests ordered to understand the problem so that appropriate treatment can be suggested or we can identify problems which are not correctable and suggest the right modality of treatment.

Sperm Functional Testing

Routine semen analysis provides useful information concerning sperm production by the testis, sperm motility and viability, the patency of the male genital tract, the secretions of the accessory organs, as well as ejaculation and emission **(Fig. 1)**. The new reporting **(Fig. 1)** shows evaluational of seminal plasmas and sperm abnormalities which aids clinicians to detect specific abnormality and plan management accordingly. Although the information revealed by this assay is obviously useful for the initial evaluation of the infertile male, it is not a test of fertility, and it provides no insights into the functional potential of the spermatozoon to fertilize an ovum or to undergo the subsequent maturation processes that are required to achieve fertilization.[19,20]

Accordingly, tests have been developed to define sperm function abnormalities in the infertile male. In the broadest sense, sperm function may simply be thought of as the ability of one spermatozoon to deliver the correct complement of chromosomes to an ovum. To do this, spermatozoa must be produced in sufficient numbers, and exhibit normal motility and shape (and these parameters generally are assessed in routine semen analysis). In addition, spermatozoa must be capable of penetrating and passing through the cervical mucus, and through the uterus to the ampulla of the oviducts, in addition to undergoing capacitation, AR, binding and penetration of the zona pellucida, and ultimately the ovum. Once the spermatozoon penetrates the ovum, it must then undergo nuclear decondensation to deliver the appropriate haploid chromosome complement; it then undergoes additional, but poorly understood, events required for fertilization and early embryonic development. Defects in any of these complex events can result in male infertility. Over the last 25 years, tests have been developed to identify abnormalities in these processes.

Often it is asked why the evaluation of the infertile male requires advanced, specialized andrology assessment of parameters, such as genetics or sperm function; all that is needed is a single spermatozoon to achieve a pregnancy with ICSI (the logic being that if fertilization can occur, a healthy baby is likely to have been conceived). Yet, we know this logic is flawed, as even healthy fertile couples may conceive a child with significant genetic or birth defects. Certainly, some of the tests of sperm function described above can provide important information to infertile couples to aid in their reproductive decision making. In some cases, sperm function testing may indicate that less expensive technologies may help a couple seeking to conceive a child; ICSI-in vitro fertilization (IVF) may not always be required. In other cases, such as men who fail the hamster Sperm Penetration Assay (SPA) test, donor spermatozoa or other options must be considered. The real strength of sperm function testing lies in its ability to identify men with normal semen parameters but who have functionally deficient spermatozoa that will fail to fertilize in routine IVF. These functional deficiencies will never be observed on a routine semen analysis. As they provide a unique insight into sperm physiology, sperm function tests may also aid in the design of improved treatment that are provided to infertile couples.

The results of such testing may allow for the use of more cost-efficient treatment or even provide the basis for a couple to cease treatment. Ultimately, it is the couple's decision to seek to achieve a pregnancy; infertile couples, however, deserve the right to decide whether this is a realistic goal with a reasonable likelihood of success. Thus, sperm function testing, as well as other genetic and andrology tests now available, allows couple to make a more informed decision.

CONCLUSION

The long march of semen analysis to join other rigorously standardized chemical pathology tests is well underway. However, the uncritical acceptance of WHO reference values and the widespread reporting of WHO standards as a "gold standard" for all situations has led to the values being used for completely unsuitable purposes lacking specific evidence which hopefully will get streamlined with the 6th manual.[21,22]

Not surprisingly, when values are taken out of context and/or uncritically, irrelevant information may be produced. The new manual attempts to dispel this unhealthy attitude. First, it provides choices of tests that depend on the needs of the laboratory, do you need to measure very low sperm numbers accurately? If not, do not. Do you need to assess normal morphological forms only for ART? If not, examine abnormal forms as well. Do you need a quick screen of sperm antibodies

Seminal fluid abnormality: NONE

Sperm abnormality Decision limits:

Sperm Concentration:	mill/ml	Pathological/Borderline/Normal
Total Motility:	%	Pathological/Borderline/Normal
Morphology:	%	Pathological/Borderline/Normal

The "normal" reference values of the 5th edition have been replaced by "decision limits" in the WHO 6th edition. **These are classified as "normal", "border-line", and "pathological".**

A "normal" concentration is ≥20×10 6/mL, " **border line " lies between 10 to 20×106/mL**, and **"pathological" is <10×106/Ml.**

For motility "normal" is defined as ≥50% progressively motile sperm**, "border-line" is 35% to 49% progressively motile, while a "pathological" sample is defined as <35% progressively motile sperm.**

Morphology has been categorized as "normal" when typical forms are ≥14%, **"borderline" is between 4% and 13%** and **"pathological" morphology is below 4%.**

Decision limits" concept is an attempt to emphasize that the purpose of the semen examination is not to label a man as fertile or infertile, but rather to decide next steps in terms of further evaluation and treatment. Those in borderline decision limit will may be improved and will need further evaluation.

CHAPTER 98

Sperm Function Tests

Anupama Deenadayal Mettler, Roopini Sathiasai Kumar

INTRODUCTION

The process of fertilization involves a series of complex interactions between the ejaculated sperm and the female genital tract. Starting from the exposure of the sperm to the hostile vaginal environment to the obstacle course that the sperms have to endure before they finally reach the oocyte to perform a series of orchestrated chemical reactions to fertilize the oocyte, this is what sperm function tests aim to quantify. With the progress in assisted reproductive technologies (ARTs) over decades, we are now faced with a situation where we endeavor to identify the functional defects in sperm to explain possible causes of fertilization failure, poor fertilization rate, recurrent implantation failure, or repeated miscarriages. The various sperm function tests available today are listed in **Box 1** and the rationale behind these tests is briefly explained in **Figure 1**.

Routine semen analysis parameters (sperm concentration, motility, progressive motility, and sperm morphology) used in daily practice have limited value in discriminating the fertile male from the subfertile male.[1] While, sperm functional tests are regarded as research tools[2] and not part of the routine semen testing. In this chapter, you will find a brief concept of all the tests that can be performed with special attention given to those tests, which can be used in daily practice and have influence on clinical decisions. Data shows that certain sperm function assays are highly predictive of ART results and can help in decision-making, especially for patients with repeated failed intrauterine insemination (IUI).[3] Eventually, sperm function tests will help clinicians to optimize male infertility diagnosis and management.[3]

FRUCTOSE ESTIMATION

Fructose secreted by the seminal vesicles provides energy dependent marker of seminal vesicle function and its absence from the ejaculate will result in almost complete ranges from 63 to 500 mg/dL (3.5–28 mmol/L) and falls as the sample ages. Fructose level should be determined in men with azoospermia as a value <13 µmol suggests low androgen-specific contribution of vascular fluid.[4] An ejaculate volume <1 mL, a low pH, and very low fructose content are suggestive of partial retrograde ejaculation, androgen deficiency, or obstructive azoospermia due to ejaculatory duct obstruction or congenital bilateral absence of the vas deferens.[5-7]

BOX 1: Classification of sperm function tests.

- Fructose estimation
- Morphology and teratozoospermia index (TZI)
- *Tests for reactive oxygen species (ROS)*:
  - Leukocyte detection test
  - Luminol or lucigenin
  - Luminol and horseradish peroxidase
- *Sperm vitality tests*:
  - Hypoosmotic swelling (HOS) test
  - Eosin staining
  - Eosin–nigrosin staining
- *Sperm–mucus interaction tests*:
  - In vivo postcoital test
  - In vitro sperm–mucus interaction
  - In vitro capillary test (Kremer test)
- Antisperm antibody tests
- Mitochondrial activity index test
- *Test for capacitation*:
  - Incubation in albumin-containing culture
  - Using CASA
  - Chlortetracycline staining
- Tests for acrosome reaction
- Hyaluronan binding assay
- *Zona binding assays*:
  - Hemizona assay
  - Competitive intact zona sperm binding test
- Sperm penetration assay
- Nuclear chromatin decondensation test
- *Sperm DNA fragmentation index*:
  - Comet assay
  - Tunnel
  - In situ nick translation
  - Acridine orange test
  - SCSA

(CASA: computer-assisted sperm analysis; SCSA: sperm chromatin structure assay)

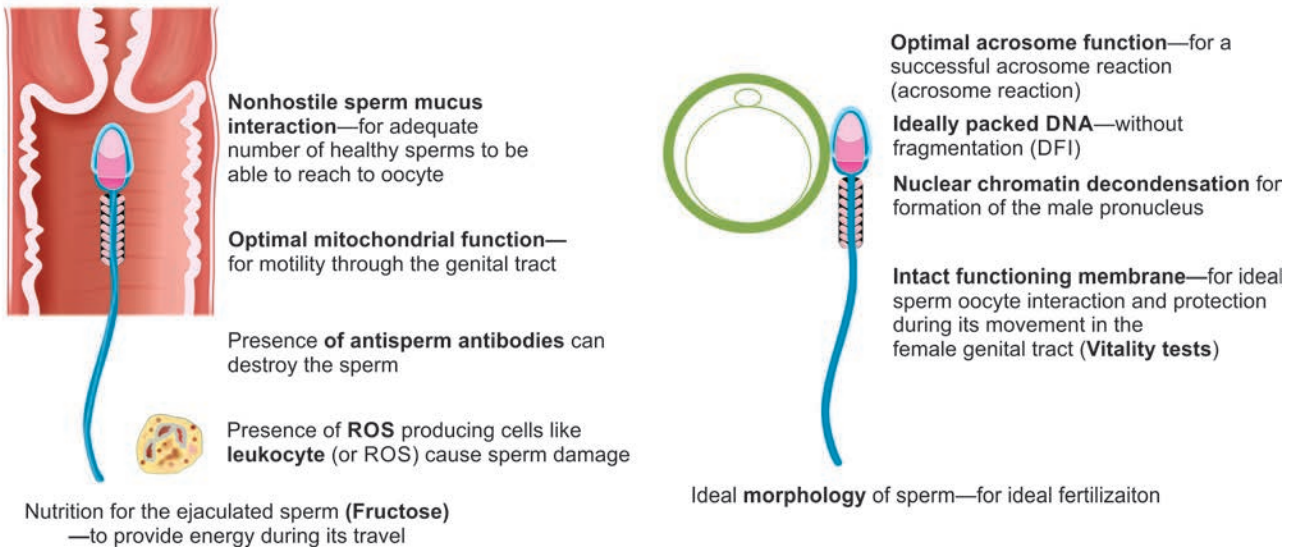

Fig. 1: Rationale behind sperm function tests—to test the sperm's various normal mechanisms and their interactions in the female genital tract leading to successful fertilization. (DFI: DNA fragmentation index; ROS: reactive oxygen species)

INDICES FOR ABNORMAL MORPHOLOGY CALCULATION

Multiple abnormalities may exist in abnormal spermatozoa, and the World Health Organization (WHO) handbook for 2021 offers three indices for this multiple entry system: Teratozoospermia index (TZI), multiple anomalies index (MAI), and sperm deformity index (SDI) (WHO andrology manual, 2021).

A strong correlation was reported between the morphology (strict Kruger criteria) and fertilization rate: Morphology of <4%, 4–14%, and >14% having a fertilization rate of 7.6%, 63.9%, and >70%, respectively. Hence, teratozoospermia is a biomarker of severe gamete dysfunction and altered oocyte interaction.[8]

Teratozoospermia index is calculated by dividing the total number of defects determined by the number of abnormal spermatozoa.[9,10] It is a good predictor of fertilization and pregnancy rate. A TZI <1.6 is normal, whereas, if the TZI is >1.8, irrespective of the count of motility, intracytoplasmic sperm injection (ICSI) is advised.

Multiple anomalies index is based on the mean number of anomalies per abnormal spermatozoan.

Sperm deformity index is the number of defects divided by the total number of spermatozoa. Specific head, midpiece, and tail sperm abnormalities were strongly correlated with particular stages of embryonic development, from the observation of pronuclei to the hatched blastocyst.[11]

TESTS FOR REACTIVE OXYGEN SPECIES

Spermatozoa require oxygen for metabolism which, in turn, damage cellular lipids, proteins, and DNA[12,13] due to the relatively large quantities of polyunsaturated fatty acids in the sperm membrane and low concentration of scavenging enzymes in the cytoplasm. Reactive oxygen species (ROS) in spermatozoa originate as a result of the monovalent reduction of molecular oxygen during oxidative phosphorylation in the mitochondria.[14-19] Presence of a varicocele, infections, or occupational exposure to toxins such as lead or cadmium causes oxidative stress and, in turn, excessive free radicles in the semen.[20-22] ROS include superoxide anions, hydrogen peroxidase, hydroxyl radicals, nitric oxide, and others. Although seminal plasma contains antioxidant enzymes, oxidative stress develops when there is an imbalance between ROS-generating and scavenging activities.

Chemiluminescence

Reactive oxygen species concentration in semen is commonly measured by using probes such as luminol and lucigenin or a mixture of luminol and horseradish peroxidase.[23,24] While luminol measures intra- and extracellular ROS by reacting with ROS such as H_2O_2 and OH, lucigenin is more specific to superoxide anions released extracellularly. The reaction produces photons which are converted to electrical signals which can be measured by a luminometer.[24] The lucigenin probe is diagnostically more useful as it measures extracellular ROS, which identifies the sperm at risk for peroxidative damage.

Cellular debris and leukocytes, which can generate 100 times greater ROS than spermatozoa, have a major influence on the chemiluminescent signals generated and the results.[25]

Nitroblue Tetrazolium Test

The test is an inexpensive, easily available test with high sensitivity.[26] It reacts with cellular superoxide ions to form a formazan derivative that can be quantitatively measured by a spectrophotometer.[27,28]

Flow Cytometry

It uses an expensive flow cytometer and special software.

Electron Spin Resonance or Electron Paramagnetic Resonance

It detects only selective oxidants and is the most direct and rapid test.[27-30]

ROS-TAC Score

Total antioxidant capacity (TAC), the total amount of enzymatic and nonenzymatic antioxidants, can reduce excessive ROS concentrations in semen.[8] According to several studies, there is a positive correlation between normal semen parameters and TAC levels. When ROS production exceeds TAC, the balance between the two could shift, leading to oxidative stress (OS). Seminal ROS level and seminal plasma TAC values are used to produce the ROS-TAC score, which serves as a marker of seminal OS. Therefore, ROS-TAC score calculation is advised for predicting male reproductive potential and differentiating between fertile and infertile patients rather than using just ROS or TAC. It was demonstrated that Asthenozoospermic men had a higher ROS levels and high DNA damage compared to the normozoospermic men. ROS-TAC score improved in men with varicocelectomy.[31]

LEUKOCYTE DETECTION TEST

Leukocytospermia (>1 × 10^6 mL^{-1} leukocytes) is currently detected by the peroxidase test, although enzyme-linked immunosorbent assay (ELISA), monoclonal antibodies against leukocyte-specific antigens (CD45), flow cytometry, and immunocytochemistry could be used. Another technique is the direct count of round cells in a wet preparation and differentiating them from immature germ cells by special differential staining.

SPERM VITALITY TESTS

Sperm vitality testing is important when <40% of the spermatozoa are progressively motile to know if the immotile spermatozoa are dead or alive. It should be performed as soon as liquefaction is complete and preferably within 1 hour of ejaculation to prevent bias due to dehydration or temperature variability. Structural flagellar defects (immotile cilia syndrome) result in numerous vital but immotile spermatozoa.[32] Whereas, numerous nonviable immotile spermatozoa may indicate epididymal pathology.[33,34] Vitality is identified by testing the membrane integrity of the spermatozoa for dye exclusion (eosin–nigrosin) or hypotonic swelling as damaged plasma membranes will allow entry of the dye into the cell and only live cells will swell in hypotonic solutions **(Fig. 2)**.

Eosin Staining

After exposure of the spermatozoa to the eosin stain, the unstained sperm are counted as live, whereas the pink or red spermatozoa are considered dead. It can be used for wet smears and can be theoretically used for sperm selection for ICSI.

Eosin–nigrosin Staining

The advantage of adding nigrosin to the eosin staining is that it provides a dark background for easy assessment, and the slides could be preserved for future records and assessment.

Hypoosmotic Swelling Test

After a 30-minute exposure to a hypoosmotic solution, the dead spermatozoa retain a normal tail shape due to a leaky membrane, while the intact spermatozoa show swelling of their tails into various sizes and shapes.[35] After counting 200 sperms, if <50% of them show tail curling, it is considered abnormal. A score between 50% and 58% is intermediate, and above 58% is considered normal. A correlation was seen between the grade of tail curling **(Fig. 3)** and DNA fragmentation with grades D, E, and F spermatozoa having lesser DNA fragmentation than grades A, B, and C. The hypoosmotic swelling (HOS) test can be used in extreme cases for the selection of sperm for ICSI by aspirating the sperm head first into the pipette and then exposing only the tail to the hypoosmotic solution while the head remains in the pipette.

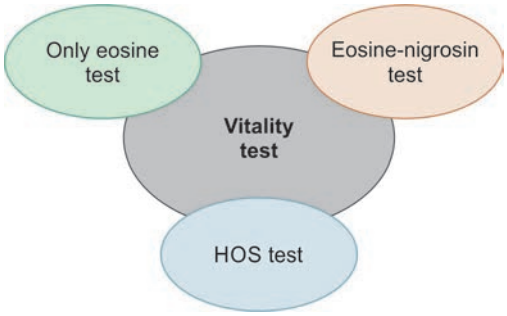

Fig. 2: Sperm vitality test.

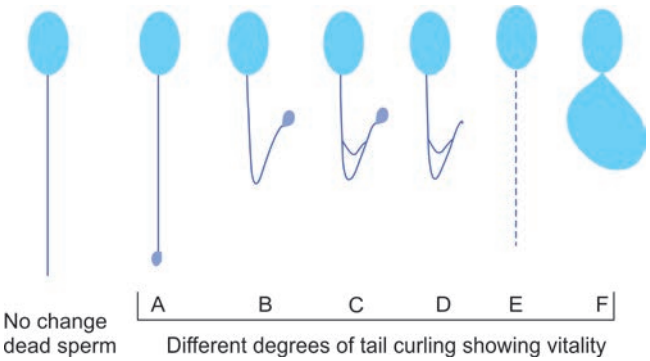

Fig. 3: Line diagram of morphological changes in the human sperm tail exposed to hypoosmotic stress.

Once a change in the shape of the tail is noticed, the sperm can be used for ICSI.

Motility Activators

The majority of the sperm population is motile following ejaculation because the spermatozoa are activated during their passage through the epididymis. The gradual switch from phosphatase to kinase activity, and consequently the gradual phosphorylation of proteins, are related to the induction of motility in the epididymis. This fundamental kind of motility is characterized by low-amplitude symmetrical tail motions that allow spermatozoa to move linearly; but, once entering the uterus, spermatozoa must undergo hyperactivation through capacitation in order to successfully fertilize an egg. The process of sperm capacitation, which entails a number of physiological changes. When signalling pathways that control sperm motility are activated in spermatozoa, calcium ions [Ca2+]i functions as a secondary messenger. The majority of the cyclic adenosine monophosphate (cAMP) produced by spermatozoa is produced by soluble adenyl cyclases (sAC), which are one of them. Serine/threonine protein kinase A (PKA), which is activated by cyclic AMP, sets off a series of protein phosphorylation events that induce sperm motility.[36] Dimethylxanthine theophylline is a phosphodiesterase inhibitor that promotes a rise in intracellular cyclic adenosine monophosphate (AMP) levels, which enhances sperm motility. It works well for sperm motility recovery after thawing, enabling the injection of live sperm, and making laboratory handling easier.[37]

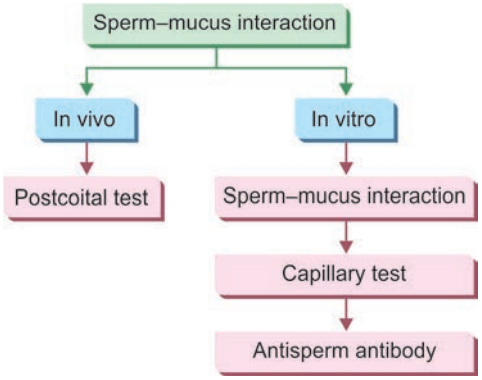
SPERM–MUCUS INTERACTION TESTS

While the cervical mucus is viscous throughout the menstrual cycle, it is penetrable only during the preovulatory days, where it forms the first barrier for sperm migration. The quality of mucus is important as it tests the strength and effectiveness of sperm motility and the surface characteristics of sperm that allow them to interact appropriately with cervical mucus. However, when the sperm–mucus interaction tests are abnormal, usually the other semen characteristics are also deficient, suggesting the need of IUI, in vitro fertilization (IVF), or ICSI **(Flowchart 1)**.

In vivo (Postcoital) Test

After determining the time of ovulation, the man is asked to have intercourse after 2 days of abstinence. The woman is asked to report to the clinic within 9–14 hours after coitus avoiding vaginal lubricants or vaginal douching. A nonlubricated vaginal speculum is inserted, and a tuberculin syringe is used to aspirate the seminal pool from the posterior fornix. Another syringe is used to aspirate cervical mucus, which is placed on a slide and fixed with a coverslip and silicone grease. The preparation is examined under 400× magnification with phase-contrast optics. Presence of sperm in the first syringe ensures that semen was deposited in the vagina. The presence of progressive spermatozoa in the cervical aspirate is the most important indicator of normal cervical function arguing against sperm autoimmunity in the male or female[38] and evaluating the reservoir role of cervical mucus.[39] Sperm antibodies should be suspected if nonprogressive spermatozoa exhibiting a shaking phenomenon are seen. If no sperm are seen or if the test is abnormal, it is advisable to repeat it. If the man cannot provide a sample for semen analysis, a simple postcoital test can help in assessing the sperm.

Flowchart 1: Sperm–mucus interaction.

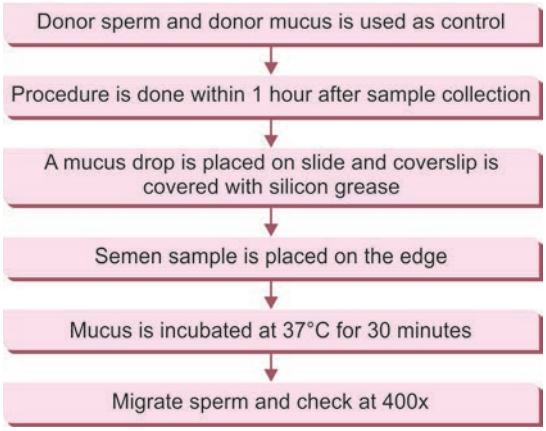


In Vitro Sperm–Mucus Interaction

A detailed sperm–cervical mucus interaction test is performed with crossover testing using donor semen and donor cervical mucus as controls. A normozoospermic sample and good quality, midcycle cervical mucus with a pH between 7 and 8.5 are taken as donor controls. Acidic mucus immobilizes sperm, whereas alkaline mucus increases motility giving a false result. The test should be performed within 1 hour of collection of the patient's semen sample and cervical mucus. After comparing the results of the interactions of the patient specimens with each other and with the donors, a conclusion can be reached regarding the significance of a positive sperm antibody test in the male or female partner.

In the in vitro simplified slide test, a mucus drop is placed in the center of slide and covered with a coverslip with silicone grease. A drop of semen is placed on each side in contact with its edges. After 30 minutes of incubation at 37°C in a humid chamber, the migration of the sperm is studied under 400× magnification with phase contrast optics. When the spermatozoa penetrate into the mucus phase and >90% are motile, it is considered normal. When there is penetration but only for about 10 sperm lengths (500 Pm), it is a poor result suggesting a problem. When there is no penetration or penetration with rapid immobilization, it suggests the presence of antisperm antibodies (AsAb) **(Flowchart 2)**.

Flowchart 2: In vitro simplified slide test.



In vitro Capillary Test (Kremer Test)

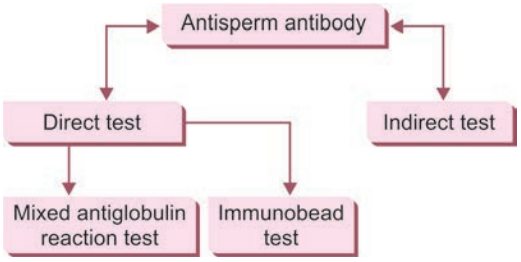
Various modifications were proposed for the original capillary tube test designed by Kremer in 1965. A flat capillary tube, 5 cm long with a 0.3 mm internal diameter, is recommended. Cervical mucus is aspirated into the tube, after which it is sealed at one end. The open end is placed in a reservoir containing the semen sample and incubated for 2 hours at 37°C in a humid chamber. It is then examined at 100× magnification with phase contrast optics. The migration distance, penetration density, migration reduction, and presence of spermatozoa with forward motility are assessed. The results are interpreted using an interpretation table. The hyaluronate migration test can be used instead without the need for relatively large quantities of midcycle cervical mucus.[40]

Antisperm Antibody Tests

While 3–12% of infertile men have AsAb, their clinical significance and treatment are controversial since some fertile men can have high levels of AsAb. AsAb interfere with fertility by causing excessive sperm agglutination, having abnormal cervical mucus penetration, and interfering with sperm–oocyte interaction. AsAb may be generated from the breakdown of the blood–testis barrier, inoculation of the host with sperm antigens, failure of immunosuppression, or acute and chronic prostatitis.[41] Head-bound AsAb is found especially in men after a vasovasostomy,[42] while immunoglobulin M (IgM) antibodies suggest cancer or recent trauma to the male reproductive tract. Immunoglobulin G (IgG) AsAb can be present in the serum or secreted in the cervical mucus of females due to repeated exposure to sperms. The evaluation is preferably performed by immunobead (IB) **(Flowchart 3)**.

Immunoglobulin A (IgA) and IgG are the two main immunoglobulins found in the semen. IgM found in large numbers is correlated with cancer and acute infection. Antisperm antibody test can be done by direct and indirect tests.

Flowchart 3: Antisperm antibody tests.



Direct test can be further divided into two types: Mixed antiglobulin reaction (MAR) test, it mainly includes unwashed spermatozoa in semen with antibody-coated beads. It is an easy, quick, and sensitive test. Direct IB includes the washed semen, which binds beads coated with covalently bound antihuman immunoglobulins. This is time-consuming, and reagents need to be prepared in the laboratory.

Indirect test includes checking of seminal plasma, cervical mucus, or blood serum. Sperm fluids should be heat inactivated before the procedure, and donor sperm is selected, which is completely washed free from seminal fluids. During the procedure, sperm-free fluids are incubated with the donor sperm which has been washed. AsAb is found binding to the donor sperm and is further assessed using direct IB test. Testing patient's sperm by *direct assay* or by *indirect assay* using male or female serum or seminal plasma can be performed by MAR (Coombs) or ELISA estimation of antibodies can also be performed.

MITOCHONDRIAL ACTIVITY INDEX TEST

The long passage of the spermatozoa through the female tract requires energy for flagellar activity, which is supplied in the form of adenosine triphosphate (ATP) by the mitochondria in the midpiece of the spermatozoa. The evaluation of the function of the mitochondrial oxidoreductive enzyme apparatus can be done using indicators such as nitro blue tetrazolium, where the good sperms get stained while the poor or nonmotile sperms are stained poorly.

TEST FOR CAPACITATION

The molecular and physiological events that occur in the female genital tract resulting in more fluid and pliable membranes that enable sperm to fertilize are known as capacitation.[43-46] The most significant changes experienced by sperm are loss of extrinsic proteins along with loss of membrane cholesterol leading to plasma membrane changes, an increase in certain intracellular messengers, and increased phosphorylation of a set of proteins by different kinases.[43-48] Hyperactivated sperm motility and a rapid spiraling movement that can be identified by computer-assisted sperm analysis (CASA) are commonly associated with sperm capacitation. Sperm capacitation can

be assessed by stimulating an acrosome reaction in vitro.[46] It can also be tested by incubating sperm in an albumin-containing culture.

Using Computer-assisted Sperm Analysis

With regard to sperm function tests, within 30 seconds, CASA performs an automated analysis of sperm concentration, motility, and morphology followed by a manual assessment of white blood cell (WBC) and immature germ cells. Around 200 moving objects (sperm) can be simultaneously tracked for several seconds. Hyperactivated sperm can be distinguished from nonhyperactivated by the high curvilinear velocity, low linearity, and large value of the amplitude of lateral head displacement of the former. CASAnova, a web-based program, was designed to compute and classify sperms based on their kinematic parameters. Vigorous sperm were classified as progressive, intermediate, or hyperactivated, and nonvigorous sperm as slow or weakly motile. The capacitated sperm showed vigorous patterns, including hyperactivated motility, while there was a loss of intermediate and hyperactivated motility patterns when sperm were exposed to noncapacitating medium.[49] Hence, proving that CASA can be used to confirm capacitation and, in the future, as an advanced sperm selection method.

Chlortetracycline Staining

Using fluorescence microscopy and antibiotic chlortetracycline, the actual capacitation process can be visualized as distinct fluorescence patterns depending on the capacitation and the acrosomal status of the sperm.[50]

TESTS FOR ACROSOME REACTION

In order to pass through the zona pellucida (ZP), the acrosomal reaction takes place where the binding of the sperm to ZP triggers fusion of the outer acrosomal membrane and the plasma membrane to discharge hydrolyzing enzymes.[51] The acrosomal status can be assessed by microscopy, flow cytometry, or fluorescently labeled lectins such as *Pisum sativum* agglutinin[52,53] after induction of the acrosome reaction either by exposing the spermatozoa to human ZP or ZP proteins.

Triple-stain Technique

This is for evaluating normal acrosome reactions of human sperm and uses trypan blue to differentiate live from dead sperm in the sperm suspension after swim-up processing. Bismarck brown and Rose Bengal staining of the postacrosomal region and the acrosome is then done.[54] The slides are examined at 1,000× with bright-field microscopy to assess the percentage of live sperm that had undergone a normal acrosome reaction.

Gelatin Assay Test

In this test, sperm are placed on a gelatin precoated glass slide where after being exposed to the proteolytic enzymes from the acrosome, a halo is formed around the sperm head. Acrosomal activity is calculated by counting the sperm with a positive and negative halo.

Additionally, the acrosome reaction of the motile sperm population exposed to a solubilized solution of a single human oocyte zona is calculated using a fluorescent stain. A 15% cutoff value was suggested as the difference between the zona-induced acrosome reaction (ZIAR) (stimulated) and the spontaneous (unstimulated) acrosome reaction.[23,25]

Reports show that 25% of normozoospermic subfertile men have a defective ZP-induced acrosomal reaction.[19] There appears to be a strong correlation between the percentage of acrosome-reacted sperm and sperm morphology: 13.4%, 16.1%, and 22.8% for sperm morphology groups <4%, 5–14%, and >14%.[55] Induced acrosome reaction tests have a high positive predictive value (PPV) and sensitivity, and can be used for prediction of fertilization[56] and referring a patient for ICSI early in their treatment.

HYALURONAN BINDING ASSAY

Hyaluronan is a major component of the cumulus complex surrounding the oocyte. The hyaluronan binding assay (HBA) is a convenient and reproducible test to identify the percentage of sperm that bind to hyaluronan through specific receptors indicating the successful completion of spermiogenic events mediated by the heat shock protein A2 (HSPA2) chaperone protein.[57-59]

The test is performed by placing 7–10 μL of the liquefied semen sample within 3 hours of collection in the center of the hyaluronan-coated assay chamber of an HBA slide. Count the number of bound motile and unbound motile sperm in the same number of grid squares after 10–20 minutes of applying the coverslip. For good assay precession, at least 100 sperm or 100 grid squares need to be counted. For acceptable results, at least 30 total motile sperm need to be counted. The more sperm counted, the lower the variance. Percent-bound sperm is calculated by dividing the bound sperm with the total (bound and unbound) motile sperm multiplied by 100. A score of ≥80% is interpreted as normal maturity with normal physiological function.

When the hemoglobin (HB) is abnormal, the patient can be counseled for ICSI rather than an IVF[60] as the HBA scores have a significant association with fertilization rates and biochemical pregnancies.[61] A physiological intracytoplasmic sperm injection (PICSI) sperm selection device has three hyaluronan microdots that select sperm similar to natural fertilization based on their ability to bind to hyaluronan hydrogel. To use the PICSI dish, a 10 μL drop of media is placed on each microdot followed by flooding of the dish with mineral oil on a surface at room temperature. Some

embryologists prefer placing a polyvinylpyrrolidone (PVP) drop in the same dish for convenience. Approximately 1,000–2,000 total sperm is added to the drop. The sperm begin to bind within 5 minutes. If binding is not seen, wait for 30 minutes or more for the microdot to hydrate to reach full binding capacity. Bound sperm should be selected from the interior of the microdot, especially those sperm with a helicopter rotor movement. The tip of the ICSI micropipette is lowered down next to the head of the sperm, and the sperm is gently sucked into the pipette. Continue collecting until 20–50 sperm and then expel the captured sperm into a PVP drop to process them for ICSI.

While some studies show an improvement in clinical pregnancy rate and a fall in miscarriage rate, others are not so promising. Worrilow et al. showed that 15% of all ICSI patients had an HBA score of ≤65%, and when a PICSI was used in these patients, there was a significant increase in pregnancy rate and a fall in the miscarriage rate.[62]

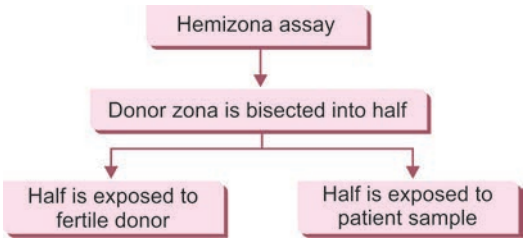
COMPETITIVE BINDING ASSAY

Hemizona assay (HZA) and competitive intact zona sperm binding test are used to assess the binding of the sperm to the ZP, in turn conforming completion of capacitation and ability to undergo acrosome reaction **(Flowchart 4)**.[63-67]

As HZA has a high predictive value for the outcome of fertilization in vitro[65,68,69] and IUI in male factor infertility, it is indicated in cases with repeated poor or no fertilization. The matching halves of human ZP (hand-sectioned hemizona or oocytes bisected by a manipulator) are exposed to populations of proven fertile and patient spermatozoa, respectively. The hemizona index (HZI) is calculated by dividing the number of bound sperm in the patient divided by the number bound in control multiplied by 100.[70,71] An HZI <30 had significantly lower pregnancy rates than an HZI >30 in patients undergoing IUI.[72] While an HZI <35% was predictive of IVF outcome.[73,74]

With a high sensitivity and negative predictive value (NPV) with low false negative rates, HZA is a useful tool in investigating and counseling couples in allocating them to different treatments (IUI vs. IVF vs. ICSI).[75-78]

Flowchart 4: Competitive binding assay.



$$\text{Calculation} = \frac{\text{Number of bound sperm from patient sample}}{\text{Number of bound sperm from fertile donor}} \times 100$$

SPERM PENETRATION ASSAY

Used widely in the pre-ICSI days, sperm penetration assay (SPA) measures sperm capacitation, spontaneous acrosome reaction (due to absence of ZP), fusion and penetration through the oolemma, and decondensation within the cytoplasm of hamster oocytes.[79] Hamster cumulus-oocyte complexes are denuded to remove the cumulus and zona by hyaluronidase and trypsin, respectively. The denuded oocytes are then incubated for around 3 hours with 1 million motile human spermatozoa. The sperm plasma membrane overlying the equatorial region initiates fusion with the hamster oocyte. The percentages for hamster oocytes penetrated are documented. Ionophore A23187 can be used as it causes an influx of calcium and cytoplasmic alkalinization to artificially induce the acrosome reaction.[26]

In spite of confounding limitations, information on the fusogenic nature of the capacitated sperm can be deducted. While the assay has poor standardization methods and reproducibility, it has good sensitivity with high false positive rates, i.e., spermatozoa of men who failed the SPA successfully fertilized human oocytes in vitro.[80] As SPA is time-consuming and relatively expensive, it should not be used till its validity and reproducibility have been established.[3]

NUCLEAR CHROMATIN DECONDENSATION TEST

The highly condensed chromatin in spermatozoa due to the S-S cross-links between its histone units undergoes decondensation prior to formation of the male pronucleus. Hence, decondensation is a predictor of the fertilizing ability of the spermatozoa. This can be induced in vitro by sodium dodecyl sulfate (SDS) and ethylenediaminetetraacetic acid (EDTA). Fertilization was found to be normal when the decondensation percent of the sperm nuclear chromatin was beyond 70%. The combined test scores of sperm penetration assay and sperm chromatin decondensation significantly predicted failed ICSI outcomes.

SPERM DNA FRAGMENTATION INDEX

In today's day and age, the sperm DNA fragmentation index is one of the sperm function tests that play an important role in clinical decisions in treatment of a patient undergoing ART. It will be dealt with in detail in another chapter.

BIOCHEMICAL ASSAY

Zinc

Concentration of Zn is high in seminal vesicle, it mainly helps in lipid flexibility and acrosome reaction during capacitation, which is essential during zona binding in vivo. During the assessment, the Zn binds with

2-(5-bromo-2-pyridylazo)-5-(N-propyl-N-sulfopropyl-amino)-phenol (5-Br-PAPS) to give a color change and absorbs maximum of 552 wavelengths in flow cytometry **(Table 1 and Box 2)**.

$$5\text{-Br-PAPS} + Zn^{2+} \rightarrow 5\text{-Br-PAPS-Zn complex}$$

Neutral Alpha-glucosidase

It is mainly found in two forms: Neutral α-glucosidase and acidic α-glucosidase. Major forms are produced from epididymis as neutral α-glucosidase, and minor forms are produced in the prostate as acidic α-glucosidase. Low range of α-glucosidase is related to poor function of epididymis, which may lead to defective sperm maturation.

Function of acidic α-glucosidase can be inhibited by using SDS during the measurement of neutral α-glucosidase. The principle behind is α-glucosidase with the addition of glucosidase converts the synthetic glucopyranoside

TABLE 1: Biochemical assay for accessory sex gland.

Prostate gland	Zinc, citric acid, or acid phosphatase
Seminal vesicle	Fructose
Epididymis	L-carnitine, GPC, and neutral α-glucosidase

(GPC: glycerophosphocholine)

BOX 2: Biochemical assay for detection of Zinc in seminal plasma.

- Centrifuge the sample for 10-15 minutes at 3,000 g; store the sperm-free plasma at –20°C until procedure
- Thaw the sample during the procedure along with the internal quality control
- Mix the seminal plasma in a vortex mixture
- Dilution 1: Dilute the seminal plasma at 1:40 dilution using purified H_2O
- Dilution 2: Dilute the sample once again at 1:4 dilution
- Add 40 µL of dilution 2 sample to 96-well + 40 µL as blank purified H_2O + 40 µL internal quality control
- Add 200 µL of color reagent to each well and mix for 5 minutes
- Read the plate at 550 nm wavelength

TABLE 2: Overview of the sperm function test performed and the reason for the test.

Physiological process	***Test***	***Reason to perform the test***
Energy supply for the sperm in the ejaculate	Fructose estimation	Absence of fructose causes immotility of sperm
Optimal sperm shape for swift movement of the sperm through the female genital tract	Morphology and teratozoospermia index	Morphology is significantly associated with fertilization rate
Minimal quantities of reactive oxygen species (ROS) are required for normal sperm function	Tests for ROS	Excessive ROS produced by sperm or leukocytes causes damage to the sperm membrane, proteins, and DNA
A functional cell membrane of a live sperm plays an important role in fertilization	Sperm vitality tests	Helps distinguish between dead and live sperms to diagnose different syndromes
Cervical mucus acts as a reservoir of sperm	Sperm–mucus interaction tests	Any abnormality in this interaction leads to a block to the sperm entering the uterus to finally reach the oocyte
Antisperm antibodies hinder the motility and travel of the sperm in the reproductive tract	Antisperm antibody tests	Detection of the presence of antibodies helps in deciding the treatment options for the patient
Energy (ATP) produced by the mitochondria is necessary for the motility of the sperm	Mitochondrial activity index test	Decrease in mitochondrial activity hinders sperm motility
Capacitation prepares the sperm for fertilization	Test for capacitation	A problem identified in capacitation can explain fertilization failure
Initiates the process of cumulus cell dispersion	Hyaluronan binding assay	It identifies the percentage of mature sperm with DNA integrity and patients at risk of failed fertilization in IVF
Acrosome reaction initiates fertilization with fusion of the plasma membranes	Tests for acrosome reaction	A poor acrosome reaction can explain poor fertilization in a normozoospermic male
Binding of the sperm to the zona	Zona binding assays	Predictive of IUI and IVF outcome
Entry of sperm nucleus in the oocyte	Sperm penetration assay	Information on the fusogenic nature of the capacitated sperm can be deducted
Prior to formation of the male pronucleus	Nuclear chromatin decondensation test	Abnormal tests predicted failed ICSI
Intact sperm DNA for successful fertilization and development of a healthy embryo	Sperm DNA fragmentation index	Abnormal tests predicted decreased pregnancy rates and increased miscarriage rates with ART

(ART: assisted reproductive technology; ATP: adenosine triphosphate; ICSI: intracytoplasmic sperm injection; IUI: intrauterine insemination; IVF: in vitro fertilization)

substrate to p-nitrophenol, which turns yellow (wavelength 405 nm) in addition to sodium carbonate.

SPERM SELECTION USING ARTIFICIAL INTELLIGENCE

Computer-assisted sperm analysis brought a level of automation and standardization to the field, wide persists in how sperm cells are assessed. New methods are needed to standardize, automate, and accelerate the sperm classification process. Artificial intelligence is gaining interest in the field of reproductive medicine. It involves image and object processing. The machine learning model will train with the images fed into the system and generate accurate results. There are AI-based smartphone apps that enable home testing of semen parameters (web- and artificial intelligence-based image recognition for sperm motility analysis: verification study). Recently developed computer software SiD uses artificial vision-based software that computes the progressive motility parameters, straight-line velocity (VSL), and linearity of the curvilinear path (LIN) of each sperm trajectory, along with a quantitative value and head movement pattern (HMP), which is an indicator of the characteristics of the sperm HMPs.[84]

CONCLUSION

The diagnostic evaluation of the male partner, particularly in the event of unexplained infertility, has found the value of sperm function testing. Understanding the effects of infertility and improving prognosis can be achieved by performing testing for additional seminal parameters in addition to the usual semen analysis.

KEY POINTS

- Many independent studies have demonstrated that a routine semen analysis lacks in providing information about the functional competence of the spermatozoa. While fructose is routinely performed for azoospermic samples, vitality tests are advised for samples with a decreased percentage of progressively motile sperm.
- The use of CASA, HBA, measurement of ROS, and DNA fragmentation have been shown to be useful in patients with fertilization failure, poor fertilization rate, recurrent implantation failure, or repeated miscarriages.
- Although, a number of sperm function tests **(Table 2)** have been invented to fill this gap, due to absence of high-quality clinical data, no standardization of methodologies, cumbersome nature of some of the assays, and the need for human material, they cannot be advised for routine use.[81,83]
- On the contrary, sperm function tests can potentially assist in important clinical decisions decreasing the time to pregnancy, expenses borne, and eliminating the physical and psychological burden the couple has to experience.
- Today, we have a strong foundation on which future research can be based[78] to develop valid and more predictive tests based on multicentric trials with strong predictive value for pregnancy outcome and have little overlap between fertile and infertile samples.

CHAPTER 99

Selection of Sperm

Muthukumar K

INTRODUCTION

Assisted reproductive technology (ART) includes intrauterine insemination (IUI), in vitro fertilization (IVF), and intracytoplasmic sperm injection (ICSI) techniques. Over the decades, various attempts have been made to optimize the sperm recovery by efficient processing methods for IUI and selection of individual sperm for ICSI. The glass wool filtration (GWF),[1] swim-up,[2] and density gradient centrifugation (DGC) methods[3] are most commonly used for the separation of morphologically normal, motile, and viable sperm. Advanced sperm selection methods for ICSI were approached based on the structural characteristics with very high magnification,[4] physiological properties of binding ability,[5] chromatin organization,[6] and removal of apoptotic sperm by processing,[7] and were reported by different authors. The validation of different selection methods by evidence-based study has drawn different conclusions in routine clinical application.

SPERM SELECTION FOR INTRAUTERINE INSEMINATION

The processing of semen from normal to mild Oligo Asthenozoospermic sample while handling IUI. Two techniques were preferred to maximize the yield of spermatozoa with potential fertilizing ability. Swim-up methods were recommended for normozoospermic samples by the World Health Organization (WHO). In contrast, the gradient method was found better for mild oligoasthenozoospermic samples.

Migration Method

Swim-up Procedure

The swim-up method of processing the sample is done by direct or indirect method.[8,9] In the direct swim-up method, the sample was overlaid with human tubal fluid (HTF) buffered with HEPES [4-(2-hydroxyethyl)-1-piperazine ethanesulfonic acid] for nearly 45 minutes at 37°C, and the sperm migrated over the fluid collected for insemination. The direct swim-up avoids the centrifugation process and potential damage caused by reactive oxygen species (ROS). But, the chances of seminal plasma contamination into the fluid cannot be avoided. The indirect swim-up method recommends to add equal amount of HTF–HEPES to the semen and aliquot of 1 mL per round, and bottom tubes were further made to centrifuge at 500 g for 10 minutes. The supernatant of centrifuged sample is removed carefully without disturbing the pellet, and the 1 mL of HEPES-HTF is overlaid and left incubated for 45 minutes at 37°C for sperms to migrate and to harvest the spermatozoa. While processing by swim-up method, hyperactivation may not occur immediately, and sufficient incubation in HTF assures capacitation.

The swim-up procedure yields high population of motile spermatozoa with less contamination of other cells, debris, and proteins.

Migration Sedimentation

This method is an extension of swim-up to evaluate the sperm function with additional sedimentation step using a special glass or plastic tube with inner cone.[10] The limitation of this method was of lower yield and not widely accepted in ART.[11]

Transmembrane Migration

The transmembrane migration method employs migration via membrane filter through the cylindrical pores at right angles to the plane of the membrane.[12] The yield of sperm is found to be less despite after modification of the method and not clinically applied in routine processing of semen sample.

Density Gradient Method

The DGC method of sperm preparation utilizes conical bottom tube with 80% gradient overlaid with 40% gradient. The principle of DGC is based on the density-based separation

and the mature morphologically normal sperm found to be higher than 80% gradient found to collect as a soft pellet at conical bottom on centrifugation at 300 g for 20 minutes and soft pellet transferred into a 9 mL of HTF-HEPES. Final spin was done for 5 minutes to remove the plasma and utilized for IUI.[13] DGC yields more morphologically normal,[14] hyperactivated spermatozoa with less DNA-fragmented spermatozoa and less of aneuploid sperm[15] compared to swim-up method. Historically, Percoll was a compound used for density gradient but later discontinued due to the presence of endotoxins and potential in vivo toxicity[16,17] and later replaced by silane-coated silica particles with equal potential of sperm isolation of morphologically normal and motile spermatozoa. DGC was shown to have less of caspase activation, disruption of mitochondrial membrane potential, and externalized phosphatidylserine.[18-21]

A combination of DGC and modified swim-up was recommended to remove human immunodeficiency virus (HIV)-1 RNA and proviral DNA.[22]

Filtration Techniques

The filtration techniques of sperm separation were followed using the glass wool, glass bead, and Sephadex columns for sperm separation.

Glass Wool Filtration

The GWF method separates spermatozoa according to the motility and size of sperm head. This method efficiently separates the leukocytes and prevents ROS-induced sperm damage. The densely packed glass wool fibers using gravitational force separates motile spermatozoa with self-propelled motion of the cells. The efficacy of each filtration depends on the properties of glass wool used and the chemical nature of glass, surface structure, charge, and thickness of glass wool which influences the efficacy of the filtration.[23,24] Transmission of glass particles into the filtration and acrosome-damaged sperm found is the limitation of this technique. In terms of functional integrity, this technique is found superior over DGC and has optimized recovery than swim-up method.

Glass Bead Filtration

Spheres of glass bead arranged in a column are used to separate highly motile spermatozoa.[25] This technique was found to be better than swim-up and also found to have positive post-thaw outcome of cryopreserved sample. The limitation of this technique was found to be due to transfer of glass bead into the filtrate.[26]

Sephadex Columns

This technique is based on the chromatographic media[27] composed of microscopic beads synthetically derived from the polysaccharide dextran. In comparison to swim-up and DGC, a high yield and more motile spermatozoa separation were reported.[28] A higher pregnancy rate in IUI using Sephadex columns sperm preparation was reported than swim-up.[29] But chromatin condensation and morphologically normal spermatozoa were found better in DGC than in Sephadex columns.[30]

SPERM SELECTION FOR INTRACYTOPLASMIC SPERM INJECTION

The sperm selection for ICSI can be broadly divided based on the motile and nonmotile spermatozoa. The selection approaches now in current practice are based on the following principles:

- Morphological analysis using ultrastructural evaluation and sperm birefringence pattern
- Physiological method of hyaluronic acid binding
- Selection based on sperm membrane surface charge
- Magnetic-activated cell sorting system (MACS)
- Microfluidics
- Selection of nonmotile but viable spermatozoa.

The different approaches are in detail below, with merits and demerits.

Morphological Analysis—Ultrastructural Evaluation

Assessing the motile-sperm organelle morphology examination (MSOME) was introduced as an advanced sperm selection method.[4] The fine nuclear morphology of motile spermatozoa was examined in real time at very high magnification. The inverted light microscope is equipped with high-power differential interference contrast (DIC) optics, resulting in an optical magnification of ×1,500, and further enhancement by digital imaging allows achieving a total magnification of up to ×6,600. This magnification allows to identify a spermatozoon with a normal nucleus, defined by an oval shape with a smooth configuration and a normal nuclear content (with <4% of the nucleus occupied by vacuoles). MSOME assessment over six sperm organelles (acrosome, postacrosomal lamina, nucleus, neck, tail, and mitochondria) found the sperm nucleus appeared to have an association with ICSI outcome[31] and a positive correlation between MSOME selected with successful ICSI outcome with previous failures.[32-34]

The vacuoles in the sperm nucleus found to have an association with apoptosis of spermatozoa and negative correlation with ICSI outcome. MSOME criteria grade vacuoles in the nucleus with large size have the most DNA-fragmented spermatozoa. The larger size vacuoles vary by definition ranging from space occupied by 4 to 50%. The number of vacuoles was considered to be significant while selecting spermatozoa.

Injection of morphologically selected spermatozoa (IMSI) with MSOME criteria does not found to improve the fertilization and cleavage rate in consensus between different groups, and contradictory report on embryo quality, blastocyst formation.[34-37] The application of IMSI has supported improvement in ongoing pregnancy rates with low abortion rates over repeated implantation failures.[38] Sperm selection by conventional ICSI seems sufficient for an unselected population,[39] as evidenced by similar pregnancy and delivery rates for ICSI and IMSI in the very first ART cycle of a couple. The technique advocated only in highly DNA-fragmented sperms as a prospective randomized control trial on frozen spermatozoa.

The practical limitation of the IMSI would be the cost and time consumption of procedure. The technique involves sperm selection at room temperature with glass Petri dish and subsequent change to another dish for ICSI.

Morphological Analysis—Sperm Birefringence

The acrosome-reacted spermatozoa with proper chromatin organization and protoplasmic nature exhibit specific birefringence when analyzed through polarized microscopy. The basis of the selection considers that human spermatozoa have characteristics of birefringence that reflect the state of inner protoplasmic structures. This noninvasive technique utilized polarized microscopy with added feature to detect type and intensity of birefringence with additional optical system.[6] Acrosome-reacted spermatozoa selected by this method, in comparison to nonreacted spermatozoa, were found to improve fertilization rate.

Physiological Method of Hyaluronic Acid Binding

The hyaluronic acid binding-based sperm selection is considered to be a physiological method. In this method, the mature normal spermatozoa considered to be only having binding ability to hyaluronic acid was claimed to get selected for ICSI.[5] In routine practice, either a commercially available Petri dish intracytoplasmic sperm injection (PICSI) dish with hyaluron gel coated as a dot or a solution form of hyaluronic acid can be utilized while selecting the population of normal spermatozoa for ICSI. The sperm preparation has to be adequate and clean to add in the coated area to assess the binding, and the room temperature is recommended for 15 minutes of incubation in hyaluronic acid to ensure the binding. The sperm selected by this method was found to show less DNA fragmented and found normal as per MSOME criteria. A combination of hyaluron-bound sperm and subsequent IMSI also has been advocated. The hyaluronic acid binding has reports on improved fertilization rates but no impact on pregnancy rates,[40] while other reports have shown improvement in embryo development rate without influencing fertilization and pregnancy rate,[41] and the discrepancy was attributed to study design. One multicenter study supports higher clinical pregnancy rates than conventional ICSI.[42]

Sperm Selection Based on Surface Charge

Electrophoretic Method

The electrophoresis-based technology (Microflow CS-10, Nusep Ltd., Frenchs Forest, Australia) separates spermatozoa based on size and electronegative charge. The sperm sample solution is loaded into the apparatus reservoirs and allowed to equilibrate with special buffer for only 5 minutes prior to application of an electric field in the form of constant applied current of 75 mA and a variable voltage of 18–21 V. Sorted sperm is retrieved from the collection chamber.[43] This method was considered relatively quick without centrifugation and found superior than density gradient separation. But this method found decreased motility and equal kinetics as compared to density gradient method. The complexity of the apparatus used limits the use of the technology.

Zeta Potential Method

This method is based on the electrokinetic potential of the sperm, an electric potential between the sperm membrane and its surrounding measuring –16 to –20 mV in mature sperm.[44] In this method, washed sperm placed into a positively charged centrifuge tubes prepared by simply rotating a tube two or three times in a latex glove. After 1 minute, the tube is centrifuged and inverted to remove all the nonadhering sperm and other contaminants. Thereafter, adhering (negatively charged, mature) sperm can be retrieved by rinsing the tube with serum-supplemented media. The zeta potential method is found simple and inexpensive, but the limitation includes low recovery over oligoasthenozoospermic sample and is not applicable over surgically retrieved sperm and charges may get neutralized if humid environment. The zeta potential selection method provided higher morphology, hyperactivation, DNA integrity, and mature sperms, but not motility, in comparison with density gradient method.[44-46]

Magnetic-activated Cell Sorting of Nonapoptotic Spermatozoa

The externalization of phosphatidylserine by apoptotic sperm forms the basis of this method. It allows for its binding with annexin-V-conjugated paramagnetic microbeads, which could be used to label and separate apoptotic spermatozoa using MACS (Miltenyi Biotec GmbH, Bergisch Gladbach, Germany).[47] The bead/sperm mixture is allowed to run through the MACS column, which is placed inside a magnet. The magnetic force will cause the retention of the cells labeled with microbeads inside the column, while

the nonlabeled cells will freely flow. This method needs to be combined with density gradient to remove leukocytes and other plasma contaminants.[48] Although this method is fast and inexpensive, the low recovery rate limits its application. Additionally, the retention of microbeads in processed samples advocates modifying by combining annexin to glass wool to improve the efficacy of the system. MACS combined with density gradient yields spermatozoa with higher membrane potential, lower active caspase-3, and phosphatidylserine externalization[49-51] compared to only density gradient separation with proven benefit with fresh and cryopreserved samples. A higher embryo development rate and clinical pregnancy rate using MACS in comparison to density gradient with abnormal semen parameters were reported with live birth in previous failed ICSI cycles due to poor fertilization and embryo development.[52]

Microfluidics-based Sperm Selection

The application of microfluidics on sperm selection was found to be of greater advantage compared to swim-up and density gradient methods. It was demonstrated in a pump-less hydrostatic pressure microfluidic device in which the sperm swim through laminar flows to reach a collecting area for motile sperm. This device differentiates motile sperm from immotile sperm, dead sperm or dead cells, and debris in raw semen, and thus opened a new era of microfluidic applications in ART. Briefly, microfluidics involves constructing the channel structures, which were fabricated from polydimethylsiloxane (PDMS) using standard photolithography and micromolding techniques. These structures were then plasma bonded to a glass microscope slide, which constituted the base of the device and the bottom surface of the microchannels. The device consisted of a 250 mm diameter microchannel with an inlet to insert media and sperm and an outlet to let air out as these elements are inserted. The length of microfluidic channels was about 3 cm. A study comparing the sperm separated by above microfluidic device in comparison to swim-up and density gradient had higher rates of average ratio of sperm, fast swimming forward average sperm activity ratio, value derivation for the curvilinear, value derivation for straight-line velocities, value derivation for average path, amplitude of lateral head displacement, amplitude of cross-frequency, progression ratios of linearity, progression ratios of wobble, progression ratios of straightness, and lower rates of deformity. In addition, the DNA integrity of sperm selection was better maintained than that selected by traditional methods.[53]

Recent advances attempted to integrate optics with microfluidics-based sperm separation.[54]

Raman spectroscopy principle plays a vital role in integrating microfluidics and optics that allows to distinguish sperm with improved nuclear integrity.[55,56] Microfluidics, along with dynamic, high-speed imaging, improved more accurate observation and quantification of the dynamics of sperm movement in a setting that mimics their natural environment by simultaneously visualizing the processes at small length and fast time scales. On-chip digital imaging approaches, within microfluidic systems, label-free 3D imaging of sperm is possible.[57] These methods employ a digital optoelectronic sensor, such as a complementary metal-oxide semiconductor chip, to digitally reconstruct the volume of the cell in 3D space by recording the interference pattern difference between a reference light wave and a light wave scattered by the specimen.[57]

Selection of Viable Nonmotile Spermatozoa

One of the challenges while encountering either ejaculate or surgically retrieved sperms while doing ICSI is the presence of only immotile sperm available and selection of viable sperm that have fertilizing ability and achieving further ongoing clinical pregnancy and live birth. Various approaches were documented in the literature to select the viable spermatozoa as discussed here.

Modified Hypoosmotic Swelling Test

The conventional hypoosmotic swelling (HOS) test described was found to induce some detrimental changes in sperm structure, found not preferred over ICSI was modified as to have a solution containing 50% culture medium and 50% deionized water. Spermatozoa are left for 10 seconds, and viable sperms chosen based on curved or swollen tail. Reactive sperms are transferred into a fresh drop and washed thrice for osmotic re-equilibration. Washed sperms are then transferred to PVP drop for ICSI. A randomized trial using the modified hypoosmotic-based sperm selection has shown higher clinical pregnancy rate of immotile testicular sperms of fresh and cryopreserved samples in comparison to no treatment.[58]

Sperm Tail—Mechanical Touch

This method is based on the mechanical stimuli and reflex observation to select viable and nonviable spermatozoa by injection pipette of ICSI. In detail, laterally pressing the sperm in the upper one third of immotile spermatozoa tail with ICSI dish forcing the tail to one side, and the response is observed. The viable spermatozoa recover and reposition the tail with flexibility. Rigid sperms are not capable to recover signs as not viable. Also, the movement of head along with the direction of tail movements is considered not viable, and the movement of head on opposite direction is found to be viable. Acceptable pregnancy rate is achieved using fresh and frozen immotile spermatozoa by the mechanical touch method.[59]

Laser-assisted Sperm Selection

The use of lasers for sperm selection was the development of a technique for the identification of viable but immotile spermatozoa.[60] A single laser shot of 129 μJ for approximately 1.2 ms being directed to the tip of the flagellum. The live but immotile spermatozoa cause a curling or coiling of the tail. If no such change is observed, then the spermatozoon is considered as nonviable. The successful application of this laser selection was the identification of viable spermatozoa in a patient with primary ciliary dyskinesia that resulted in a pregnancy.[61] The use of the technique on ejaculated asthenozoospermic samples and immotile spermatozoa from testicular biopsies demonstrated its ability to identify numbers of viable spermatozoa in a sample was comparable to that of the HOS test (22.0 vs. 21.5%). Fertilization rate increased significantly from 20.4% in the randomly selected testicular sperm extraction (TESE) spermatozoa group to 45.4% in the laser selection group; accordingly, the take-home baby rate increased from 5.9% to 19.0%. Furthermore, if laser-selected spermatozoa from asthenozoospermic samples were used for ICSI, significantly higher fertilization and embryo cleavage rates were achieved in comparison to those resulting from randomly selected spermatozoa. Laser-tested TESE spermatozoa selection over immotile situation was found to be quick, easy, repeatable, and a safe means of viability testing.[62]

Chemical Stimulators-mediated Sperm Selection

The use of pentoxifylline and theophylline to induce sperm motility by inhibiting the phosphodiesterase activity, and thus increasing intracellular cAMP levels was found to ensure motile sperm selection from a population of immotile sperms that have viability and can become motile on stimulation.[63]

In conditions of oligozoospermia or asthenozoospermia where fertilization failure in previous IVF cycles was overcome by incubation with pentoxifylline[63] with no influence on acrosome reaction[64] under different concentrations. In testicular samples,[65] the addition of 3.6 mM pentoxifylline was found to induce significant motility after only 30 minutes incubation. It is recommended to wash the exposed sperm thoroughly before using ICSI. An improved fertilization rate and embryo development were reported in comparison to no artificial activation without improvement in clinical pregnancy rate.[66] The use of pentoxifylline significantly reduces the time spent finding and selecting motile spermatozoa.[67] In a study where pentoxifylline treated against HOS-identified spermatozoa,[68] the addition of pentoxifylline proved to significantly increase the fertilization (62.05 vs. 41.07%) and clinical pregnancy rates (32 vs. 16%).

The compound pentoxifylline is efficient in the selection of spermatozoa with structural defects such as axonemal, enzymatic, or functional tail defects[69] and is able to activate ejaculated spermatozoa from a patient with Kartagener's syndrome that resulted in a viable pregnancy.[70]

Theophylline, another member of xanthine family, has been used in a prospective clinical sibling oocyte trial where it was found to have an immediate but short-term effect on sperm motility and showed to have the additional benefits of shorter searching time, significantly higher fertilization rates increasing from 63.3 to 79.9% in the treatment group. The concerns with respect to the safety of these chemical compounds recommend the benefit on shorter exposure.

Birefringence

The sperm birefringence property was explored while choosing immotile but viable for ICSI. In one study, it has proved patients with complete asthenozoospermia superior quality zygotes, embryos and pregnancy rates can be produced than the HOS test.[71] In immotile testicular sperm selection for ICSI, the birefringence property can be applied to optimize the outcome. The cost of the polarizing microscopy arrangement has limitations to apply universally in all clinics.

CONCLUSION

Sperm selection for ICSI found to be approached by various methods but still not found one approach as highly superior than other methods. It is suggestive to individualize the technique according to each type of sample. The available evidence remains preliminary to draw strong conclusion on various methods.

KEY POINTS

- The sperm preparation for ART found to be approached with different modalities and the single sperm selection was also found to be with various advanced techniques.
- Systematic review published early concluded application of advanced sperm selection techniques are encouraging in terms of fertilization and pregnancy rates but most of the studies are underpowered to conclude the benefit over pregnancy and live birth rate.[74]
- The advanced technique like IMSI involves cost and time factor as well as reports of certain detrimental effects.[75]
- Most of the techniques also involves approaches with combination of techniques with prolonged exposure in vitro during sperm selections that may cause iatrogenic damage to the sperm and long-term effects on the offspring but remains inconclusive due to lacking evidence and further to conclude, considering all the present constraints over sperm selection the future research can evolve a safer and rapid alternative to sperm selection.
- In an retrospective study of data[76] comparing neonatal outcomes between IMSI and ICSI found no significant

difference. The mean pregnancy duration and mean birth weight were almost identical in both groups. There was no significant difference in major congenital malformations between the two groups.

- Recent evidence from Cochrane study[77] after careful meta-analysis of available evidence found sperm selected by hyaluronic acid binding may have little or no effect on live birth or clinical pregnancy but may reduce the miscarriage rate and uncertain about zeta sperm selection on live birth, clinical pregnancy and miscarriage rate as available evidence of very low quality. Further MACS-based selection in comparison to conventional ICSI also found to be very low quality evidence uncertain to provide reducing miscarriage and improving clinical pregnancy rate.
- With regard to IMSI over ICSI and birth defects a recent meta-analysis study reported[78] as children conceived after IMSI have decreased structural chromosomal defect compared to ICSI. The other chromosomal abnormalities like trisomy 13, 18, 21 and triple X similar between children conceived after IMSI and ICSI.

CHAPTER 100

Sperm Chromatin Assessment

Priya Kannan

INTRODUCTION

Male fertility assessment has been traditionally assessed by measuring the concentration, motility, and morphology of the sperms in the ejaculate.

The primary function of the sperm is to deliver the paternal genome to the oocyte. The head of a mature spermatozoon has deoxyribonucleic acid (DNA) in a condensed and compact structure in insoluble form. Up to 85% of the sperm DNA is bound by protamine and exists as DNA-protamine complexes. The DNA-protamine complexes are more compact than DNA-histamine complexes.[1,2]

During spermiogenesis, protamines, which are half the size of histones, replace the majority of histones, and the sperm chromatin is wound into a supercoiled structure named toroids.[3] As the sperm passes through the epididymis, the protamines are cross-linked by sulfide bonds reducing the chromatin to one-sixth of volume taken up in somatic cells.[4] The sperm DNA is thus protected while the sperm is transported through the male and female genital tract. Postfertilization, the chromatin in the sperm must decondense correctly. Any abnormality in the sperm DNA, such as protamine deficiency,[5] oxidative stress[6] or failure to repair DNA strand breaks,[7] has the capacity to reduce the ability of the sperm to produce viable embryo. Damage can also occur due to iatrogenic factors, such as storage temperatures, handling conditions, lapse of time after ejaculation, infections, and reactions to medicines or post-testicular oxidative stress.[8]

Sperm DNA damage can be defined as any chemically induced change in the structure of the DNA. Sperm DNA fragmentation (sDF) is one of the most common disturbances that affects the genetic material. It can occur as single or double strand breaks. sDF may be triggered by different processes, including the defective packaging of the DNA during spermatogenesis, and processes of cell death and oxidative stress, which may be associated with several pathological and environmental conditions.

CLINICAL SIGNIFICANCE

The clinical relevance of sperm DNA integrity to human reproduction and its influence on both natural and assisted reproductive technology (ART), conceptions have been researched over the past decade. During intracytoplasmic sperm injection (ICSI), only morphologically normal and motile spermatozoa are used to fertilize an oocyte. It has been reported that spermatozoa with apparently normal morphology may have DNA fragmentation. With this, it is but a natural conclusion that spermatozoa with normal-shaped appearance, but with DNA fragmentation could be mistakenly selected to fertilize oocytes during ICSI. This concern became more clinically significant following a study that suggested a highly statistically significant negative correlation between the percentage of sperm DNA fragmentation and embryo quality.[9] Accumulating evidence indicates that a negative correlation exists between disturbances in the organization of the genomic material in sperm nuclei and the fertility potential of spermatozoa, whether in vivo or in vitro.

There have been certain areas in reproduction where the integrity of sperm nucleus seems to be important.

- *Reduced fertility:*
  - Increased DNA fragmentation has been associated with reduced fertility.[10-12]
  - There have been studies that found correlation between sperms with abnormal DNA integrity and impaired sperm concentration and motility.[13]
- *Time to pregnancy:*
  - In some studies, it was found that sperm DNA integrity correlated with time to pregnancy using procedures such as intrauterine insemination (IUI), in vitro fertilization (IVF), and ICSI.[1,14-16]
  - But there is insufficient evidence to use sperm DNA fragmentation as predictor of fertility.[15]
- *Predictor of outcome in IVF/ICSI:*
  - There are varying results regarding the correlation between sperm DNA fragmentation with pregnancy

in IVF/ICSI cycles. Some studies have shown a highly statistically significant negative correlation between the percentage of sperm DNA fragmentation and embryo quality.[9,17] There are some meta-analyses that suggested small but statistically significant correlation between sperm DNA integrity tests and pregnancy in IVF/ICSI cycles.[18] As the evidence is inconclusive, routine testing for DNA integrity for patients undergoing IVF/ICSI is not recommended.[19]

- *Spontaneous abortion rates:* There has been evidence, including a recent systematic review and meta-analysis, suggesting that a higher rate of DNA fragmentation in sperms may be significantly associated with pregnancy loss after IVF or ICSI.[20-22]

CAUSES OF SPERM DNA DAMAGE

The DNA repair systems in sperms are thought to be less active in the later stages of spermatogenesis and so sperms with breaks in DNA are found in the ejaculate.[6]

There are many causes that can cause sperm DNA damage. But the mechanism is not well elucidated. Some of the accepted causes are protamine deficiency or mutation, genetic disorders,[14] and oxidative stress such as varicocele.[12]

Factors, such as irradiation, leukocytospermia, chemotherapy, and high speed centrifugation, also contribute to damages to the sperm chromatin.

ASSAYS FOR DETECTION OF SPERM DNA INTEGRITY

There are many tests that measure sperm DNA integrity and report the percentage of sperms with DNA fragmentation. At the present time, it has been suggested that a sperm chromatin structure of poor quality may be indicative of male subfertility. Sperm chromatin structure evaluation has been evolving as an independent measure of sperm quality.

Two different methods have been used to assess DNA fragmentation. The first one includes those methodologies that are used to detect DNA breaks. This group would include tests such as the terminal deoxyuridine triphosphate (dUTP) nick-end labeling (TUNEL), or *in situ* nick translation (ISNT). The second type of technique measures the susceptibility of chromatin to denaturation under certain treatments. This group would include the sperm chromatin structure assay (SCSA), the DNA breakage detection-fluorescence in situ hybridization (DBD-FISH), a methodology that uses in situ acid nucleic hybridization, the comet assay, and sperm chromatin dispersion (SCD). The standardized methodology for the methods has been published in the 6th edition of WHO laboratory manual for the examination and processing of human semen.[40]

The tests that are used to assess sperm chromatin assessments are:

- SCSA
- TUNEL
- Comet
- SCD
- Acridine orange test
- Acidic aniline blue
- Toluidine blue stain
- DBD-FISH
- ISNT
- Chromomycin A3
- 8-hydroxy-2′-deoxyguanosine (8-OHdG) measurement.

Sperm Chromatin Structure Assay

Sperm chromatin structure assay technique, developed by Evenson et al.[23] almost 25 years ago, is considered a reference in the analysis of spermatic DNA fragmentation. This test is based on the principle that abnormal sperm chromatin has a greater susceptibility to the physical induction of partial DNA denaturation *in situ*. It measures the stability of the sperm DNA in hot or acid media. The assay utilizes acridine orange, a DNA probe and flow cytometry. This protocol has been classified as SCSA acid and SCSA heat to distinguish the means of inducing DNA denaturation.

The proportion of the sperm with fragmented DNA is measured and expressed as DNA fragmentation index (DFI). This is the most commonly used assay. Sperm chromatin structure assay data are not well correlated with classical sperm quality parameters and have been solidly shown to predict sub/infertility. This assay is ideally suited to human and animal fertility clinics to assess male sperm DNA integrity as related to fertility potential and embryo development as well as effects of reproductive toxicants.[24] A DFI threshold was established that identifies samples compatible with pregnancy (<30%).[25] SCSA is the most successful assay in predicting the various outcomes of ART including the fertilization and implantation rates.[26]

The SCSA requires the presence of expensive instrumentation and highly skilled technicians, but has a cutoff point (30% DFI) to differentiate between fertile and infertile samples.

Terminal dUTP Nick End Labeling (TUNEL) Assay

In this assay, in a reaction catalyzed by the terminal transferase, the ends of the fragmented DNA are tagged with labeled nucleotides. Later, the modified nucleotides are detected by a fluorochrome antibody.[27] The TUNEL assay quantifies the incorporated dUTP at single-strand and double-strand DNA breaks. Sperms with normal DNA show only background staining or fluorescence, while the sperms with fragmented DNA are seen with bright stain or fluoresce. This assay is also popularly used.

Presently, many commercial kits have been made available. The kits provide tagged probes and the enzyme necessary to bind the probe to the DNA breaks. After labelling, the percentage of fluorescent spermatozoa can be determined by fluorescent microscopy or a flow cytometer. For assessment of clinical semen samples, TUNEL is best coupled with flow-cytometry. When using fluorescent microscope, at least 200 spermatozoa should be scored.

Comet

The comet assay is a method to evaluate sperm DNA fragmentation and the principle is alkaline denaturation of DNA. It is based on the differential migration of broken DNA strands in an electric field depending on the charge. The name of the test is so because of the "comet" like appearance of the stained unwound DNA fragments under fluorescence microscope. It is a single cell electrophoresis assay that quantifies single and double-stranded breaks in fluorochrome-labeled sperms. It was first introduced by Ostling and Johanson in 1984.[28] This test is based on the principle that abnormal chromatin structure with DNA breaks, will mobilize and more freely toward the positive pole in an electric field neutral.[29] The test was originally set in neutral buffer. This was modified by Singh et al. in 1988 by using alkaline electrophoresis buffer that increased the sensitivity of this test.[30]

During electrophoresis, strands of DNA move in the gel sideways to form a tail of the comet. DNA without breaks remains in the head of the comet. This migration of the genetic material resulted in the "Comet Head and Tail". The extent of migration was proportional to the extent of damage inflicted on the cell.[28] Hence, the length of the tail is indicative of the extent of damage. The comet is a well-standardized assay that correlates significantly with TUNEL and SCSA assays. It is recommended that least 50 comets per duplicate slide should be scored. Commercial kits and detection software are also available.

Sperm Chromatin Dispersion

Calvin and Bedford in 1971,[31] reported the role of disulfide bridges in the compaction and stabilization of the sperm nucleus. If disulfide cross-links break and a specific lysis solution is used to extract proteins, DNA's loops relax constituting haloes around the residual nuclear central structure. This method involves light microscopy method to evaluate the susceptibility of sperm DNA to acid denaturation. This method is based on the principle that intact DNA loops expand following denaturation, however when DNA is fragmented, expansion does not happen or is minimal. The SCD test is based on the principle that sperm with fragmented DNA fail to produce a characteristic halo when mixed with an aqueous agarose following acid denaturation and removal of nuclear proteins.[32,33] In this test, after dissolution of the nuclear protein using acid/salt treatment, the sperms are mixed with agarose. The sperms which fail to produce the "halo" are identified as sperms with fragmented DNA.

This valuation can be automated, using computer programs associated with systems type computer-assisted sperm analyzer (CASA). The technique needs the inclusion of sperms in agarose gels, but without electrophoresis. The principal advantage of this technique is that result interpretation does not need color determination or fluorescence intensity. Neither does it require complex equipment, nor specialized personnel.[34] Due to the simplicity of this methodology, it has been proposed that SCD can be potentially used as a routine test in the study of spermatic DNA fragmentation in basic andrology laboratories. The SCD test is available as commercial kits. The kits which provide all the reagents of the assay to ensure its easy application and technical operation and to provide repeatable and consistent results in different clinical laboratories.

Acridine Orange Test

The test uses the metachromatic properties of acridine orange. This test is based on the unique property of acridine orange to emit green fluorescence when intercalated between double-stranded DNA, and red fluorescence when associated with single-stranded DNA. This test is also based on fluorescence, similar to SCSA but lacks the precision in measurement. The fluorochrome acridine orange intercalates into double-stranded DNA and binds to single-stranded DNA as an aggregate. The acridine orange bound to native DNA fluoresces green, whereas the aggregated acridine orange on denatured DNA fluoresces red.[35]

DNA Breakage Detection-Fluorescence In Situ Hybridization

It is a relatively recent methodology. Discrimination of sperm cells containing fragmented DNA relies on high pH induced DNA denaturation originated in simple or double-strand breaks. After denaturation and extraction of proteins using a lysis solution, the simple strand generated DNA is hybridized with a DNA probe.

This test allows a direct estimation of DFI in a sperm sample.[36,37] From the research point of view, this methodology has a lot of interest, since it is the only available technique that allows evaluation of damage cell to cell, *in situ*, in specific DNA sequences.

In Situ Nick Translation Test

In situ nick translation test, similar to TUNEL, quantifies the degree of DNA damage. This assay quantifies the incorporation of biotinylated dUTP at single-strand DNA breaks in a reaction that is catalyzed by the template-dependent enzyme DNA polymerase I.

The results of ISNT analysis have been used for the study of the anomalies originated during the remodeling of the spermatic chromatin. From a practical point of view, this technique would have the same provisions and disadvantages as the TUNEL, but there is no commercial kit available for its direct application on sperms.

Toluidine Blue

Toluidine is a sensitive structural probe for DNA structure and packaging. When this stain joins chromatin rich in histones, it presents a violet-bluish coloration. But when it joins with chromatin rich in protamines, it gives a pale blue coloration.[38]

This technique is simple, low cost and has the advantage of providing permanent preparations for its use in an ordinary microscope, though the intermediate tints are of difficult valuation. Unfortunately, the results have a poor reproducibility.

Chromomycin A3

The chromomycin A3 (CMA3) anchors specifically to rich guanine-cytosine regions and competes with protamines. Therefore, when sperms present an intense CMA3 staining, it is interpreted that this cellular population shows protamine deficiency. Therefore, high CMA3 fluorescence is a strong indicator of the low protamination state of spermatozoa.[39] One of the most important limitations of this technique is the interobserver subjectivity.

DRAWBACK OF SPERM DNA TESTING

The tests used for measuring DNA fragmentation have been under the scanner as the results are not always consistent. This is due to a variety of factors such as lack of RCTs, different testing assays with varying cut-off values, inconsistent cut-off values defining the normal and abnormal ranges and non-standardized protocols.

CLINICAL GUIDELINE FOR USE OF SPERM DNA FRAGMENTATION

As per the ASRM-AUA Guidelines, published in 2020:[41]

1. Sperm DNA fragmentation analysis is not recommended in the initial evaluation of the infertile couple (moderate recommendation-evidence level grade: (c) as there were no prospective studies that had directly evaluated the impact of DNA fragmentation testing on the clinical management of infertile couples.
2. Further, the committee concluded that the presently available data were inadequate to recommend SDF assay to be routinely performed in the initial evaluation of the infertile male.
3. Although in presently available studies, high sperm DNA fragmentation was negatively associated with pregnancy rates and positively associated with miscarriages, the association was unclear due to the variability in the normal range in different studies and the use of different tests. Hence it was recommended that for male partners with high sperm DNA fragmentation, a clinician may choose to counsel the possible association with infertility and compromised outcome after ART.
4. In a patient with high sperm DNA fragmentation, a clinician may consider using surgically obtained sperm for ICSI. Hence it was recommended that, DNA fragmentation testing may be advantageous for men in couples undergoing IVF especially in a clinical situation of repeated IVF failure. This was based on a prospective cohort study of over 100 couples with high DNA fragmentation, testicular sperm yielded substantially higher live birth rates than ejaculated sperm.

CONCLUSION

The sperm chromatin quality is being considered a new parameter of seminal quality, possibly related to the fertility of the individual and will continue to evolve. The threshold for DNA fragmentation value proposed by Evenson, establishes that the probability of fertilization *in vivo* is near to zero if the proportion of damaged sperms exceeds 30%. Though DNA fragmentation does not have correlation with the classic parameters of seminal quality, it may be used as a predictor of the fertilizing capacity of an individual. Therefore, its study is advised in order to have a more complete vision of the seminal quality.

In view of the current level of knowledge and with easy-to-use commercial kits, which does not require expensive equipment being rolled out for use in clinical laboratories, the most appropriate thing is to diagnose and treat DNA fragmentation, when necessary. Sperm chromatin assessment, as an additional parameter, would complement the study of the semen, in order to obtain a much more complete vision of each particular situation. However, regular use of this test is not warranted and scientifically not supported at this point in time.

CHAPTER 101

Advanced Sperm Preparation Techniques in Assisted Reproductive Technology

Natchandra Chimote, Bindu Chimote

INTRODUCTION

About 12–15% couples all over the world face the problem of infertility for various reasons. Out of which almost 50% of the infertility cases are due to male factor. For last five decades, assisted reproductive technology (ART) has been trying to become a viable solution to overcome the inability of male patients' spermatozoa to fertilize the oocyte and obtain a viable pregnancy and subsequently a healthy child, yet the efficiency of the different techniques has still the scope to improve on the results of ART. According to the latest reports of the European Society of Human Reproduction and Embryology (ESHRE) and the Centers for Disease Control and Prevention (CDC) of the United States, the percentages of deliveries per ART cycle in 2014 and 2016 were 21 and 22%, respectively. Among many reasons for this relatively low efficiency, the quality of the spermatozoa has been turned out to be critical factor. Mainly the occurrence of high percentages of fragmented deoxyribonucleic acid (DNA) of spermatozoa in ejaculates is possibly one of the major factors causing limited outcomes in ART. Thus, to ensure separation or selection of highest quality of spermatozoa has become one of the main challenges in reproductive medicine, particularly their genetic integrity. The most modern techniques for separation and selection of human spermatozoa are discussed in this chapter with a main focus on sperm DNA integrity, the fertilizing potential, top quality embryo development in vitro, implantation potential, viable pregnancy and live birth following in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI).

At ejaculation, tens of millions of spermatozoa are deposited by the human male into the upper part of the vagina near the cervical orifice. Their journey starts from here through the genital tract like a competitive race to reach the oocyte first and fertilize it in ampulla part of fallopian tube.[1,2] In the human, out of the total number of ejaculated spermatozoa, only about 10% will enter the cervix, 1% the uterus, and 0.1% the fallopian tube. Eventually, out of the 10^2–10^3 spermatozoa that will reach the cumulus-oocyte complex, usually only one spermatozoon will fertilize the egg.[1] Hence, it follows that an extremely stringent selection process of spermatozoa, which is essential for fertilization to produce healthy offspring, is occurring, in which the female genital tract is involved. With the advent of ART, sperm separation strategies from seminal plasma were developed, which are mainly based on motility, and adhesion and filtration processes.[3,4] While in the early years of ART, the focus was rather on obtaining motile spermatozoa, in later years, the focus shifted to the isolation of functional spermatozoa, a requirement dictated by the observations that functional sperm parameters are correlated with the results of fertilization in vitro.[5] The spermatozoa of all placental (eutherian) mammals, including humans, are in a protective, nonlabile state at ejaculation and are incapable of fertilization even if they are placed in direct contact with an oocyte. Consequently, they must undergo a subsequent period of final maturation during which they acquire the capacity to interact with the oocyte-cumulus complex and achieve fertilization. This process, which was discovered independently by Austin and Chang in 1951, was termed capacitation, and spermatozoa in the ejaculate are prevented from undergoing capacitation by one or more decapacitation factors that are present in the seminal plasma.[6] Capacitation of eutherian spermatozoa is essential for fertilization not only in vivo but also in vitro, and underlies the manipulation of spermatozoa for clinical IVF.

Seminal plasma not only contain one or more decapacitation factors that prevent natural capacitation of spermatozoa after ejaculation, but also contains one or more factors that have adverse effects on sperm functions such as its ability to penetrate though viscous cervical mucus[7], to undergo acrosome reaction in vitro, and overall fertilization process.[8-10] Therefore, to avoid these factors and to retain capacity to fertilize oocyte, separation of spermatozoa from seminal plasma is the essential prerequisite step to maintain ability for capacitation and express their intrinsic fertilizing

ability. In ART laboratories, this requirement is manifested in the process commonly referred to as *sperm washing*, in which spermatozoa are removed from the seminal plasma and resuspended in culture medium.

It must be noted that, prolonged exposure to seminal plasma (>30 minutes) can permanently diminish the fertilizing potential of spermatozoa after ejaculation in vitro.[8] Even contamination caused by small traces of seminal plasma in the prepared sperm sample can diminish or totally inhibit their fertilizing potential.[11] Therefore, spermatozoa for clinical procedures such as intrauterine insemination (IUI) or IVF (and also for laboratory tests of sperm fertilizing ability) must be separated from the seminal plasma environment not only as soon as possible after ejaculation (allowing for the required waiting time for liquefaction) but also as efficiently as possible.

Approximately 2–4% of births in developed countries involve the use of ART.[12] With ART, semen samples must first be processed before they can be used for insemination. In fact, sperm preparation methods in vitro imitate the natural process in which viable sperm are separated from other constituents of the ejaculate as they actively migrate through the cervical mucus.[13]

If spermatozoa are not separated from seminal plasma within 30 minutes of ejaculation, the fertilizing capacity permanently diminishes[14], hence the World Health Organization (WHO)[15] recommends separating sperm cells from the seminal plasma within 1 hour after ejaculation to limit damage from leukocytes and other cells present in the seminal plasma.

Various sperm separation or isolation methods exist to select sperm cells. These include swim-up methods, two-layer discontinuous gradient centrifugation, pentoxifylline wash, test-yolk buffer, sedimentation methods and polyvinylpyrrolidone (PVP) droplet swim-out, electrophoresis, and fluorescence cell sorting methods.[16] A number of these have been developed to separate viable sperm from the seminal ejaculate for use in ART such as swim-down, swim-up, migration-sedimentation, density gradient centrifugation, magnetic activated cell sorting (MACS), and glass wool filtration. This chapter will discuss these techniques—the more commonly used procedures are explained in detail. It will also explain the procedures used to prepare viscous semen samples as well as when to obtain and prepare semen samples using epididymal and testicular spermatozoa, assisted ejaculation, and retrograde ejaculation. The ideal sperm separation technique should:

- Be quick, easy, and cost-effective,
- Isolate as much motile spermatozoa as possible,
- Not cause sperm damage or nonphysiological alterations of the separated sperm cells,
- Eliminate dead spermatozoa and other cells, including leukocytes and bacteria,
- Eliminate toxic or bioactive substances like decapacitation factors or reactive oxygen species (ROS), and
- Allow processing of larger volumes of ejaculates.

Since none of the methods available meets all these requirements, a variety of sperm separation techniques are mandatory in clinical practice to obtain an optimal yield of functionally competent spermatozoa for insemination purposes. Depending on the ejaculate quality, these methods have different efficiency and areas of use. In the conventional swim-up technique, functional spermatozoa can come into close cell-to-cell contact with defective sperm or leukocytes by centrifugation, thus causing massive oxidative damages of the sperm plasma membrane by ROS and consequently of sperm functions.[17] Therefore, the quality of the ejaculates has direct consequences on the choice of a sperm separation method.

SIMPLE WASH METHOD

In the simple wash method, following complete liquefaction, culture medium is added to the ejaculate (2:1 parts ratio) and centrifuged twice to remove the seminal plasma. It is essential to use lower centrifugal forces (<500 g) and fewer centrifugation steps to minimize the damage caused by formation of ROS by nonviable spermatozoa and leukocytes.[14] Increased levels of ROS result in DNA damage in spermatozoa, decreased sperm motility, increased numbers of apoptotic spermatozoa, and decreased sperm plasma membrane integrity.[18] Additionally, the presence of large numbers of nonviable spermatozoa in the prepared sample can inhibit capacitation a physiological process that confers spermatozoa with the ability to fertilize an oocyte.[18] The simple wash technique is usually used when the semen sample has optimal parameters. This technique is often used to prepare sperm cells for IUI because it produces very high-yields of spermatozoa.

MIGRATION-BASED TECHNIQUES

Swim-up

Swim-up is one of the most commonly used techniques for sperm preparation. Swim-up can be performed using a cell pellet or a liquefied semen sample. In conventional swim-up, a prewashed sperm pellet obtained by a soft spin is placed in an overlaying culture medium in a conical tube **(Fig. 1)**. The common steps of this method (using a cell pellet) are as follows:

- Allow specimen to liquefy completely for 15–30 minutes in a 37°C incubator before processing.
- Measure volume using a sterile 2 mL pipette.
- Transfer specimen from a plastic cup to a sterile 15 mL-conical centrifuge tube. If specimen is >3 mL, split the specimen into two aliquots.

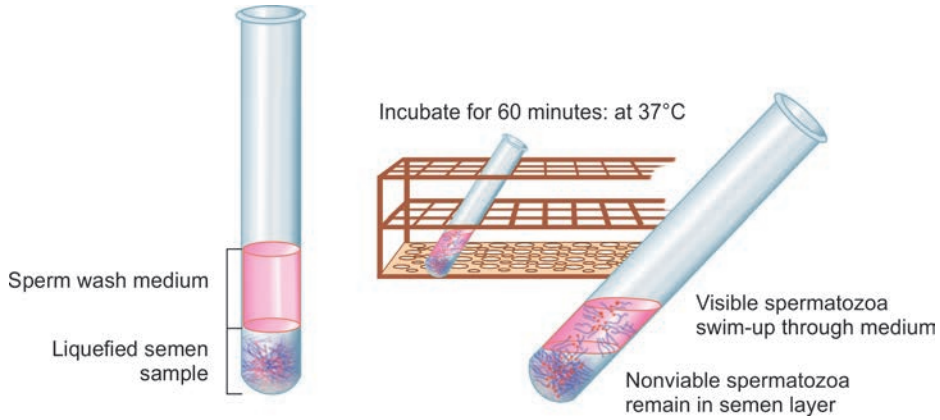

Fig. 1: A prewashed sperm pellet obtained by a soft spin.

- Gently mix the specimen with Quinn's Sperm Wash Media [human tubal fluid (HTF)] in a ratio of 1:4 using a sterile Pasteur Pipette.
- Centrifuge the tubes at 1,600 rpm for 10 minutes.
- Examine for sperm count and motility. Carefully aspirate the supernatant without disturbing the pellet and resuspend the pellet in 3 mL of fresh HTF. Transfer the resuspended sample into two 15 mL sterile round bottom tubes using a sterile serological pipette (1.5 mL in each).
- Centrifuge the tubes at 500 rpm for 5 minutes.
- Incubate the tubes at a 45° angle for 1 hour for swim-up in vertical rack in a 37°C incubator.
- After the incubation period, aspirate the entire supernatant from the round bottom tube. Use a Pasteur Pipette, with the tip placed just about the pellet surface.
- Pool supernatant from the two round bottom tubes into a single 15 mL conical centrifuge tube. Centrifuge the tube at 1,600 rpm for 7 minutes.
- Aspirate the supernatant from the top of the meniscus using a Pasteur Pipette.
- Resuspend the pellet in a volume of 0.5 mL HTF using a 1 mL sterile pipette. Record the final volume.

Note: Sterile techniques should be used throughout specimen processing. When examining the specimen, it is important to pay particular attention to extraneous round cells, debris, and bacteria that may be present. The medium used in this technique provides the sperm with a nourishing environment and attracts the sperm cells. The spermatozoa leave the pellet and swim into the medium. The sperm cells furthest away from the pellet are retrieved since they have the greatest probability of being motile and morphologically normal.

The swim-up method has been modified for oligozoospermic men.[19] This modified method is called direct swim-up and involves swim-up from semen rather than swim-up from the cell pellet. Direct swim-up is the simplest and fastest method for separating sperm by migration. Round-bottom tubes are used for direct swim-up to maximize the surface area between the semen and medium.[14] Multiple tubes with small volumes can be used to further increase this interface area and increase the number of motile sperm retrieved.[19] With this particular procedure, incubation is performed at 34.5°C, which has been reported to result in higher motility than incubation at 37°C.[20]

The swim-up method is simple and relatively inexpensive.[3] Yet, it has some disadvantages:

- Centrifugation, which is performed to create a cell pellet before conventional swim-up, has been shown to generate ROS.[21]
- The amount of motile spermatozoa retrieved is relatively low.
- Only 5–10% of the sperm cells subjected to swim-up are retrieved.
- When a concentrated cell pellet is used, some motile spermatozoa may be trapped in the middle of the pellet and thus may not travel as far as the sperm cells at the edges of the pellet.

Considering that the efficiency of the technique is based on the surface of the cell pellet and the initial sperm motility in the ejaculate, the yield of motile spermatozoa is limited. Many layers of cells in the pellet may cause potentially motile spermatozoa in the lower levels of the pellet never to reach the interface with the culture medium layer. In addition, a significant decrease in the percentage of normally chromatin-condensed spermatozoa has been reported after the swim-up procedure.[22] Another major disadvantage of this technique is the fact that for its use spermatozoa are pelleted, thus coming into close cell-to-cell contact with each other, cell debris and leukocytes, which are known to produce very high levels of ROS.[23] Due to the extraordinary high amount of polyunsaturated fatty acids in the sperm's plasma membranes,[24] these ROS cause lipid peroxidation and therefore a dramatic decrease in sperm functions, including motility.[25] Overall, although many men's spermatozoa may not be impaired to the extent of inhibiting fertilization, some couples' chances of successful IVF will certainly be

TABLE 1: Advantages and disadvantages of the original migration-sedimentation method according to Tea, et al., (1984).

Advantages	*Disadvantages*
Usually very clean fraction of highly motile spermatozoa	The original method is restricted to ejaculates of high sperm count and good motility. The original method has a very low recovery rate
Reactive oxygen species are reduced	• Special glass or plastic tubes are required • Tubes are more expensive and relatively sensitive
Very gentle separation method	For repeated use in in vitro fertilization, glass and plastic tubes must be sterilized

compromised. It is therefore not reasonable to continue and to use a technique, such as swim-up from pelleted semen with the inherent potential to cause irrevocable damage to spermatozoa prejudicial to a desired functional endpoint. Eventually, this knowledge led to the development of other more gentle sperm separation methods that also allow a higher recovery of motile and functional spermatozoa. The advantages and disadvantages of the conventional swim-up are summarized in **Table 1**.

Migration-sedimentation

Direct swim-up from semen is used for sperm samples with average or good motility. On the other hand, migration-sedimentation is usually used for samples with low motility.[26] Migration-sedimentation uses the swim-up technique but also relies on the natural settling of spermatozoa due to gravity. Sperm cells migrate from a ring-shaped well into a culture medium above and then settle through the central hole of the ring. Special tubes called Tea–Jondet tubes are used for migration-sedimentation.[26]

The advantage of this technique is that it is a gentle method, and thus the amount of ROS produced is not very significant. On the other hand, the special tubes that are needed are relatively expensive.[24]

Swim-down

This technique relies on the natural movement of spermatozoa. A discontinuous bovine serum albumin medium is prepared. This medium becomes progressively less concentrated moving from top to bottom. The semen sample is placed onto the top of the medium, and the tube is incubated at 37°C for 1 hour.[26] During migration, the most motile sperm move downward into the gradient.

Density Gradient Centrifugation

Density gradient centrifugation separates sperm cells based on their density. Thus, at the end of centrifugation, each spermatozoon is located at the gradient level that matches its density.[14] Morphologically, normal and abnormal spermatozoa have different densities. A mature morphologically normal spermatozoon has a density of at least 1.10 g/mL whereas an immature and morphologically abnormal spermatozoon has a density between 1.06 g/mL and 1.09 g/mL.[27] As a result, the resulting interphases between seminal plasma and 40% density gradient, 40 and 80% density gradients containing leukocytes, cell debris and morphologically abnormal sperm with poor motility, are discarded. The highly motile, morphologically normal, viable spermatozoa form a pellet at the bottom of the tube. Centrifugal force and time should be kept at the lowest possible values (<300 g) in order to minimize the production of ROS by leukocytes and nonviable sperm cells.[28] Also, nonviable sperm cells and debris should be separated from viable sperm cells as soon as possible to minimize oxidative damage.[29]

Density gradients can either be continuous or discontinuous. Density gradually increases from the top of a continuous gradient to its bottom. There are clear boundaries between layers of discontinuous gradients.[3] The latter gradient is formed when a number of layers of decreasing density are placed on top of each other.[14] Double density gradients comprise the commonly used sperm preparation protocol for ART.[14] Components of the density gradient sperm separation procedure include a colloidal suspension of silica particles stabilized with covalently bonded hydrophilic silane supplied in {[4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid] HEPES}. There are two gradients: (1) a lower phase (90%) and (2) an upper phase (45%). Sperm washing medium (modified HTF with 5.0 mg/mL human albumin) is used to wash and resuspend the final pellet **(Fig. 2)**.

Below are some of the main steps of the process:

- Place all components of the upper and lower phase and semen samples in an incubator at 37°C for 20 minutes.
- Transfer 2 mL of the lower phase into a sterile conical-bottom, disposable centrifuge tube.
- Layer 2 mL of the upper phase on top of the lower phase using a transfer pipette. Slowly dispense the upper phase lifting the pipette up the side of the tube as the level of the upper phase rises. A distinct line separating the two layers will be observed. This two-layer gradient is stable for up to 2 hours.
- Measure semen volume to be loaded using a sterile 2 mL pipette. Remove a drop of semen using sterile technique for count, percent motility, and presence of round cells.
- Gently place up to 3 mL of liquefied semen onto the upper phase (leaving approximately 0.1 mL in original container for a prewash analysis). If volume is >3 mL, it may be necessary to split the specimen into two tubes before processing.
- Centrifuge for 20 minutes at 1,600 rpm.

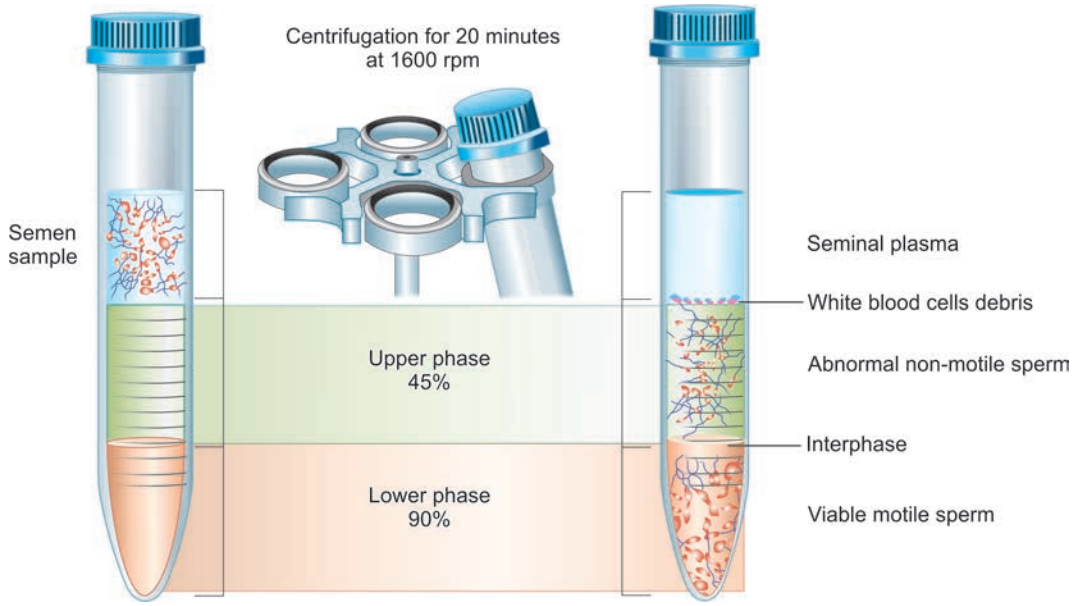

Fig. 2: Density gradient centrifugation. The lower and upper gradients are carefully layered and the seminal ejaculate layered on the top. The sample is centrifuged at 1,600 rpm for 20 minutes. Clear seminal plasma is retained on the uppermost part of the gradient followed by a clear separation of white blood cells, debris, and other cells. The immature, abnormal sperm are seen along the gradient based on their density and motility. Highly motile normal sperm move actively to the bottom of the gradient and collected as a pellet.

Note: Occasionally, samples that do not liquefy properly and remain too viscous to pass through the gradient will be encountered. Increasing the centrifugal force up to but no >600 × g will aid in separating the sperm in these cases.

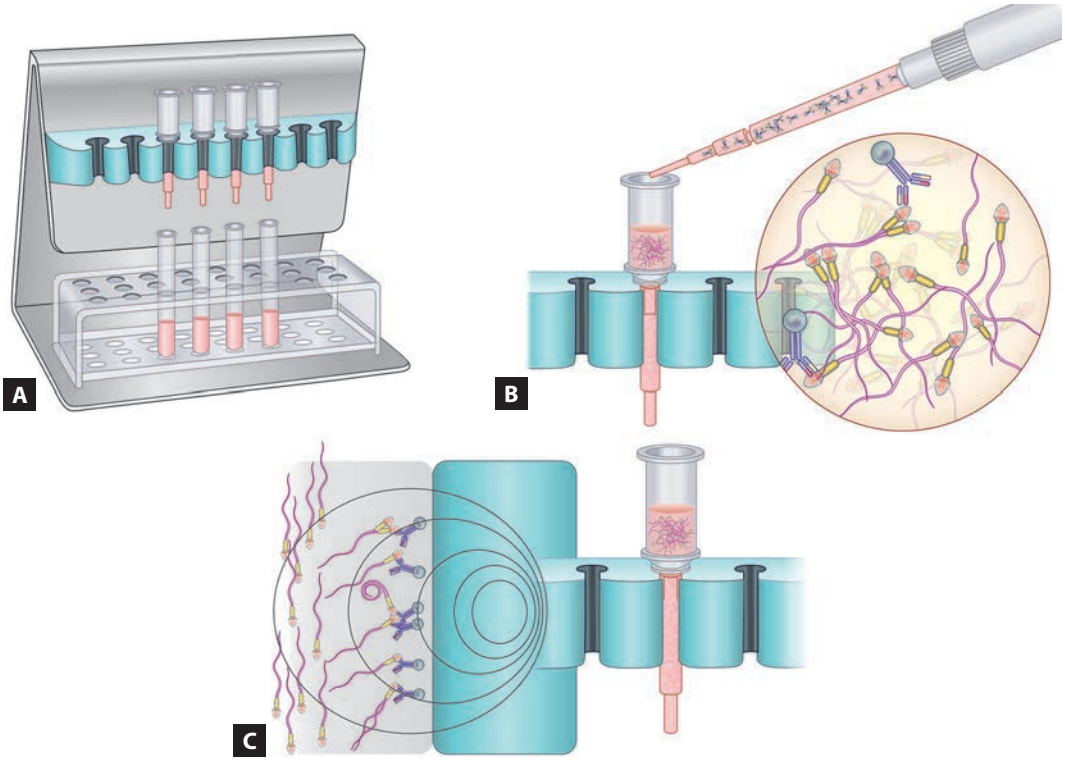
- Using a transfer pipette, add 2 mL of HTF and resuspend pellet. Mix gently with pipette until sperm pellet is in suspension.
- Centrifuge for 7 minutes at 1,600 rpm.
- Again, remove supernatant from the centrifuge tube using a transfer pipette down to the pellet.
- Resuspend the final pellet in a volume of 0.5 mL using a 1 mL sterile pipette with HTF. Record the final volume.
- The advantages and disadvantages of density gradient centrifugation are listed in **Table 2**.

TABLE 2: The advantages and disadvantages of density gradient centrifugation.

Advantages of density gradient centrifugation	***Disadvantages of density gradient centrifugation***
Density gradient centrifugation requires maximally a 30 minutes centrifugation. It takes less time than the swim-up technique which requires 1 hour incubation	Production of good interphases between layers can take some time
Density gradient centrifugation is relatively easy to perform under sterile conditions	There is a risk of contamination with endotoxins
Spermatozoa from oligozoospermic semen can be effectively separated with density gradient centrifugation[3]	Some scientists have claimed that density gradient centrifugation negatively affects sperm DNA integrity. For instance, spermatozoa recovered after density gradient centrifugation possess lower DNA integrity than spermatozoa recovered after swim-up[23]
Density gradient centrifugation eliminates the majority of leukocytes in the ejaculate	

TIPS TO MAXIMIZE THE SPERM YIELD

- It is important to make sure that all components of the gradient and sperm wash medium are at room to body temperature before use. This will protect spermatozoa from *cold shock*. In addition, any condensation on the media bottles will disappear, which aids in the visual detection of contamination. Any bottle whose contents appear in any way cloudy or hazy should not be used.
- Do not use the same pipette in more than one bottle of media.
- Prolonged exposure to a 5% CO_2 environment will alter the pH of these products, which may in turn affect their nature and performance.
- Highly viscous semen usually should be treated with 5 mg of trypsin, dissolved in 1.0 mL of sperm washing media and added to the ejaculate 5 minutes before loading on the upper gradient. This will increase the motile sperm yield without causing any measurable damage to the motile sperm.
- Avoid overloading the gradient as it causes a phenomenon called *rafting*. Rafting is the aggregation of desirable as



Figs. 3A to C: Magnetic activated cell sorting: (A) The Octet magnetic collection device can be used for loading up to a maximum of 8 samples. The tubes are placed between each open slot surrounded by the magnetic field; (B) The apoptotic and the nonapoptotic cells are labeled with the annexin V antibody beads (magnetic). These attach to the outer surface of the sperm that are apoptotic. Annexin V beads (magnetic) do not bind to the sperm that are nonapoptotic and have intact membranes; (C) Apoptotic sperm with annexin V beads (magnetic) are retained in the column while the nonapoptotic sperm are eluted out and collected in a tube below the collection device.

well as undesirable components of the semen that will be present in the postcentrifugation pellet. Use the gradient within 1 hour after creating it—eventually the two phases over time blend into each other and a sharp interface will not exist.

- Percoll™, a colloidal suspension of silica particles coated with polyvinylpyrrolidone, was widely used by ART laboratories until it was withdrawn from the market for clinical use. Nowadays, media containing silane-coated silica particles are commonly used. Isolate™ (Irvine Scientific, Santa Ana, CA), Ixa Prep™, Sperm preparation medium™ and Supra Sperm™ (ORIGIO, MediCult, Copenhagen, Denmark), SpermGrad™ (Vitrolife, San Diego, CA), SilSelect™ (Ferti Pro NV, Beernem, Belgium), and PureSperm™ (Nidacon Laboratories AB, Gothenburg, Sweden) are commonly used.[3]

MAGNETIC-ACTIVATED CELL SORTING

Magnetic-activated cell sorting separates apoptotic spermatozoa from nonapoptotic spermatozoa. During apoptosis (programmed cell death), phosphatidyl serine residues are translocated from the inner membrane of the spermatozoa to the outside. Annexin V has a strong affinity for phosphatidyl serine but cannot pass through the intact sperm membrane. Colloidal superparamagnetic beads (~50 nm in diameter) are conjugated to highly specific antibodies to annexin V and used to separate dead and apoptotic spermatozoa by MACS. Annexin V binding to spermatozoa indicates compromised sperm membrane integrity.

A 100 µL sperm sample is mixed with 100 µL of MACS microbeads and incubated at room temperature for 15 minutes. The mixture is loaded on top of the separation column which is placed in the magnetic field [0.5 Tesla (T) between the poles of the magnet and 1.5 T within the iron globes of the column]; 1 Tesla = 10,000 gauss **(Figs. 3A and B)**. The column is rinsed with buffer. All the unlabeled (annexin V-negative) nonapoptotic spermatozoa pass through the column **(Fig. 3C)**. The annexin V-positive (apoptotic) fraction is retained in the column. The column is removed from the magnetic field, and annexin V-positive fraction is eluted using the annexin V-binding buffer.[16] The procedure is explained in **Figures 3A to C**.

Spermatozoa prepared by density gradient centrifugation followed by MACS have a higher percentage of motility, higher percentage viability, and a lower expression of apoptotic markers than spermatozoa prepared by density gradient centrifugation alone.[30] Annexin V-negative spermatozoa have a higher motility, lower caspase activation, lower membrane mitochondrial potential disruption, lowers amount of DNA damage, and

TABLE 3: The advantages and disadvantages of magnetic activated cell sorting (MACS).

Advantages of MACS	*Disadvantages of MACS*
• MACS acts at the molecular level as opposed to routine sperm preparation techniques that rely on sperm density and motility • MACS is the only known technique which separates apoptotic spermatozoa from nonapoptotic spermatozoa • MACS is rapid, convenient, and noninvasive • Bead detachment after MACS is not necessary • MACS provides optimal purity and recovery with reliable and consistent results • MACS can used to optimize the cryopreservation-thawing outcome and enhance cryosurvival rates following cryopreservation	Viable spermatozoa ought to be separated from all substances in the ejaculate such as apoptotic spermatozoa, leukocytes, and seminal plasma. MACS, which removes apoptotic spermatozoa, needs to be used in conjunction with other techniques such as density gradient centrifugation to remove the other substances

higher oocyte penetration capacity than annexin V-positive spermatozoa.[29] MACS improves the acrosome reaction in couples with unexplained fertility.[27,31] Annexin V-negative sperm cells show significantly higher motility and survival rates following cryopreservation than annexin V-positive sperm cells.[32] Dirican, et al.,[33] reported that spermatozoa selected by MACS were associated with higher cleavage and pregnancy rates than spermatozoa selected by density gradient centrifugation in oligoasthenozoospermia cases.

The advantages and disadvantages of MACS are outlined in **Table 3**.

GLASS WOOL FILTRATION

During glass wool filtration, which has already been described by Paulson and Polakoski in 1977,[34] motile spermatozoa are separated from immotile sperm cells by means of densely packed glass wool fibers. The principle of this sperm separation technique lies in both the self-propelled movement of the spermatozoa and the filtration effect of the glass wool. The success of this method is directly linked to the kind of glass wool used.[35] Thus, factors like the chemical nature of the glass (i.e., borate glass, silicate glass, or quartz glass), the surface structure and charge of the glass wool, thickness of the glass wool fibers or the pore size of the filter have to be taken into consideration. Potential risks of the technique such as damages of the spermatozoa or the occurrence of glass wool fragments in the filtrate essentially depend on the kind of glass wool used and on the intensity of the washing prior to the filtration.

Compared with the swim-up or migration-sedimentation, glass wool filtration, just as density gradient centrifugation, is a technique that uses the whole volume of the ejaculate and therefore yields a significantly higher total number of motile spermatozoa.[22,36] Thus, it can also be used for patients with oligo- and/or asthenozoospermia.[36] Like density gradient centrifugation, glass wool filtration also provides the advantage that the sperm separation can directly be performed from the ejaculate. Only after the separation of the functional spermatozoa from the immotile ones, leukocytes and debris, a centrifugation step will be necessary to remove the seminal plasma. This is an important aspect as this procedure reduces cellular damage by ROS.

By means of glass wool filtration, it is even possible to prepare motile spermatozoa from patients with retrograde ejaculation.[4] In these cases, the procedure includes adjustment of the osmolarity of the patient's urine to values of about 350 mOsmol/kg by drinking water. Prior to the ejaculation, the patients are requested to urinate most of the urine in the bladder. The small amount of antegrade-produced ejaculate is collected in a plastic beaker, while the retrograde fraction of the ejaculate needs to be urinated immediately into a jar with 50 mL culture medium containing human serum albumin to dilute the urine. Finally, the urine/medium mixture has to be centrifuged, resuspended in 3–4 mL of fresh medium and filtrated on the glass wool column. As constituents of the urine can damage the spermatozoa, a speedy work-up of such ejaculates is mandatory. In addition to the separation of spermatozoa, glass wool filtration has been shown to eliminate leukocytes to an extent of up to 90%.[37] Since leukocytes are frequent even in normal ejaculates[38] and produce 100-times more ROS than spermatozoa,[23] this effect significantly contributes to a reduction of free radicals in the ejaculate.[35,37] This is of paramount importance for the functionality of spermatozoa because the male germ cells are particularly susceptible to oxidation by ROS because of their extraordinary high content of polyunsaturated fatty acids in their plasma membrane.[24,39,40]

Another clinically interesting aspect related to glass wool filtration is chromatin condensation, which has repeatedly been shown to be predictive of fertilization in vitro.[40-43] Glass wool filtration[22] like the density gradient centrifugation with Pure Sperm®[44] or the migration-sedimentation technique[45] significantly selects normally chromatin-condensed spermatozoa, while conventional swim-up or Percoll® centrifugation decrease this sperm parameter. As human sperm chromatin condensation follows a seasonal rhythm, which even shows a shift of about half a year on the southern hemisphere,[46] this might have a clinical impact on the results in IVF. Should a patient be examined in winter when the quality of sperm chromatin condensation is high[46] and referred to IVF in summer when the percentage of normally chromatin-condensed spermatozoa is significantly lower,

TABLE 4: The advantages and disadvantages of glass wool filtration.

Advantages	*Disadvantages*
• Simple to perform • Normally, recovery of spermatozoa with good motility • Spermatozoa from ejaculates with a very low sperm density can be separated • Good yield • Leukocytes are eliminated to a large extent • Reactive oxygen species are significantly reduced	• Bit more expensive • The filtrate is not as clean as it is with other sperm separation methods • Remnants of debris are still present

IVF for this patient might fail. Thus, for these patients a sperm separation by means of glass wool filtration, Pure Sperm® or migration-sedimentation might be beneficial.

The advantages and disadvantages of this method are summarized in **Table 4**.

GLASS BEADS

This method has been used for the preparation of hamster spermatozoa for in vitro capacitation[47] and resulted in an efficient, high-yield selection of motile human spermatozoa from semen.[48] However, there were concerns regarding the possible spillover of beads into the insemination medium. As a result, the use of glass beads for effective sperm preparation for assisted reproduction has not widely been accepted.

SEPHADEX COLUMNS

In the early nineties sperm separation by means of Sephadex beads emerged[49] and a commercial sperm separation kit based on this principle (Sperm Prep®) has become available. Compared to migration-sedimentation and swim-up from pelleted semen it produced significantly higher yields.[50] Moreover, morphologically normal sperm cells could be enriched in the filtrate after Sperm Prep® separation as well as significantly higher pregnancy rates for IUI as compared with the conventional swim-up method.[51] Sperm Prep® method when compared to and Percoll® centrifugation, Percoll® separated spermatozoa showed a significantly higher percentage of normally chromatin-condensed and morphologically normal spermatozoa.[52] However, the fertilization rates reported by these authors were similar. López, et al.,[53] used a prepacked PD-10 column containing Sephadex G-25 particles (Pharmacia Biotechnology, Uppsala, Sweden), which is normally used to desalt proteins in solutions, to separate human spermatozoa and compared the results with the Sperm Prep® method and Percoll® centrifugation. The PD-10 column and density gradient centrifugation in Percoll® yielded a comparable number of spermatozoa and showed similar percentages of morphologically normal spermatozoa after sperm separation. On the contrary, the Sperm Prep® method resulted in significantly lower values of sperm count and morphology.

TRANSMEMBRANE MIGRATION

Another alternative sperm separation technique that was also developed in the late eighties is migration/filtration of motile spermatozoa through a Nuclepore membrane filter. These filters are unusual because their pores are cylindrical and at right angles to the plane of the membrane.[54] The spermatozoa, therefore, have straight channels to swim through the membrane. Unfortunately, these membranes had a very low ratio of the total cross-sectional area of the pores to the overall membrane area. Consequently, the yield is extremely low. Primarily, this method was used for testing the motility of sperm populations treated with various pharmacological agents, but not as a preparation method for assisted reproduction.[55]

Another approach of separating viable human spermatozoa by means of membranes was undertaken by Agarwal, et al.,[56] using a membrane which has been developed for selective removal of leukocytes (L4 membrane). Besides, a significant increase of motility, ejaculates filtered through this membrane have been shown to contain fewer leukocytes. This fact is, of course, of importance in those cases that have increased numbers of leukocytes in the ejaculate as a result of infections. Moreover, this membrane seems to be selective for spermatozoa with normal membrane integrity [57, 58] and sperm producing low amounts of ROS.[59] However, despite these advantages of the membrane it has never come into practical clinical use for human assisted reproduction.

REDUCTION OF SEMEN VISCOSITY

Human semen normally liquefies within 5–20 minutes after ejaculation.[9] However, some ejaculates fail to liquefy and some are viscous by nature. Semen viscosity is a problem since it can reduce sperm motility. To reduce viscosity, the semen can be mixed with a medium. Liquefaction achieved by this method might not be adequate for highly viscous samples. Forcing the viscous semen through a needle with a narrow gauge is another option. However, this technique damages the sperm cells.[9] A commonly used viscosity treatment system involves enzymatic liquefaction using trypsin (5 mg). These can also be obtained prepackaged in 5 mg vials (VTS; Vitrolife, San Diego, CA). If the sample fails to completely liquefy following 20 minutes of incubation at 37°C, trypsin is added directly to the semen specimen. The specimen is then swirled and incubated for an additional 10 minutes. This results in complete liquefaction of the sample.

WHEN TO USE A PARTICULAR SPERM PREPARATION TECHNIQUE

The choice of sperm preparation method depends on the characteristics of the semen sample. When sperm parameters such as concentration and motility are within the normal ranges, the direct swim-up technique is preferred.[15] For significantly oligozoospermic, teratozoospermic, and asthenozoospermic samples, density gradient centrifugation is preferred since density gradient centrifugation leads to a higher recovery of motile sperm cells than the swim-up technique. Also, density gradient centrifugation can be modified to address the issues of each individual specimen, and it is the method of choice for sperm preparation in the majority of ART and andrology laboratories.[4] Glass wool filtration is also effective for the separation of sperm cells from semen with suboptimal parameters.[15]

Sperm Preparation for Assisted Reproductive Techniques

Density gradient centrifugation is usually used to prepare sperm cells for standard IVF. If the semen sample is poor in terms of motility and concentration, ICSI should be considered.[29]

The sperm sample can be prepared for ICSI with density gradient centrifugation or swim-up. Oligozoospermic samples can be prepared using the swim-up technique if there are some viable spermatozoa with forward motility.[29] If needed, sperm cells in oligozoospermic samples can be concentrated with a wash and resuspension. These concentrated samples can be used directly or be subjected to density gradient centrifugation or swim-up before being used. Density gradient centrifugation is a better option than swim-up for significantly oligozoospermic and significantly asthenozoospermic samples as well as for samples with high quantities of debris.[29] The hyposmotic swelling test is also an efficient method for selecting sperm for ICSI.[60]

Preparation of Epididymal and Testicular Spermatozoa

In case of epididymal obstruction or complete azoospermia, spermatozoa can be obtained from the epididymis or the testicular tissue, both require special preparation. Usually, large numbers of sperm cells can be collected from the epididymis. Sperm samples obtained from the epididymis do not contain a significant amount of nongerm cells such as red blood cells. If sufficient numbers of epididymal sperm cells are collected, density gradient centrifugation can be used to prepare the spermatozoa for ART. On the other hand, the simple wash technique will be used if the number of spermatozoa aspirated is low.[15]

Spermatozoa can be retrieved from the testes by open biopsy or by percutaneous needle biopsy.[15] Testicular samples contain large numbers of nongerm cells such as red blood cells. Spermatozoa need to be separated from these nongerm cells. Also, the elongated spermatids, which are bound to the seminiferous tubules, must be freed. Sperm cells collected from the testes are used in ICSI because low numbers of spermatozoa with poor motility are generally aspirated. Pentoxifylline is occasionally used to increase the motility of epididymal and testicular spermatozoa before ICSI.

Preparation of Assisted Ejaculation Samples

Direct penile vibratory stimulation or indirect rectal stimulation is used to retrieve semen from men who have disturbed ejaculation or who cannot ejaculate due to health issues such as spinal cord injury. Patients with spinal cord injury often have ejaculates with a high sperm concentration and low sperm motility. These ejaculates are also contaminated with red blood cells and white blood cells.[15] Ejaculates obtained by electroejaculation are most effectively prepared with density gradient centrifugation.[4] It has been reported that semen obtained by vibratory stimulation is of better quality than semen obtained by electroejaculation for men with spinal cord injuries.[61]

Preparation of Retrograde Ejaculation Samples

Retrograde ejaculation occurs when semen is directed into the urinary bladder during ejaculation. If there is an inadequate number of spermatozoa in the ejaculate, sperm cells in the urine need to be retrieved. At the laboratory, the patient is first asked to urinate without entirely emptying his bladder. Then, he is asked to ejaculate and urinate again into another specimen cup containing 5–6 mL of culture medium, which alkalinizes the urine. The urine sample volume is noted and analyzed after centrifugation.[62] The concentrated retrograde specimen and the antegrade specimen are usually prepared with density gradient centrifugation.[15] The Liverpool solution containing sodium bicarbonate given orally to alkalinize urine have been recently described and was demonstrated to be associated with improved sperm motility.[63]

LIMITATIONS OF CONVENTIONAL SPERM PREPARATION TECHNIQUES

By employing conventional sperm preparation strategies for ART, natural sperm selection processes taking place at various levels of the female genital tract are bypassed to varying extents. In the case of ICSI, where a single spermatozoon is injected into the oocyte, all natural barriers for fertilization are bypassed and even sperm components that normally do not enter the female gamete are introduced. Thereby, oocyte activation and embryo development could possibly be impaired.[63] Since spermatozoa with nuclear DNA damage

are capable of fertilizing oocytes,[64,65] this, depending on the severity of the damage, may cause recurrent pregnancy loss.[66] Additionally, serious concerns regarding the health of the offspring were raised.[67-69] On the other hand, embryos deriving from such germ cells can develop to full term.[70,71] Thus, conventional sperm separation techniques show distinct limitations in that they do not necessarily select spermatozoa according to their functional competence or genetic quality as it is achieved in the female genital tract.

ADVANCED STRATEGIES OF SPERM SELECTION

Advanced strategies of sperm selection are defined as being based on sophisticated principles that employ physiological selection procedures. These principles are founded either on a more stringent assessment of sperm morphology, which is a sperm characteristic selected for at three different sites in the female **(Fig. 4)**, or on molecular characteristics of mature spermatozoa, which are associated with proper cellular function and genomic integrity.

Currently, advanced selection procedures can be divided into three groups, on the basis of:

1. Sophisticated morphological assessment
2. Electrical charge
3. Molecular binding.

The latter two principles in part mimic female selection mechanisms.

Selection Based on Morphology

Normal sperm morphology evaluated after fixation on the basis of strict criteria[72] at ×1,000 magnification is regarded as a good predictor of fertilization success in vitro.[73] For ICSI, however, the embryologist selects the most normal (least abnormal)-looking spermatozoon on the basis of light microscopy at magnifications of ×400 in unfixed, unstained, and wet sperm preparations. Success of assisted reproduction is also dependent on the ultramorphology of the spermatozoon that is taken for injection. Therefore, morphological discrimination by means of light microscopy is not good enough as subtle malformations, particularly DNA damage and chromosomal aberrations,[74,75] cannot be detected and defective spermatozoa might be accepted for normal ICSI procedure.[76,77] Ryu, et al.,[78] highlighted the relationship between sperm morphology and genetic abnormalities by showing significantly higher frequencies of aneuploidy in infertile patients.

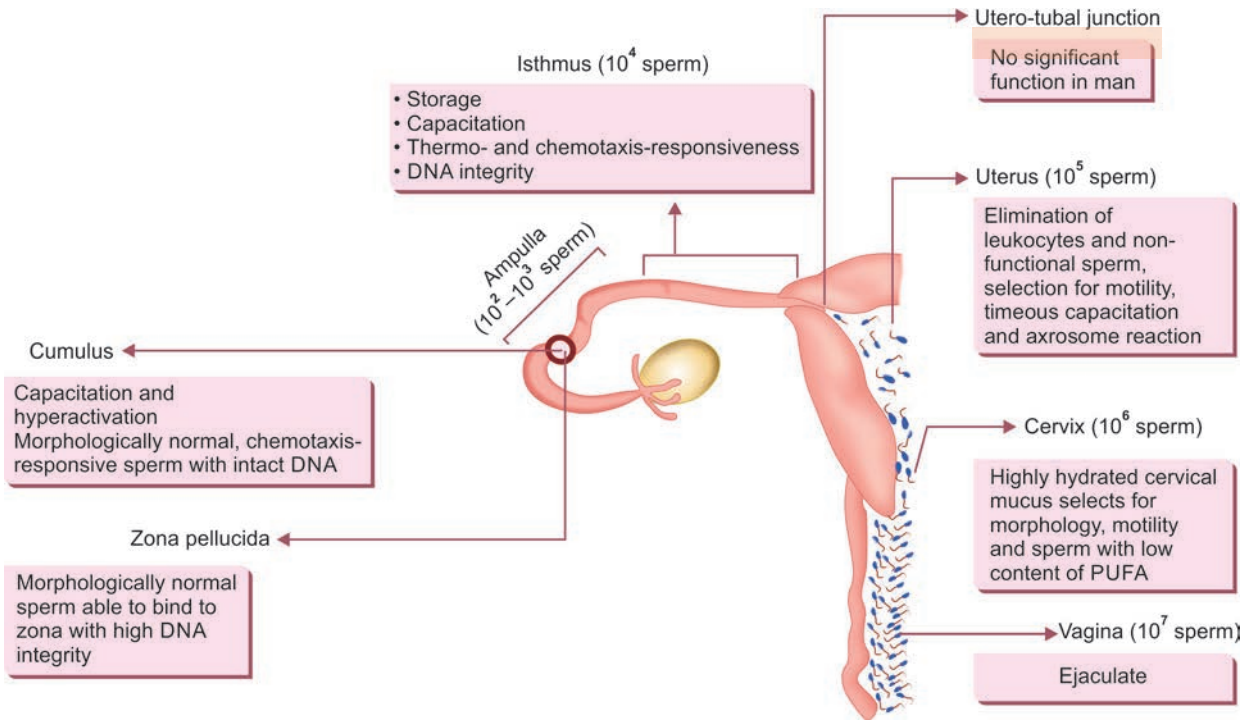


Fig. 4: Sites of sperm selection in the human female. Estimated numbers of spermatozoa in the respective sections of the female genital tract are given in brackets. Soon after deposition in the vagina, spermatozoa move out of the seminal plasma and enter the highly hydrated cervical mucus where sperm selection for morphology and motility takes place. Spermatozoa that are selected here are characterized by a low plasma membrane content of polyunsaturated fatty acids (PUFA). Subsequently, spermatozoa are transported through the uterus where male germ cells are selected for motility and timely capacitation. Dysfunctional spermatozoa are eliminated. After passing the uterotubal junction, which has, in contrast to numerous animal species, no significant functions in man, spermatozoa enter the isthmus of the fallopian tube. In the isthmus, spermatozoa can be stored for up to 5 days. In the isthmus and the cumulus, spermatozoa are selected for capacitation, thermo- and chemotaxis-responsiveness and DNA integrity. Finally, after passing through the cumulus, spermatozoa bind to the zona pellucida where another morphological selection takes place. Moreover, male germ cells are further selected for zona-binding ability and DNA integrity PUFA.

Motile Sperm Organelle Morphological Examination

Since light microscopically invisible damage may be the reason that chromosomal or DNA damage in spermatozoa can be transferred to the progeny,[79] a method that evaluates sperm morphology at higher, digital magnification (×6,300) using Nomarski interference contrast has been developed.[80] With motile sperm organelle morphological examination (MSOME), the morphological status of the acrosome, postacrosomal lamina, neck, mitochondria, flagellum, and the sperm nucleus is examined. For the latter, the shape, as well as the presence and size of vacuoles, is observed. MSOME is now included into ICSI protocols in an increasing number of centers for ART. The combination of MSOME and ICSI has been named intracytoplasmic morphologically selected sperm injection (IMSI) **(Fig. 5)**.[81] Compared with standard ICSI procedures, IMSI has been shown not only to increase fertilization rates,[81] but also implantation and pregnancy rates.[81,82] Concerns have been raised about IMSI because it is expensive and takes with 1.5–5 hours[83] longer than ICSI. Since the normal ICSI procedure is performed at 37°C, the extended exposure of spermatozoa to this temperature might pose a risk to the male germ cell. Peer et al.,[84] exposed human spermatozoa to different temperatures for extended times and found that sperm morphology deteriorated significantly after incubation for 2 hours at 37°C, which was not the case after incubation at 21°C. Therefore, the authors recommended the performance of IMSI at 21°C.

Indications for Intracytoplasmic Morphologically Sperm Injection

The only confirmed indication of IMSI is recurrent implantation failure following ICSI. The literature review results suggest that IMSI is only of value (in terms of higher clinical pregnancy and live birth rates) for patients with one or more previous ICSI failure and not for unselected patients or those undergoing their first treatment attempt.

i. Vacuoles were shown to be linked to chromatin condensation failure[85-88]
ii. Chromatin condensation failure is associated with recurrent abortions[89,90], and
iii. A growing body of evidence suggests that the degree of sperm chromatin condensation at the time of fertilization can influence early and late embryo development.[91]

Current work postulates that the higher pregnancy and delivery rates and lower miscarriage rates observed for IMSI after ICSI failure can be explained (at least in part) by the exclusion of spermatozoa containing sperm head vacuoles of nuclear origin.

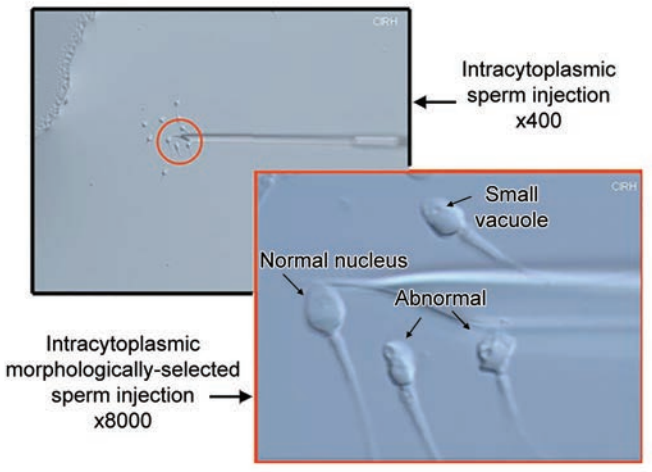

Fig. 5: Magnetic sperm organelle morphological examination–intracytoplasmic sperm injection (ICSI): intracytoplasmic morphologically sperm injection (IMSI).

Potential Indications of Intracytoplasmic Morphologically Sperm Injection

Teratozoospermia: It has already been shown that individual spermatozoa differ in their ability to produce an embryo capable of implanting. Indeed, the use of morphometrically normal spermatozoa with no vacuoles or less than two small vacuoles has been associated with significantly higher blastocyst rates than all other types of spermatozoa (i.e., those with more than two small vacuoles, those with one large vacuole and those with morphometric abnormalities).[92,93] In contrast, one study has reported lower blastocyst rates when vacuole-free spermatozoa were used for injection (relative to spermatozoa with vacuoles).

In summary, IMSI might be indicated in some cases of teratozoospermia. However, given that only one randomized study observed higher clinical pregnancy rates for IMSI than for ICSI in patients with teratozoospermia and the threshold for the number of morphometrically normal spermatozoa (as assessed by MSOME) below which IMSI might produce higher clinical pregnancy and delivery rates than ICSI remains to be determined, further studies of the potential value of IMSI in patients with teratozoospermia are required.

Intracytoplasmic Morphologically Sperm Injection and Spermatozoa with Nuclear Abnormalities

The use of IMSI might help to avoid the selection of spermatozoa with nuclear abnormalities such as chromatin condensation failure, DNA fragmentation, and an abnormal chromosomal content. First, given that the nuclear origin of sperm head vacuoles has been linked to chromatin condensation failure, a high proportion of noncondensed chromatin could be considered as an indication for IMSI. No data are available but this question deserves to be evaluated in large-scale, randomized trials.

A second potential indication of interest is sperm DNA fragmentation. Indeed, it has been shown that spermatozoa judged to be normal at ICSI-like magnifications can

present DNA fragmentation and that normal vacuole-free spermatozoa selected at an IMSI-like magnification are less DNA fragmented than normal spermatozoa selected at an ICSI-like magnification.[94]

Thirdly, sperm aneuploidy may be considered. Although two studies have reported that spermatozoa with large vacuoles are more likely to be aneuploid than normal, vacuole-free spermatozoa[74] or spermatozoa from whole semen,[88] IMSI was found to be no more efficient than ICSI for selecting euploid spermatozoa in patients with a high proportion of aneuploid spermatozoa (e.g., patients with a high proportion of spermatozoa with enlarged heads[95] or translocations.[96,97] Hence, it has not been proved that IMSI can be used to efficiently select euploid spermatozoa. Indeed, one can even consider that the opposite is true (i.e., a demonstrated lack of efficiency).

Intracytoplasmic Morphologically Sperm Injection for Older Women

Interestingly, only one research group has evaluated IMSI in older women. In a randomized study of patients with a mean age of 37 years, preimplantation genetic diagnosis showed that ICSI (n = 60) was associated with significantly higher sex chromosome aneuploidy in the embryo and a significantly greater proportion of chaotic embryos (i.e., with two or more chromosomal number abnormalities) relative to IMSI (n = 60). The researchers postulated that, in older women, oocytes were less able to repair the injected spermatozoon's DNA and hence that use of IMSI to select spermatozoa with fewer nuclear abnormalities could be of value for aged oocytes and older women.[98] This indication also deserves to be evaluated in large-scale, randomized trials.

CONCLUSION

Almost two decade after the introduction of IMSI, this technique continues to divide assisted reproduction professionals. There are few confirmed indications of IMSI, partly because few randomized, head-to-head studies have been performed. According to this systematic literature review, the only currently and consistently acknowledged indication of IMSI is recurrent implantation failure following ICSI. All other potential indications of IMSI must be further assessed.

ZETA POTENTIAL

The electrical charge (216 mV–220 mV) of the sperm plasma membrane is called electrokinetic potential or *zeta potential*[16] **(Fig. 6)**. Sperm membrane is negatively charged.[16,99] On this basis, methods for separating X- and Y-bearing spermatozoa[99] and for the separation of pure sperm heads from disintegrated mammalian spermatozoa[100] were developed decades ago. Later, the methods developed by Ainsworth, et al., (2005)[101] allowed to collect the

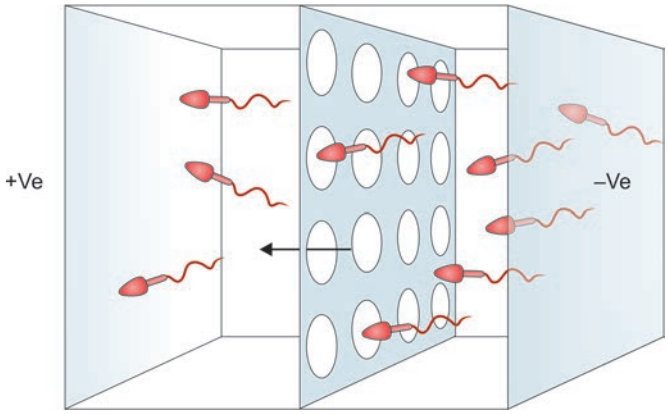

Fig. 6: Example of sperm selection by the Z-method developed by Ainsworth, et al., (2005): Spermatozoa are placed in a well-isolated from another adjacent well by a porous membrane and filled with a medium free of cells. An electric field is then applied with the anode in the well free of cells and the cathode in the well containing the sperm suspension. Due to the negative charge of the sperm membrane, spermatozoa migrate toward the compartment free of cells passing through the porous membrane. Spermatozoa can be then collected for downstream applications.

charged spermatozoa adhered to the wall of a centrifuge tube or migrating within an electric field, respectively. With both methodologies, downstream analysis of the selected spermatozoa revealed an increased percentage of spermatozoa with higher quality and porting high integrity DNA.[102-104]

This procedure, known as Zeta method, has allowed the selection of spermatozoa with reduced DNA fragmentation compared to the HA-coated dish selection.[105] Also, sperm DNA fragmentation has been proven to be lower using DGC-Zeta than DGC by itself[103] or MACS-DGZ.[104] However, despite these promising results, only one randomized study has been published using spermatozoa selected by Zeta method in patients undergoing ICSI.[105] In this research, significant increases in top quality embryos [45.83 ± 3.11% versus 35.38 ± 4.64% (P = 0.04)] and pregnancy rates [39.2 versus 21.8% (P = 0.009)] were obtained with DGC/Zeta compared to DGC, respectively. However, further analysis is needed to know the potential of Zeta method for improving ARTs.

MOLECULAR BINDING

Now it has been very well-documented and established by numerous studies that during epididymal maturation of sperm, certain surface molecules not only change but also get associated with normal sperm function. To identify capability of spermatozoa to fertilize human oocyte, based on these molecular bindings, two methods are being currently used: (1) sperm binding to Annexin V and (2) hyaluronic acid (HA).

The plasma membrane of the spermatozoa takes part in number of cell metabolism, capacitation, zona binding, and acrosome reaction which are very crucial for their functionality. Its accessibility and relation with sperm

vitality and quality make this organelle, its integrity, and variable characteristics, a logical target for the development of selection methods of high quality spermatozoa for their use in ART.

Annexin V Magnetic Activated Cell Sorting

Magnetic activated cell sorting is a method that allows the separation of cell populations based on their surface antigens.[106] These antigens are coated with a molecule with magnetic nanoparticles that have affinity for these antigens. This coating allows the trapping of the desired cell subpopulation and its separation within a column subject to a strong magnetic field as described earlier. Thus, trapped cell expressing the antigen remain in the column while other undesired cells flow through for downstream applications. If membrane integrity is lost in an early event of the apoptotic response, it leads to the extrusion of phosphatidylserine.[107] On this basis, Annexin V, a molecule showing high affinity for phosphatidylserine,[108] is coated on nanoparticles which bind to apoptotic spermatozoa so that they are retained in the MACS column, allowing the recovery of nonapoptotic spermatozoa for their use in ARTs[109] **(Fig. 7)**.

This technique was first used by Grunewald, et al.,[110] in 2001 for selection of sperm enriched in nonapoptotic spermatozoa which retained membrane integrity using Annexin V MACS (AV-MACS) in the human clinical practice, demonstrating the utility of this technique. In a study of selection of sperm from semen samples of 35 healthy donors by Said, et al., (2006)[30], AV-MACS method reported spermatozoa enriched with lower DNA fragmentation and higher oocyte penetration capacity. Similarly, using this method, Zahedi, et al., (2013)[103] also reported in both fertile and nonfertile (terato- and asthenozoospermia) males, an enrichment of spermatozoa with lower DNA fragmentation. Interestingly, spermatozoa from idiopathic infertile males and patients affected by varicocele, in the studies carried out by Lee, et al., (2010)[31] and Degheidy, et al., (2015)[111], when subjected to AV-MACS technique of sperm selection showed significantly low DNA fragmentation and intact motility compared to original semen sample. However, a number of studies comparing AV-MACS with SU and DGC questioned the actual efficiency of this technique for the enhancement of spermatozoa with higher quality. So, semen form infertile patients with variable etiologies were treated with AV-MACS followed by DGC by Tavalaee, et al., (2012).[112] The combination of these two techniques proved to be more efficient at enriching permatozoa with lower DNA fragmentation than both procedures individually or DGC followed by AV-MACS. Nadalini, et al., (2014)[113] obtained better results with DGC followed by SU than with DGC followed by AV-MACS in terms of sperm quality. However, no significant differences were found in overall sperm quality and DNA fragmentation by using AV-MACS, SU, DG, SU/AV-MACS, and DG/AV-MACS[114] perhaps due to the low sample size of the study.

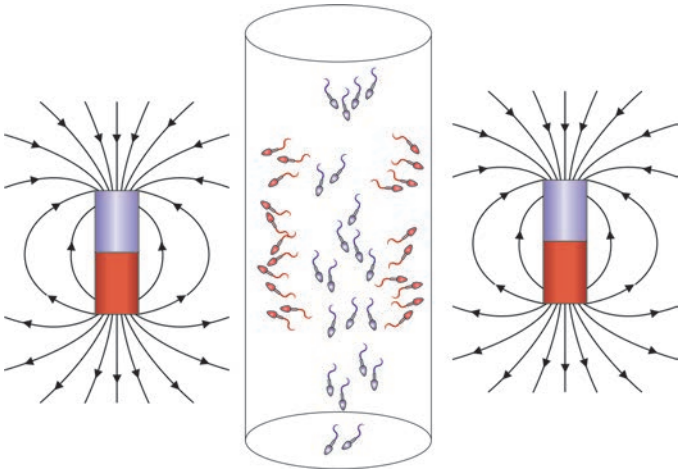

Fig. 7: Example of Annexin V magnetic activated cell sorting: Apoptotic spermatozoa (red in the figure) are bound to magnetic nanoparticles coated with Annexin V and affinity to the externalized phosphatidylserine in this sperm population. Semen is then passed through a column with magnetos on the side, thus apoptotic spermatozoa are retained and nonapoptotic are washed out for downstream applications.

On the contrary, a better quality of motility and DNA fragmentation in spermatozoa selected by AV-MACS followed by DCG was obtained by Berteli, et al., (2017)[115] compared to the other combinations tested: DCG and AV-MACS alone or DCG followed by AV-MACS. Recently, Zhang et al. (2018)[116] reported similar results with the combination of DCG followed by AV-MACS in immotile sperm samples resulting in the recovery of a sperm population with lower DNA fragmentation compared to DGC alone. This result is in agreement with Esbert, et al., (2017)[117] who reported that DGC followed by AV-MACS reduced the number of spermatozoa having chromosomal abnormalities.

Earlier, the results were scarce and unclear in using sperm selection technique of AV-MACS for ART. In comparison with DGC, sperm selected by AV-MACS prior to ICSI in 196 oligoasthenozoospemic patients showed higher cleavage and pregnancy rates in an early study by Dirican, et al., (2008).[33] Sperm selected from cryopreserved semen samples in 237 infertile couples by SU preparation method or SU followed by AV-MACS method before ICSI in donor oocyte cycles resulted in no difference in fertilization rates, embryo quality, implantation and live birth rates.[118] García-Ferreyra et al. (2014)[119] reported higher, but not statically significant pregnancy and implantation rates when semen showing basal high DNA fragmentation was selected by AV-MACS followed by DGC, compared to DGC alone in ICSI treatments. These results are supported by those reported by Stimpfel et al. (2018)[120] in couples of teratozoospermic patients and women over 30 years old undergoing ICSI, showing higher quality blastocysts when spermatozoa were selected by DGC/SU followed by AV-MACS, compared to

DGC/SU. Recently, a significantly higher top quality embryos and clinical pregnancies were reported by Ziarati, et al., (2019)[121] reported a significant increase in the percentage of high-quality embryos and clinical pregnancies in 80 infertile couples undergoing ICSI with mainly moderate or severe male factor employing DGC followed by when compared to DGC alone.

Collectively these studies indicate that the combination of DGC and MACS can provide slight benefits in patients with male factor undergoing ICSI in terms of clinical pregnancy. However, it is not clear to which extent live birth rate is actually improved. Thus, the combination of AV-MACS with other sperm preparation methods could be determinant for improving ART. More experiments, comprising larger number of patients, and exploring the different variables involved, are needed in order to confirm the utility of AV-MACS for the human clinical practice.

HYALURONIC ACID BINDING

One of the main components of the extracellular matrix surrounding the cumulus-oocyte complex (COC) is the hyaluronic acid (HA).[122] During completion of spermatogenesis followed by adequate maturation in spermiogenesis, mature human sperm membrane develop and exhibit binding sites to it.[123,124] Based on sperm–HA interaction or binding, two techniques of sperm selection have been developed:

i. Recovering spermatozoa that are trapped and stuck on the surface of HA coated dish.[124]
ii. Picking up spermatozoa those move very slowly while swimming in a medium containing HA in solution[125] **(Fig. 8)**.

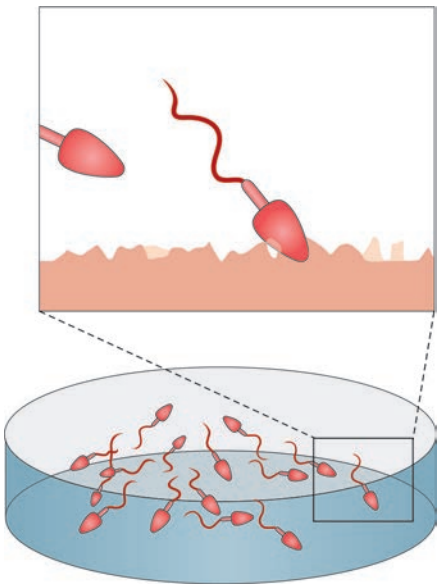

Fig. 8: Example of method for sperm selection based on hyaluronic acid-binding. Spermatozoa are placed on a dish coated with hyaluronic acid (HA, orange in the figure). Matured spermatozoa bind to the surface due to their interaction with the HA. These spermatozoa can be then recovered for ICSI using a micromanipulation system.

To date, two methods for HA binding are in use, namely, the picked spermatozoa for ICSI (PICSI) dish (hyaluronan-coated chamber) and a hyaluronan-containing medium. Both methods are ready to use systems that are commercially available and have received official recognition for conformity with health and safety requirements in the EU and the United States.

PICSI DISH

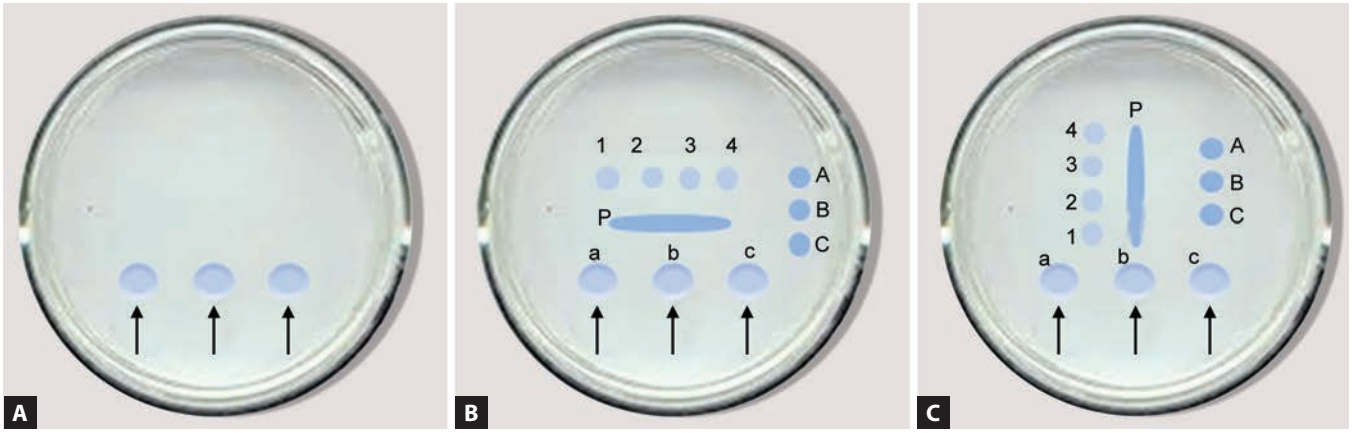
Principally, the PICSI dish is a Petri dish that has spots of immobilized HA on it as shown in **Figures 9A to C**. Washed or density gradient-prepared spermatozoa suspensions are placed on top of these spots of HA and incubated for 15 minutes at 37°C. Subsequently, the freely moving spermatozoa are removed by gently rinsing the HA droplet and removing the nonbound sperm. Finally, the bound spermatozoa can be picked (P) with an ICSI pipette (hence, PICSI)[126] as shown in **Figures 9A to C**.

HYALURONAN-CONTAINING MEDIUM

The alternative to the PICSI dish is a viscous medium containing HA. Here, a 5 mL droplet of density gradient-prepared spermatozoa is connected with a pipette tip to a 5 mL droplet of sperm slow medium by dragging the suspension into contact and incubated for 15 minutes at 37°C under oil. Afterward, spermatozoa bound to HA at the interface of the two droplets are selected with an ICSI pipette[127] as shown in **Figure 10**.

Both these methods have capacity to select spermatozoa which have reduced DNA fragmentation. While using HA-coated dish for sperm selection, an inverse correlation was established, among HA bound spermatozoa and protamine deficiency, DNA fragmentation, and abnormal sperm morphology in original sample.[128] In contrast, Razavi, et al., (2010)[104] reported same DNA fragmentation in spermatozoa isolated using HA coated dish and the ones in which dish was not used. But very soon, many others reported higher DNA integrity in spermatozoa selected by HA-binding technique.[126,129,130] Furthermore, Parmegiani, et al., (2010)[128] and Huang, et al., (2015)[131] observed lower DNA fragmentation in spermatozoa selected in HA solution compared to SU, and by HA coated dishes compared to DGC, respectively. However, both HA and HA coated dish studies reported similar levels of DNA fragmentation when compared to spermatozoa selected under the microscope regarding motility and morphological features. Similarly, Mongkolchaipak and Vutyavanich (2013)[129,130] did not find any difference between DGC/HA coated dishes and DGC/intracytoplasmic IMSI respect to sperm DNA fragmentation. These results question the utility of sperm selection based on HA-binding.

Parmegiani, et al., (2010)[132] compared reproductive outcome in 331 patients undergoing ICSI using HA solution



Figs. 9A to C: PICSI dish.

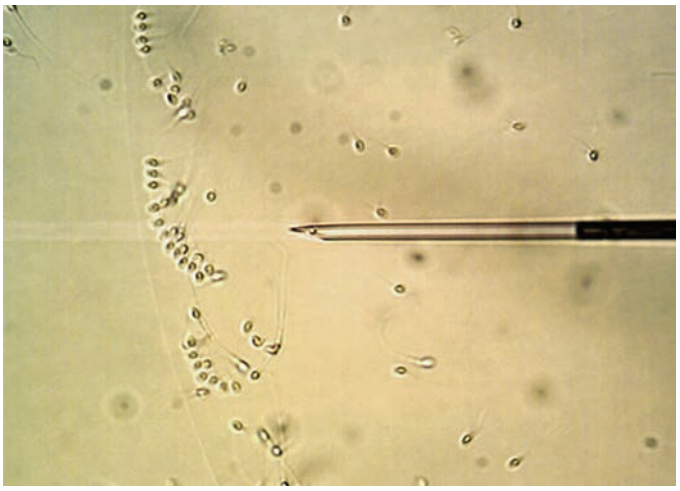


Fig. 10: Hyaluronan containing medium.

(293 patients) and conventional ICSI (86 patients) with no differences in clinical pregnancies or live birth ratios though an improved in embryo quality and implantation rate was observed. In another study, the same authors reported comparable results employing 206 oligozoospermic patients (Parmegiani, et al., 2010).[126] Subsequent studies reported similar results using either HA-coated dishes or HA solution.[133-136] Interestingly however, Worrilow, et al., (2013)[137] found that HA-coated dishes in sperm selection significantly increased pregnancy [136,137] and live birth rate (Mokánszki, et al., 2014)[136] in patients undergoing ICSI when selected sperm had HA-binding capacity ≤65%, as measured by the Hyaluronan binding assay. As a result of which a conclusion can be derived that the HA-binding selection method could be useful only in specific cases and indicates the need of a basic semen analysis for determining the suitability of the technique. Erberelli, et al., (2017)[138] therefore reported a significant improvement of ICSI using HA-coated dishes in patients with various categories of male factor. The results suggested that the benefit of this method could be higher for teratozoospermic patients. In a randomized study employing a large number of patients (2772 couples), Miller et al. (2019)[139] did not find any significant benefit of HA-coated dishes compared to conventional ICSI and either detected an association between results of Hyaluronan binding assay and ICSI outcomes, contradicting previous works above described. These results collectively show a poor capacity of HA binding methods for improving ICSI; however, more studies are needed to identify the types of patients that could benefit from this procedure.

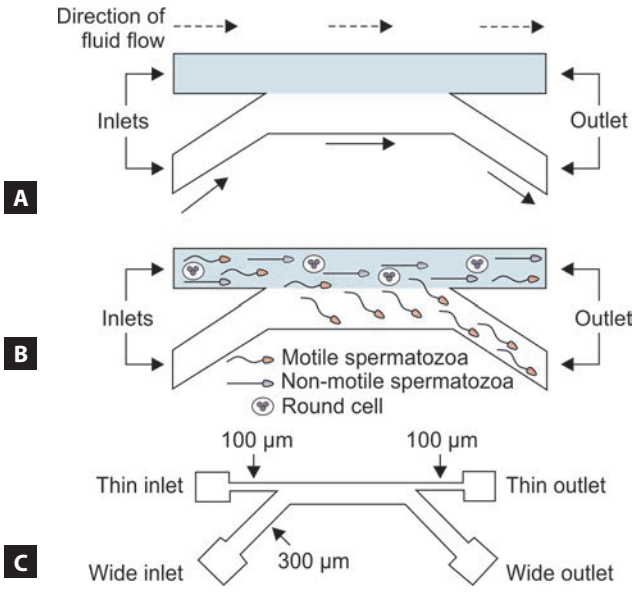
MICROFLUIDIC ISOLATION OF MOTILE SPERMATOZOA

With the advent of (ICSI), men with severe oligozoospermia are now offered the opportunity to reproduce their own child. In addition to low sperm counts, semen samples from these patients often have large amounts of cellular debris. Consequently, swim-up from a pellet is not a viable option to prepare these sperm samples. Additionally, due to the extremely low yield of motile spermatozoa with the other isolation methods discussed, the number of viable spermatozoa available after processing for use in ICSI is limited and occasionally prohibitive for this group of men. Because of this, new sperm isolation methods are required for this patient population.

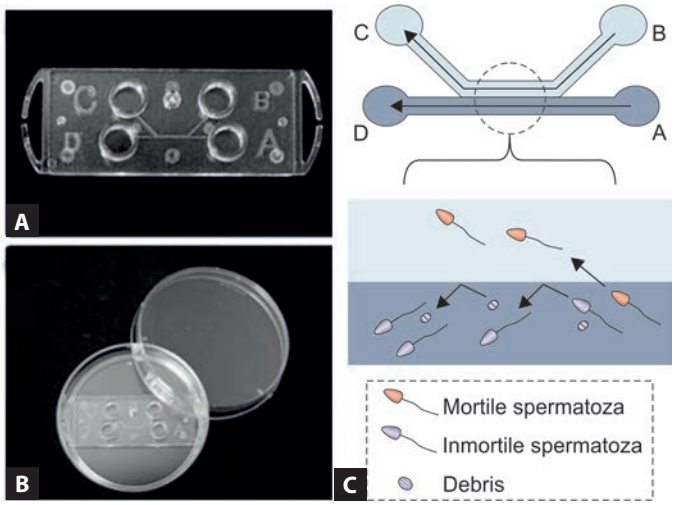
The field of microfluidics is a new area of biomedical engineering concerned with the microscopic flow of fluids. At the microscopic level, streams of fluid will maintain laminar rather than turbulent flow. Because viscous forces dominate over inertial forces in these small flows, two separate streams of fluid with laminar flow can be placed parallel to each other with the two streams mixing only by diffusion despite there being no physical barrier between them. Multiple laminar flow systems have previously been utilized to perform diffusion based separation,[140] to detect molecules,[141] to fabricate microstructures in capillaries,[142] and to pattern cells and their environments.[143] It was thought that this unique feature of microscopic fluid flow could be

utilized to separate motile spermatozoa from the remainder of the semen sample **(Figs. 11A to C)**. Theoretically, a stream of semen could be flowed in parallel to a stream of media. Given the nature of laminar flow, only motile spermatozoa could cross from semen into the parallel stream and subsequently be sorted from the initial stream when the two fluids move away **(Figs. 12A to C)**.

The microfluidic sperm sorting channel was designed to provide a laminar flow sorting system where nonmotile spermatozoa and debris would flow along their initial streamlines and exit one outlet whereas motile spermatozoa would have a higher probability of deviating into the parallel stream and exiting through a different outlet. The widths of the streams were designed for a ratio of 1:3 with the intention of placing the unsorted samples in the thinner inlet channel. Additionally, a microfluidic gravity and capillary force driven pump was designed to maintain a steady flow rate of ~8 nL/s regardless of the fluid level in the reservoir. Channels were made using photolithography for fabrication of the silicon wafer master with the design shown in **Figure 11B** and replica moulding for preparing the polydimethylsiloxane (PDMS) channels from the master. The channels and a glass slide were plasma oxidized for 5 minutes using a Plasma Prep IITM Chamber. This allowed the channels to seal onto the slide and to make the inner surface of the channels hydrophilic, which improved liquid flow inside the channels enough that no additional bovine serum albumin (BSA) was needed for most semen samples.



Figs. 11A to C: Passively driven microfluidic device for sperm sorting based on motility. (A) Represents the flow direction; (B) Illustrates the sperm cells crossing streams; (C) Dimensions of the channels are at the micrometer scale.



Figs. 12A to C: (A) A microfluidic sperm sorter (MFSS) device; (B) The MFSS fixed in a 60-mm dish for easy handling; (C) Schematic representation of the microfluidic sperm sorting principle: an illustration of two laminar flows (A→D and B→C) in the MFSS channel.

Semen samples are obtained from men undergoing evaluation for infertility after a minimum of 3 days of abstinence. After liquefaction, a semen analysis is performed by a single individual and consisted of assessment of semen volume, pH, viscosity, liquefaction, sperm count, sperm motility, sperm agglutination, strict sperm morphology, and cell contamination. Semen samples containing spermatozoa with forward progression are selected for separation.

The other half of each semen sample is processed using the microfluidic sperm sorter (MFSS) QUALIS, which is a cycloolefin polymer-based microfluidics sperm sorting chip. Before sperm separation, semen samples were filtered using a 20 mm pore size filter to remove foreign bodies. Each ejaculated sample was carefully diluted 1:1 with sperm sorting medium [HTF medium with 10% serum substitute supplement (SSS)] and maintained at approximately 37°C before using the MFSS.

After fixing the MFSS in a 60 mm dish, 100 mL of the sperm-sorting medium was loaded in chambers A, B, C, and D to create streamlines in the microfluidics channels as shown in lower half of **Figure 12B**. After the medium was removed from all chambers, 20 µL of the medium is loaded in chambers C and D, 100 µL of the medium is loaded in chamber B, and 65 µL of sperm suspension is loaded in chamber A. The average number of spermatozoa in 65 µL of sperm suspension is 300×10^3 sperm. The amount of medium in chamber B is adjusted such that the width of the laminar flow from chamber A is approximately 40% of the overall width of the central microchannel under the microscope. After 30 minutes, completely isolated spermatozoa (25–30 mL) were extracted from chamber C. The contents of chamber C are collected and stored together before IUI, IVF, or ICSI depending quality of semen.

In a study,[144] the MFSS method was significantly more effective than the centrifugation and swim-up procedure in regards to higher motility and lower DNA fragmentation

index (DFI) of sperm but not for number of sperm isolated. The MFSS method allows selection of sperm with high DNA integrity.[145] The study reported the possibility of decreasing sperm DFI to 1% by using an MFSS device. In a previous study,[146] DNA fragmentation after the centrifugation and swim-up processing was 12 and 6%, respectively, and motility after only centrifugation and combination with centrifugation and swim-up processing was 67 and 84%, respectively.

Thus, the MFSS method is considerably more efficient than the centrifugation and swim-up procedure. The risk of selecting sperm with DNA fragmentation decreases to 1 in 10 by using the MFSS method compared with the centrifugation and swim-up procedure.

A very small quantity of sperm can be collected from compromised semen quality samples using the MFSS. However, even a small number of normal sperm are sufficient for ICSI. The MFSS is adequate for clinical use in ICSI. Semen processing using the centrifugation and swim-up procedure may take up to 2 hours. However, with the MFSS, a one-step sorting protocol without centrifugation is possible and it can complete processing within 30–45 minutes.[147] Reducing the treatment time and eliminating the centrifugation step may minimize sperm exposure to concentrated ROS and prevent DNA fragmentation.[25]

SPERM SELECTION BASED ON GUIDANCE MECHANISMS

A physiological mechanism for guidance of sperm within the female genital tract has been suggested for selection of spermatozoa which are capable of fertilizing an oocyte, development of a viable embryo to ensure implantation that is carried forward to full term. Hence, a strategy should be employed to develop new sperm selection technique in vitro that is based on the same principle of guidance of spermatozoa in the female genital tract. As a result of which, three known mechanisms have been proposed to guide the spermatozoa within the oviduct and they are being tested accordingly for their capacity to select spermatozoa with the aim of improving ART results.

Rheotaxis

It is proved that human and mice spermatozoa swim against the direction of fluid flow.[148,149] This natural feature of sperm is known as "rheotaxis." The first study conducted by De Martin, et al.,[150] (2017) to select sperm from donors with normozoospermia employing rheotaxis process. It reported that sperm selected in this manner were enriched with higher chromatin compaction (99%) as compared to (71%) in original sample before selection. It was higher than even sperm selected using DGC (83%) **(Fig. 13)**.

Thus, the results in animal studies reported to date are promising, but the passive nature of rheotaxis, which is based on the hydrodynamics of the motile spermatozoa,[151] indicates that this mechanism has poor selective potential beyond the separation of those spermatozoa with a correct swimming behavior. Although this is the in vitro situation, the in vivo picture could be drastically different.

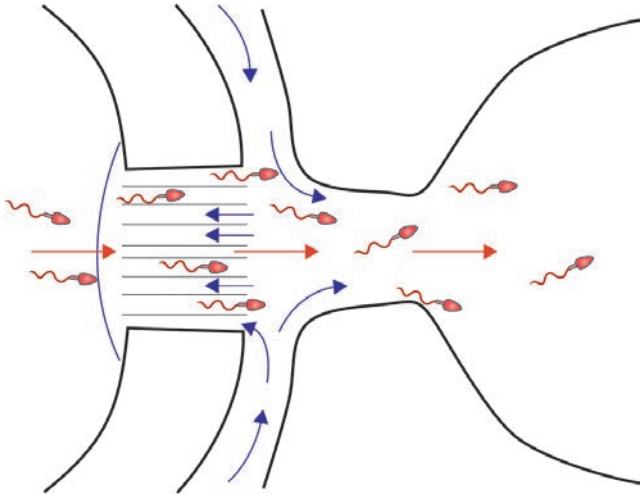


Fig. 13: Method of sperm selection by rheotaxis developed by Nagata, et al., (2018). A flow (blue arrows) is created through a serial of microchannels toward a well were sperm sample is placed. In response to the flow the spermatozoa swim toward it passing through the microchannels and accumulating in a receptive well where they can be collected for downstream applications (red arrows indicate migration of the sperm).

So, rheotaxis would be part of a selection system of capacitated spermatozoa allowing only this subpopulation of spermatozoa to migrate toward the in vivo fertilization site. In vitro developed procedures could test this hypothesis for sperm selection by rheotaxis. That would be an effective way of selecting capacitated spermatozoa for improving ART results.

Chemotaxis

Chemotaxis, a mechanism of navigation used by spermatozoa when they come in the proximity of oocyte where chemical components released by combined estrogen and progestin oral contraceptive pill (COC) such as progesterone (P4) attracts them (P4 acts as chemoattractant) to orient their swimming pattern toward zona of an oocyte.[152] It is important to note that only capacitated spermatozoa are attracted by chemotaxis. That is how the property of capacitated sperm allows the selection of this specific subpopulation[152] **(Fig. 14)**.

Gatica, et al.,[153] (2013) selected spermatozoa from both normozoospermic donors and subfertile patients by employing P4 gradient in a simple device named "Sperm Selection Assay" (SSA). It was found that the selected spermatozoa had three fold capacitated sperm with much lesser DNA fragmentation and less oxidative stress than the original semen sample, in both the cases. Li, et al.,[154]

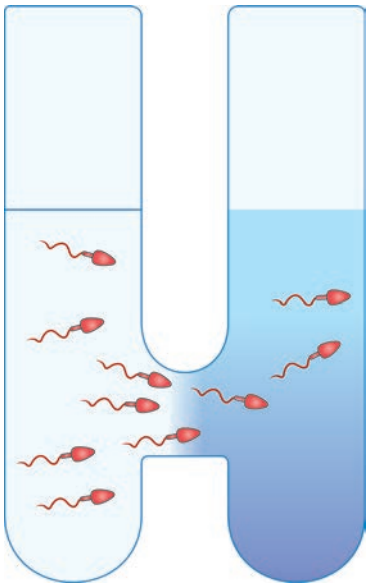

Fig. 14: Method of sperm selection by chemotaxis developed by Gatica, et al., (2013): Two wells are connected by a 2 mm length per 2.5 mm diameter tube. One of the wells is filled with a medium containing the chemoattractant molecule in solution (colored in blue) and the other well is filled with the spermatozoa suspension. The chemoattractant diffuses through the connecting tube generating a gradient and the spermatozoa respond by migrating toward the higher concentration and accumulating in the initial well free of cells where they can be collected for downstream applications.

(2018) also reported an improvement in the sperm quality from normozoospermic donors in terms of normal morphology, lower DNA fragmentation, and lower percentage of apoptotic spermatozoa when using another device composed of a system of microfluidic channels. However, the effectiveness of sperm selection by chemotaxis in the improvement of ART in clinical practice has not been studied to date.

Thermotaxis

Thermotaxis is a process in which sperm is oriented to swim in the direction of higher temperature in a gradient.[155] Evidence indicates that this mechanism allows sperm to orient itself in the fallopian tubes to ascend to the ampulla.[148] As in chemotaxis, only capacitated spermatozoa respond to thermotactic stimuli, so based on it, this subpopulation could be selected[155] **(Fig. 15)**.

The use of these selected spermatozoa for ICSI in mice increased cleavage rates and blastocyst production, as well as implantation and live birth rate as opposed to the use of spermatozoa selected by SU. Although this is the only work in thermotaxis in ART, a recent study carried out in bulls has shown that seminal samples delivering high pregnancy rates after artificial insemination show a greater response to thermotaxis.[156] However, as in the case of rheotaxis and chemotaxis, there are still no available publications showing

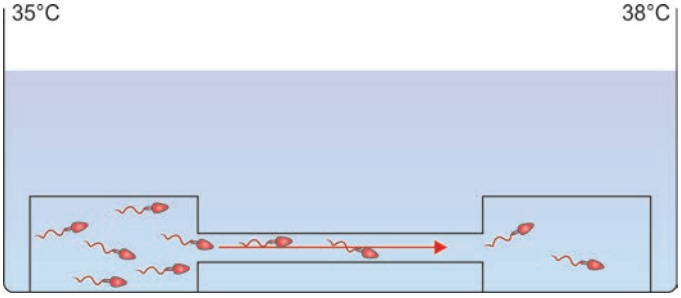

Fig. 15: Method of sperm selection by thermotaxis developed by Pérez-Cerezales, et al., (2018). Spermatozoa are placed on a drop of a medium connected by a capillary to a second drop free of cells. A temperature gradient is generated between both drops being the highest temperature at the place of the drop free of cells. Spermatozoa respond by thermotaxis migrating toward the warmer temperature and accumulating in the second drop where they can be collected for downstream applications (2003).

the capability of sperm selection by thermotaxis to improve the ART efficiency in the human clinic.

CONCLUSION

The efficiency of ART has tremendous scope for improvement in terms of laboratory techniques, developmental embryology and pregnancy outcome. Sperm selection is an important factor for achieving higher live birth rates in ART, especially in compromised male factor. However, the techniques developed to date have failed partially to be useful for their routine application in the clinical practice and seemed to have limited scope only in specific cases of malefactor. Some novel methods described in this chapter based on the principles of physiological selection operating in vivo and on microfluidic environments have delivered promising results yet to be confirmed in large studies in the context of clinical practice. These studies should be randomized and strict in the confrontation of results with several compromised semen samples minimizing the female factor. The key factor is to combine various sperm selection techniques to increase the efficiency of the ART.

FUTURE DEVELOPMENT OF SPERM PREPARATION TECHNIQUES

As sperm selection by a fertile female usually permits only those male germ cells that exhibit normal nuclear DNA integrity access to the oocyte, any artificial selection method mimicking the biological situation should monitor this essential parameter. However, all currently employed methods to determine DNA damage (TUNEL assay, SCSA, COMET assay, Halosperm assay, etc.) are invasive and therefore consumptive.

Clinical application of novel, more physiological sperm selection techniques demands that such techniques are noninvasive, safe, highly discriminative, and relatively easy to perform. Moreover, it is imperative for any new method

that sperm functions are maintained as much as possible and not compromised. These requirements might come at the cost of relatively expensive equipment or procedures.

Recently developed techniques that are noninvasive and therefore have the potential to be used for isolation of potentially fertilizing spermatozoa are more sophisticated and more expensive than those that are currently used in ART and include Raman microspectrometry, confocal light absorption, and scattering spectroscopic microscopy and polarization microscopy. At present, all of these are only in experimental stages and specific recommendations for routine application cannot be made.

KEY POINTS

Despite significant improvements in human sperm preparation methods during recent years, our knowledge about the physiological sperm selection processes in the female reproductive tract is still fragmentary, as can be noticed from contradictory reports of the effect of certain selection methods on sperm function and IVF/ICSI results. If the physiological processes could be mimicked, the number of spermatozoa used for insemination in IUI or IVF would not only be drastically reduced, but the quality of spermatozoa that would be used for ICSI would increase. Additionally, success rates of assisted reproduction would improve, as good quality spermatozoa bearing a genome of highest integrity would be selected.

Nevertheless, no simple solution to this dilemma is available, and certainly, the efforts in minimizing mutagenic or lethal effects of DNA damage will not come cheap, which might also be a problem, particularly in developing countries. Human reproductive scientists and clinicians are not only doing their utmost to assist infertile couples to fulfil their wish for a child, as the WHO recognizes infertility as disease, but have also the duty to minimize the risks of ART for both the parents and progeny. Consequently, scientists have to understand the fertilization process better and search for the most physiological methods for human sperm selection. Nevertheless, despite progress that has been made to select and identify the most suitable spermatozoa for human-assisted reproduction, most of the new techniques are large-scaled and therefore expensive. With respect to future developments, more confirming and expanded data remain to be seen as individual groups have presented only preliminary results.

CHAPTER 102

Semen Banking

Guruprasad Kalthur, Sandhya Kumari, Satish Kumar Adiga

INTRODUCTION

Semen banking has become an integral part of reproductive medicine field, in which spermatozoa in the ejaculate are stored at subzero temperatures for future purpose. Theoretically, the spermatozoa can be maintained in its viable form for an indefinite period provided the storage conditions are good. The concept of semen banking has completely changed the infertility practice and cancer treatment in the recent years. This chapter gives an overview of various aspects of semen banking and the latest developments in the semen cryopreservation field.

HISTORY OF SEMEN BANKING

The first observation of semen cryopreservation was made by an Italian physiologist Lazzaro Spallanzani in 1776. He observed that the spermatozoa from frog which were motionless when cooled by snow were able to regain their motility upon warming. Even though Montegazza was the first one to propose the concept of semen banking for soldiers as a method of having a legal heir with their frozen semen in mid 1800s itself, the first major breakthrough in semen cryopreservation was achieved only in 1949 by Polge, Smith and Parke1 using glycerol as cryoprotective agent. The first successful pregnancy from frozen-thawed spermatozoa was reported in 1953 by Bunge and Sherman. Their report also indicated that cryopreservation does not affect the fertilizing ability of the spermatozoa and development of embryos derived from such spermatozoa.[2] Ever since this report, in last five decades, a steady progress has been witnessed in the methodological approach to the cryobiology of human spermatozoa **(Table 1)**.

PROTOCOLS

Despite the fact that semen cryopreservation is practiced since several years, we still do not have a gold standard method, which is universally accepted and induces minimum damage to spermatozoa. The currently employed semen cryopreservation techniques vary with respect to the components present in the freezing medium, type of sample used, and the freezing method followed.

Media Composition

The conventional semen cryopreservation medium is usually composed of a penetrating cryoprotectant (glycerol), nonpenetrating cryoprotectant (sucrose), semen extender (egg yolk/serum albumin/lipoproteins), and buffer system

TABLE 1: Milestones in semen cryopreservation.

Year	*Breakthrough*	*Group*
1776	Viable sperm recovered from dead man buried in ice	Lazzaro Spallanzani[34,38]
1866	Suggested that soldier could produce a legal heir with stored semen sample	Paolo Montegazza[35,39]
1949	Spermatozoa can be frozen and thawed without loss of motility by includingglycerol in the suspending medium	Polge et al.[1]
1953	Normal embryonic development from freeze-dried spermatozoa	Bunge and Sherman[2]
1964	First child born from sperm frozen in liquid nitrogen	Perloff et al.[36,40]
1970s	Mandatory semen freezing for the United States military men	—
1995	First birth from frozen epididymal sperm	Devroey et al.[37,41]
1996	First birth from frozen testicular sperm	Gil-Salom et al.[38,42]
At present	Integral part of andrology lab/assisted reproductive technique clinic	—

{Tris/2-[4-(2-Hydroxyethyl)-1-piperazinyl]ethanesulfonic acid (HEPES)/citrate buffer} and osmolytes (glycine). Egg yolk, though rich in membrane lipids such as cholesterol and phospholipids, the major drawbacks are its variability in composition based on the nutritional status and health conditions of hen, infectious microorganisms of avian origin and, possible risk of endotoxins. In this direction, efforts to cryopreserve the human spermatozoa in medium devoid of egg yolk have been successfully achieved.[3] Use of low density lipoprotein has been shown to enhance the cryosurvival of bull,[4] buffalo[5] and rabbit[6] spermatozoa. For short-term storage, electrolyte free medium has been successfully demonstrated in human spermatozoa at low temperature.[7] Further studies are necessary to confirm whether it is possible to store the spermatozoa in liquid nitrogen using electrolyte free medium

Type of Sample

- *Cryopreservation of neat ejaculate:* In this approach, the liquefied semen samples are mixed with semen freezing medium and subjected to cryopreservation. The advantage with this approach is that the seminal plasma is very rich in some of the antioxidants, which can minimize the freeze-thaw-induced damage.[8] In addition, the decapacitation factors present in the seminal plasma prevent the spermatozoa from undergoing premature capacitation or acrosome reaction.[9] However, the disadvantage with this approach is that the neat ejaculate contains dead spermatozoa, abnormal spermatozoa, round cells, etc., which can increase the generation of reactive oxygen species (ROS) during the cryopreservation process, and thus can reduce the functional competence of the spermatozoa.
- *Cryopreservation of sorted spermatozoa:* To overcome the drawbacks of using neat ejaculate, sorting of the spermatozoa with respect to their quality prior to cryopreservation has been attempted earlier.[10] Extraction of motile spermatozoa fraction from the ejaculate and, elimination of apoptotic spermatozoa, leukocytes and abnormal spermatozoa by simple sperm preparation methods like swim up technique or density gradient separation methods have demonstrated considerable improvement in the outcome of semen cryopreservation.[10,11] However, the major drawback with this approach is that the loss of antioxidants and decapacitation factors present in the seminal plasma, which may lead to poor freeze-thaw outcome.

Storage Devices

Semen samples can be stored in variety of devices. The initial experiments of semen cryopreservation were conducted with glass ampoules as storage materials. However, due to their low surface to volume ratio and fragile nature of the material, loss of precious stored samples due to breakage is most likely. Most popular storage devices currently used are high security plastic straws and cryovials with screw caps. To keep the samples secure and avoid any contact with liquid nitrogen, plastic straws require sealing after loading the semen samples either with any nontoxic adhesive materials, clay, polyvinyl plugs or by heat sealing method. To enable correct identification of the sample, the storage devices have to be labeled with proper patient details.

Cooling and Storage

The storage device containing semen samples are usually exposed to gradual decrease in temperature instead of directly plunging into liquid nitrogen. There are two different protocols—rapid freezing, where the samples are kept at 4°C for 10 minutes followed by 10–15 minutes exposure to liquid nitrogen vapor and then finally placed in liquid nitrogen; in slow cooling protocol, the samples are gradually exposed to decreasing temperature with the help of a programmable freezer. Theoretically, the semen samples can be stored indefinitely provided the storage conditions are maintained properly. There are reports available in the literature indicating successful pregnancy from the semen samples cryopreserved for >20 years.[12,13]

Semen Vitrification

Vitrification is an ultrarapid method of freezing. It is an alternative method of sperm cryopreservation based on the solidification of solution into glass-like state without formation of crystallization or expansion.[14] Increased rate of freezing and the concentration of cryoprotectant in freezing medium help in avoiding ice crystal formation. However, due to toxicity of high concentration of cryoprotectants and direct contact of liquid nitrogen this procedure did not find any advantage compared to conventional cryofreezing method.[15] Cryoprotectant-free technique of vitrification has advantage over other methods since it does not use any permeable cryoprotectants and therefore does not cause any osmotic shock. Birth of two healthy babies from spermatozoa vitrified in absence of permeating cryoprotectant has been reported by Isachenko et al.[16]

Storage Duration

The semen samples can be cryopreserved for long duration provided the storage conditions such as liquid nitrogen level is maintained properly. Few studies have shown that long-term storage of semen sample does not lead to any adverse effects on the motility potential and chromatin integrity of the spermatozoa.[17,18] Clarke et al.[18] have shown that the ability of spermatozoa to undergo acrosome reaction and zona binding potential were retained even after prolonged storage period. Live births have been achieved following intrauterine insemination (IUI) and intracytoplasmic sperm

injection (ICSI) with spermatozoa stored for 28 and 21 years, respectively[12,13] indicating that the storage duration may not have any adverse effect on the functional competence of the spermatozoa. However, genetic instability in spermatozoa due to cosmic radiation is a matter of concern.

Thawing: Like the cooling rate, thawing temperature is also very critical for achieving good post-thaw survival of the spermatozoa. Rapid thawing by incubating the cryovials or the high security straws in a water bath maintained at 37°C is most commonly followed. Once the frozen sample is completely thawed, it is very essential to remove the cryoprotectants completely by washing so that the toxicity exerted by the cryoprotectants can be minimized.

Documentation: A proper documentation system should be used for maintaining the details of the samples stored in liquid nitrogen. Location of each sample, date of semen freezing, number of samples stored from a particular person (donor/infertile man/man opting for fertility preservation), date of expiry of the legal agreement between semen bank and the party for the storage of semen sample, etc., has to be maintained safely. Loss of stored material due to loss of la beling, improper storage method, faulty sealing, etc., can be disastrous situation for the laboratory director. The number of semen samples stored from a particular donor, number of samples released for insemination, number of pregnancies achieved from that particular donor should be recorded. It is very essential to have a signed document that clearly states who will have the rights to access to the spermatozoa of the husband following his death. Usually, the wife becomes the legal heir, who can decide whether to discard the sample or donate it for research.

Indications for Semen Cryopreservation

- *Donor semen samples:* Using donor semen samples for treating male factor infertility is widely accepted method. Since the fresh ejaculates cannot be used for insemination, it is mandatory to cryopreserve the semen samples and quarantine for at least 6 months. Repeated investigation during this quarantine period will help in identification and exclusion of the donor samples infected with sexually transmitted diseases (STDs). Cryopreservation of semen samples from suitable donors will help in creating a bank with wide variety of samples with different blood groups and phenotypes for achieving the best possible matching with recipient.

Selection and recruitment of semen donor: As per the current Indian guidelines,[19,20] semen donors should be anonymous to the recipient. The semen donor should be at least 21-years and not more than 55-years of age, free of any STDs and identifiable genetic disorders. Donor should produce Aadhar card as his proof of identity with a written consent from his wife. Ideally, the semen donor should not have any multiple sexual partners, with good educational background and with good lifestyle habits. The donor should be asked to provide his ejaculate preferably collected in the masturbatorium of the semen bank. As per the current ART (assisted reproductive technique) bill[19] a donor can donate maximum of 25 ejaculates. The ejaculates should be cryopreserved (quarantined) for at least 6 months prior to their release for insemination. The donor should be screened for serostatus once in every 6 months to rule out any sexually transmitted disease (STDs).

The semen bank, which can operate as an independent organization with professionally qualified and trained people, can store the ejaculates from donors with various phenotypic features and blood group. Donor can get a suitable financial remuneration from the bank. It is the responsibility of the semen bank to maintain complete details of the donor including height, weight, age, educational qualifications, profession, color of the skin and the eyes, record of major diseases including any psychiatric disorder, and the family background with respect to history of any familial disorder, number of samples used for insemination, details of blood investigation, etc. The donor should be giving a written consent for using his stored semen samples for insemination. He should be made aware that he will not know the identity of the recipients and the details of the child born through his spermatozoa and will not have any parental rights over the child. The do's and don'ts of semen banking is summarized in **Table 2**.

- *Convenient cryopreservation:* It has become a routine practice now to cryopreserve the semen sample of male partner well in advance of insemination time, whether it is for IUI, in vitro fertilization (IVF) or ICSI. Sometimes, male partner may fail to provide the ejaculate on demand due to psychological stress or anxiety, erectile dysfunction, unscheduled travelling, or poor quality ejaculate may be obtained on the day of the procedure. Cryopreservation of one or two ejaculates well in advance will avoid the cancellation of cycle due to the nonavailability of the spermatozoa, which will have huge psychological and financial burden on the infertile couple.
- *Pooling of ejaculates from men with severe oligozoospermia:* The sperm count and motility in the ejaculate can fluctuate, which can have an impact on the infertility treatment using assisted reproductive technology. Especially in ejaculates from severe oligoasthenoteratozoospermia (OAT), finding the motile spermatozoa on the day of the oocyte retrieval may be technically difficult. Therefore, in OAT, transient azoospermia and in virtual azoospermic cases, storage of multiple ejaculates from male partner can aid in increasing the number of motile spermatozoa fraction in the *safety pool* of the spermatozoa by pooling of many ejaculates. This will be beneficial in the management

TABLE 2: Summary of *do's* and *don'ts* of semen banking as per the recent Assisted Reproductive Technology [(ART) Regulation)] Act 2021, India.[43]

Do's	*Don'ts*
• Registration or renewal of registration under the national ART board • Screening of sperm donors, the collection, screening of semen sample, and storage of semen • Recruiting the donor aged between 21 and 55 years • Obtaining all necessary information about a sperm donor- name of donor, Aadhaar number, address, etc • Taking undertaking in writing from donor about the confidentiality of information. • After 10 years of storage period, allowing the sample to perish or donating to research organizations registered under the national ART Act for research purposes with the consent of the individual • Submission of information about number of donors sample screened, maintained and supplied to the National Registry within a period of one month from the date of receipt of request for such information • Maintaining the records of semen bank for at least 10 years • Transferring the records to a central database of the National Registry upon expiry of the bank • Ensuring the records are available for inspection to the National Board or the National Registry or the State Board or to any other person authorized by the National Board	• Storing donor sample for more than 10 years • Treating woman with sperm derived from more than one man during any one treatment cycle • Mixing the semen from two individuals for the ART procedures • Supplying the sperm of a single donor to more than one commissioning couple • The sale, transfer or use of sperm to any party within or outside India

of ICSI for cryptozoospermic and oligozoospermic men to increase the number of progressively motile spermatozoa[20] and can avoid unnecessary testicular biopsy. In addition, pooling of ejaculates for IUI may be an option in men with borderline semen parameters who cannot afford to undergo expensive treatments like IVF or ICSI.

- *Preoperative and postoperative cryopreservation:* Semen samples can be cryopreserved prior to any surgical treatments such as varicocele ligation, vasectomy or orchidectomy, to protect against possible azoospermia due to any postoperative complication or any unforeseen postoperative course. It is advisable to cryopreserve the spermatozoa prior to planning transurethral resection of the ejaculatory ducts (TURED). This approach will give an opportunity for the men to have children through their cryopreserved spermatozoa with the help of ART in future, if situation make them to plan for a progeny. Spermatozoa collected at the time of surgical procedures (intraoperative cryopreservation) performed for unreconstructable obstructive azoospermia (OA), such as congenital bilateral absence of the vas deferens (CBAVD) can be cryopreserved and used later for ART. Various approaches such as microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), electroejaculation (EE) and TURED have been followed for the sperm retrieval. In addition, it may be a wise option to store the spermatozoa obtained during surgical reconstructive procedures such as vasovasostomy and vasoepididymostomy.

It has become a routine practice now to cryopreserve the testicular spermatozoa obtained during diagnostic testicular biopsy or testicular sperm extraction (TESE). It avoids the pain and cost caused by repeated invasive procedures and, allows proper planning of ovarian stimulation of the female partner without leading to any situation of ICSI cycle getting cancelled with no spermatozoa available for microinjection after oocyte retrieval.

- *Cryopreservation prior to treatment for malignancies:* With advancement in diagnosis and understanding the biology of deadly diseases such as cancer, the disease-free survival rate has gone up. However, the cytotoxic treatments using chemotherapy and/or radiotherapy with other treatment modalities may lead to partial or complete arrest of spermatogenesis.[21] Even if the spermatogenesis is restored, the quality of the spermatozoa produced is known to be poor with high incidence of genetic and epigenetic defects.[22] Since it is difficult to predict the extent of testicular damage and the future fertility potential, it is recommended if the patient can store his semen sample before starting chemotherapy, which can be used by the cancer survivors to have the progeny from their own gametes at a later stage.
- *Cryopreservation prior to treatment for nonmalignant diseases:* Semen cryopreservation prior to any treatment is not only limited to malignant diseases. Men diagnosed with nonmalignant, systemic disease or undergoing any treatment which may have gonadotoxic disease can store their semen sample in advance. Patients undergoing immunosuppressive or cytotoxic therapy for treatment of autoimmune disorders, kidney disorders, diabetes, ulcerative colitis and heart transplants which has risk of loss of testicular function can also store their semen sample. For example, prolonged treatment with sulfasalazine has been shown to depress semen quality and cause reversible infertility.[23]

- *High-risk profession:* Spermatozoa from men involved in high-risk profession such as military services, nuclear reactor, pesticide or heavy metal industries, etc., can be encouraged to store their semen samples well in advance so that loss of fertility due to their high-risk profession can be avoided. However, still there is lack of awareness among people to make use of this option to retain their fertility potential. Even though the postmortem sperm collection and cryopreservation for the wife of the deceased to achieve pregnancy has been attempted in the past, there is a lot of legal and ethical issues involved. Written consent from wife for postmortem sperm retrieval is required and the following points may have to be taken into consideration.
  - Couple must have been planning for a family prior to the death of the husband
  - Death was sudden
  - Death was not due to any disease known to affect spermatogenesis
  - Death was not due to any infective disease that can cause transmission of disease
  - Spermatozoa should be retrieved from the dead man within 24 hours after death
  - Wife must consent for specimen quarantine.
- *Consequences of semen cryopreservation technique on functional competence of spermatozoa:* Studies have shown that at least 50% of spermatozoa are damaged or destroyed by freezing and thawing, due to chemical, physical, and oxidative stress as a result of changes in intracellular and extracellular environment.[24,25] Membrane damage, acrosome swelling, acrosome loss, damaged mitochondrial sheath, etc., are common ultrastructural changes reported. High polyunsaturated fatty acid content and limited cytoplasmic antioxidant defense system makes the spermatozoa highly susceptible to the oxidative stress generated during freeze-thaw process.[26-28] The lipid peroxides generated through oxidative stress and mitochondrial damage leads to high degree of DNA damage[25,29] and epigenetic changes in spermatozoa.[30] In spite of these ultrastructural, genetic and epigenetic changes induced by cryopreservation on spermatozoa, in humans no significant health problems was observed in the progenies born from frozen-thawed spermatozoa.[31]

FUTURE DIRECTION

The goal of semen cryopreservation protocol is to prevent detrimental effects of freeze-thaw process on the sperm functional competence. However, the process is complicated due to biochemically and physically diverse compartments present in the spermatozoa (acrosome, nucleus, mitochondrial-flagellar network), all of which may respond quite differently to freezing and thawing. Since the detrimental effects are thought to be mainly mediated through oxidative stress, supplementation of various antioxidants is considered as future of research in the field of semen cryopreservation. Adding antioxidant enzymes and molecules such as catalase,[32] superoxide dismutase,[33] vitamin E,[34] vitamin C[35] to cryopreservation media has shown promising beneficial role in enhancing the post-thaw functional competence of spermatozoa. Trace elements with known biological functions such as copper, selenium, zinc, etc., have also been shown to prevent the freeze-thaw-induced damage to spermatozoa.[36,37]

CHAPTER 103

History of In Vitro Fertilization

Neelima Gupta

INTRODUCTION

This chapter today would not have been written, rather I should say that there would have been no "history" in in vitro fertilization (IVF), had our pioneers in the field not thought of this innovation and breakthrough in science.

So, I would like to start this chapter by paying tribute to all of them, especially Sir Professor Bob Edwards (September 27, 1925–April 10, 2013), whose sad demise was a huge loss to the whole IVF fraternity.

Although research and great work were constantly happening on this subject, the history of which dates back to 1890 (details here), the world's first IVF baby, Louise Brown, was delivered in July 1978,[1] and the success and development in the field continue thereafter till date.

In 1973, the Monash University team reported in The Lancet, the first pregnancy achieved through IVF of a human oocyte.[2] This pregnancy lasted for only a few days and was a biochemical pregnancy. In the same year, Mr Landrum Shettles made an unsuccessful attempt to perform an IVF due to interdiction by the department chairman at the last minute.[3,4] In 1976, Patrick Steptoe and Robert Edwards reported an ectopic pregnancy. On July 25, 1978, Louise Brown was born in Oldham General Hospital, Greater Manchester, UK, who is the world's first baby to be conceived by IVF due to a successful procedure carried out by Steptoe and Edwards in 1977.[1,5,6] In October 1978, it was reported that Subhash Mukhopadhyay, a relatively unknown physician from Kolkata, India, was performing experiments on his own with primitive instruments and a household refrigerator and this resulted in a test tube baby, later named as "Durga" (alias Kanupriya Agarwal) who was born on October 3, 1978.[7] However, state authorities prevented him from presenting his work at scientific conferences,[8] and in the absence of scientific evidence, his work is not recognized by the international scientific community.

Steptoe and Edwards were responsible for the world's second (confirmed) baby conceived by IVF, Alastair Macdonald, born on January 14, 1979, in Glasgow.[9] A team led by Ian Johnston and Alex Lopata was responsible for Australia's first baby conceived by IVF, Candice Reed, born on June 23, 1980 in Melbourne.[10] It was the subsequent use of stimulated cycles with clomiphene citrate and the use of human chorionic gonadotropin (hCG) to control the time of oocyte maturation, thus controlling the time of collection, that converted IVF from a research tool to clinical treatment.

This was followed by a total of 14 pregnancies resulting in nine births in 1981 with the Monash University team. The Jones team[11] at the Eastern Virginia Medical School in Norfolk, Virginia, further improved stimulated cycles by incorporating the use of a follicle-stimulating hormone (FSH) [urinary human menopausal gonadotropin (uhMG)]. This then became known as controlled ovarian hyperstimulation (COH). Another step forward was the use of gonadotropin-releasing hormone (GnRH) agonists, thus decreasing the need for monitoring by preventing premature ovulation, and more recently, GnRH antagonists, which have a similar function. The additional use of the oral contraceptive pill has allowed the scheduling of IVF cycles, which has made the treatment far more convenient for both staff and patients.

The ability to freeze and subsequently thaw and transfer embryos has significantly improved the feasibility of IVF use.[12] The other very significant milestone in IVF was the development of the intracytoplasmic sperm injection (ICSI) of single sperm by André van Steirteghem and Paul Devroey in Brussels (UZ Brussel), 1992. This has enabled men with minimal sperm production to achieve pregnancies. ICSI is sometimes used in conjunction with sperm recovery, using a testicular fine needle or open testicular biopsy. Using this method, some men with Klinefelter's syndrome, and who would be otherwise infertile, have occasionally been able to achieve pregnancy.[12,13] Thus, IVF has become the final solution for most fertility problems, moving from tubal disease to male factor, idiopathic subfertility, endometriosis, advanced maternal age, and anovulation not responding to ovulation induction.

Robert Edwards was awarded the 2010 Nobel Prize in Physiology or Medicine "for the development of IVF."[14]

HISTORY OF IN VITRO FERTILIZATION

The Milestones

In the 1890s, Walter Heape, a professor and physician at the University of Cambridge, England, used to conduct research on reproduction in animal species. He reported the first case of embryo transplantation in rabbits. This was before the use of IVF and embryo transfer (ET) in human fertility.[15] "Brave New World," a science fiction novel, was published in 1932 by Aldous Huxley, which described the technique of IVF. Then in 1937, an editorial appeared in the New England Journal of Medicine (NEJM 1937, October 21), which is noteworthy.

Pincus and Enzmann first demonstrated successful pregnancy in unmated animals by isolating rabbit ovum and fertilizing and culturing it in a watch glass and later transferring it in a doe, following which they published a paper in 1934 from the Laboratory of General Physiology at Harvard University which was published in the Proceedings of National Academy of Sciences of the United States of America, indicating the possibility of in vitro development of mammalian eggs.

Later, Miriam Menken and John Rock published a paper almost 14 years later, in 1948, in the American Journal of Obstetrics and Gynecology, sharing their experience of IVF of human oocytes retrieved during operations for various medical conditions.

An indisputable evidence of the first successful birth of a mammal (rabbit) by Chang through IVF was published in Nature in 1959. He cultured the newly ovulated eggs with capacitated sperms for 4 hours in a small Carrel flask, paving the way for assisted conception.

Professionals from engineering, cell biology, and anatomy joined hands for further achievements in the field by improving the laboratory equipment quality, refinement of procedures, improved culture media, dishes, and embryo biopsy, which was supported by worldwide social and scientific interactions for further continuation.

Given here is a comprehensive list and review of the major milestones achieved in the field of IVF year-wise, in a chronological order, with relevant references, along with a few pictures of our pioneers.

1965

Robert Edwards along with Georgeanna and Howard Jones attempted in vitro human oocyte fertilization at Johns Hopkins Hospital in the USA **(Figs. 1 to 3)**.[16]

1973

Carl Wood and John Leeton from Monash, Australia, reported the first IVF pregnancy but it resulted in early miscarriage **(Figs. 4 to 6)**.[17]

1976

- First B2 culture medium was developed by Menezo, which was known as "French medium," composition of which reflects tubal and uterine environments of rabbits, sheep, and humans **(Fig. 7)**.

Fig. 1: Laparoscopic retrieval.

Fig. 2: Georgeanna and Howard Jones.

Fig. 3: Robert Edwards.

Fig. 4: Fertilized human oocyte.

Fig. 7: Yves Menezo.

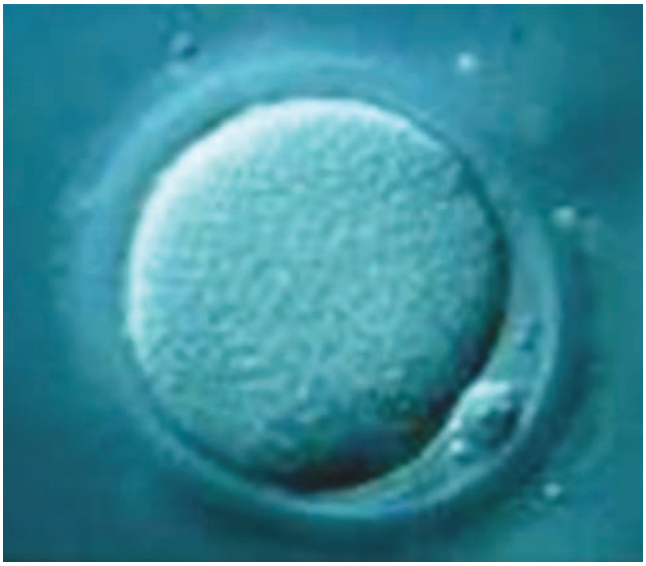

Fig. 5: Human oocyte.

Fig. 8: Birth of Louise Brown.

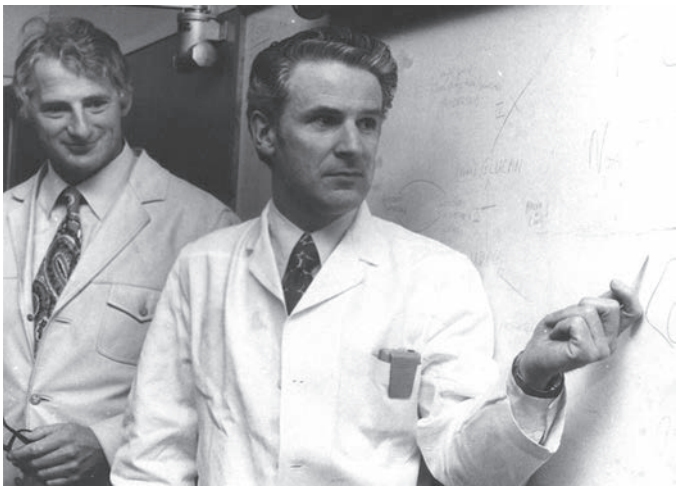

Fig. 6: Carl Wood and John Leeton.

Fig. 9: Steptoe and Edwards.

- In the same year, Steptoe and Edwards published a report in "The Lancet" on an ectopic pregnancy following transfer of a human embryo.[18]

1978

- Steptoe and Edwards reported the first ever IVF birth in Oldham, England, on July 25, 1978 **(Figs. 8 to 10)**.[19]
- First ever clomiphene citrate-stimulated cycle was reported by Lopata in Melbourne **(Fig. 11)**.[20]

Fig. 10: Patrick Steptoe.

Fig. 12: Jacques Testart.

Fig. 11: Alex Lopata.

Fig. 13: Rene Frydman.

1979

- Pez et al. documented the first tracking of the growth of follicles by ultrasound and the relationship between the echographic and laparoscopic observations.[21]
- Use of ultrasound in identifying the growing follicles.[22]

1980

- A joint team by Monash–Melbourne reported the first IVF birth in Australia.[20]
- Introduction of culture medium.[23]

1981

- Delivery of the first IVF baby in the USA by using hMG by Howard and Georgeanna Seegar Jones.
- Introduction of a foot-controlled fixed aspiration pressure control by Wood et al.[24]
- Introduction of clomiphene citrate and human menopausal gonadotropin (hMG) in the IVF treatment protocol.[25]
- First luteinizing hormone (LH) assay to detect initial rise in LH to monitor accurate timing for oocyte retrieval developed by "The Clamart Group in France".[26]

Fig. 14: Lars Hamberger.

1982

- The first French IVF birth occurred in Clamart, France, by the group of Frydman and Testart **(Figs. 12 to 14)**.
- The first IVF birth in Sweden.[27]
- Birth of first Austrian "test tube baby" (twin pregnancy)[28]

Fig. 15: Richard Fleming.

Fig. 17: World's first in vitro fertilization (IVF) conference at Bourn Hall. Front row, from left to right: Bob Edwards, Jean Purdy, Patrick Steptoe, John Webster, and Simon Fishel.

Fig. 16: Susan Lenz.

Fig. 18: Frozen embryos.

- In the same year, use of GnRH was introduced to avoid premature luteinization to get better control on ovarian stimulation **(Fig. 15)**.[29]
- The first publication on the need to delay insemination in order to allow the collected oocytes to complete their maturation over the next 2–4 hours.[30]
- Susan Lenz and Jurgen G. Lauritsen demonstrated transabdominal transvesical oocyte aspiration using an ultrasound-guided needle **(Fig. 16)**.[31]
- Ian Craft in London reported a pregnancy from transfer of gametes to the uterus **(Fig. 17)**.[32]

1983

- First pregnancy was reported by the Monash IVF team in women without ovaries using donor eggs and exogenous hormones to induce artificial menstruation and support the pregnancy for the first 10 weeks.[33]
- The same team reported the first human frozen ET delivered baby **(Fig. 18)** although Cambridge had already reported the same in cattle.[34]
- In vitro maturation (IVM) of morphologically immature oocytes followed by fertilization of the same **(Fig. 19)**.[35]
- Embryo donation followed by pregnancy and successful delivery[33,36]
- Casper and his colleagues for the first time described the luteal phase support by using low-dose hCG in assisted reproductive technology (ART) cycle **(Fig. 20)**.[37]
- First time egg retrieval per vagina by Gleicher and his group by using abdominal ultrasound **(Fig. 21)**.[38]
- University of British Columbia reported its first Canadian IVF baby **(Fig. 22)**.
- Christopher Chen reported the world's first triplets through IVF.
- The first report on transfer of freeze–thaw eight-cell embryo, which led to pregnancy[34]
- First report on the use of follicular steroids as a prognostic indicator for successful IVF **(Fig. 23)**[39]

Fig. 19: Alan Trounson.

Fig. 22: Victor Gomel.

Fig. 20: Robert Casper.

Fig. 23: Simon Fishel.

Fig. 21: Norbert Gleicher.

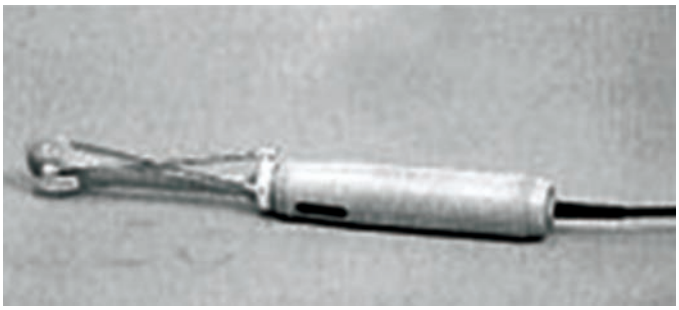

Fig. 24: Kretztechnik's mechanical rotary vaginal scanner in 1985 with puncture attachment.

1984

- The Government of Victoria established the first legislation to regulate IVF and the research on human embryos, which led to the proclamation of Medical Procedures Act, 1984.
- California reported its first baby born through surrogacy.
- First successful translaparoscopic gamete intrafallopian transfer (GIFT) procedure of pregnancy **(Fig. 24)**.[40]
- The first report on successful pregnancy in women with primary ovarian failure following egg donation.[41]
- GnRH agonists were introduced the first time for IVF protocol.[42]
- A report on the transfer of first intact frozen–thawed embryo followed by pregnancy.[43]

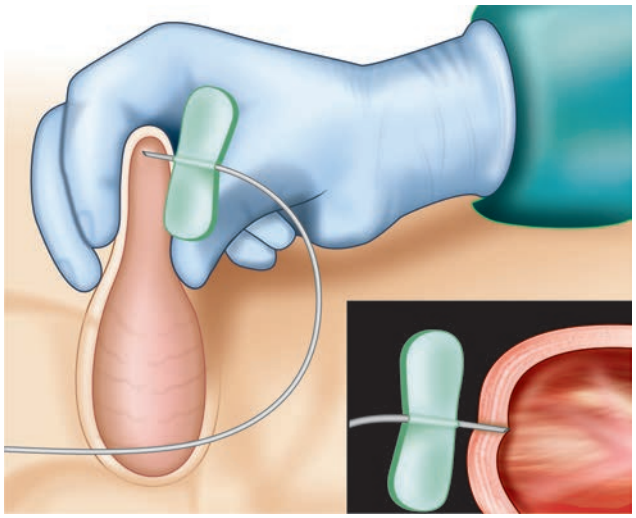

Fig. 25: Epididymis sperm aspiration.

Fig. 27: Ultrasound image of follicles.

Fig. 26: Vaginal oocyte aspiration.

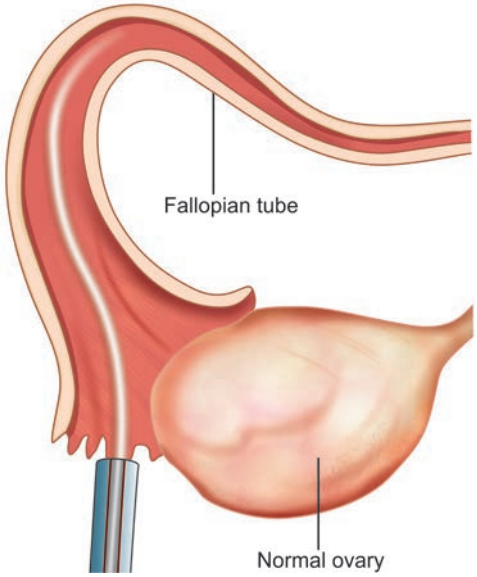

Fig. 28: Gamete intrafallopian transfer (GIFT) procedure.

- A novel work about the possibility that abnormal spermatozoa could be enriched and give rise to healthy babies were reported.[44]
- Demonstrating of hCG secretion by the human embryo.[45]
- The world's first quadruplets through IVF in Melbourne.

1985

- Human pregnancy by IVF using sperm aspirated from the epididymis **(Fig. 25)**.[46]
- Matts Wikland and associates for the first time described the possibility of oocyte aspiration using a vaginal sector scanner (transvaginal technique) **(Fig. 26)**.[47]
- First report on ET with the help of abdominal ultrasound guidance **(Fig. 27)**[48]
- Freeze–thaw transfer of hatched blastocyst followed by successful birth **(Fig. 28)**[49]
- Introduction of human tubal fluid (HTF) by Quinn and Warnes that mimics the in vivo environment[50]
- First delivery resulting from gestational surrogacy[51]
- First successful egg donation in Europe[52]
- Artificial induction of the endometrial cycle in the absence of ovaries was reported by Navot et al.,[53] although it was published 1 year later in 1986.

1986

- World's first pregnancy was reported by the Monash IVF team from surgical retrieval of sperm on a patient with a blocked sperm duct **(Fig. 29)**.
- First description of transvaginal sector scan sonography for needle-guided transvaginal follicle aspiration[54]
- First pregnancy, following IVF donated oocytes, in a nonovarian failure patient **(Fig. 30)**[55]
- First report on pregnancy after translaparoscopic zygote intrafallopian transfer.[56] In parallel, the group at the Royal Women's Hospital (RWH) was involved too in studies on GIFT **(Fig. 31)**.[57]

Fig. 29: W Feichtinger.

Fig. 30: Paul Devroey.

Fig. 31: Zev Rosenwaks.

- Delivery of twins from frozen human eggs **(Fig. 32)**.[58]
- Jacqueline Mandelbaum with Daniel Szollosi described the microstructures of the human oocyte, which came to be known as "oocyte dysmorphia."[59]

Fig. 32: Daniel Navot.

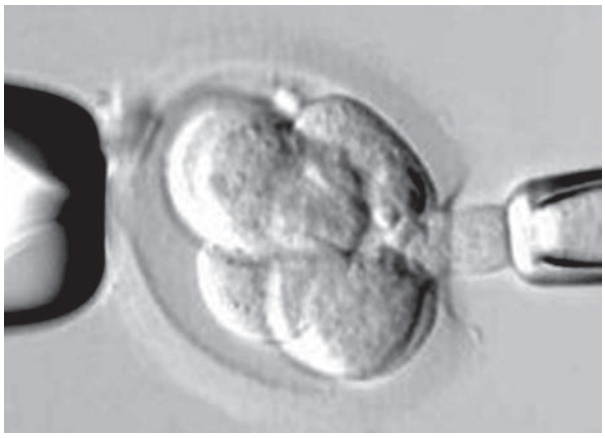

Fig. 33: Biopsy of an embryo.

1987

Fertilization of human oocytes by microinjection of a single sperm under the zona pellucida took place.[60]

1988

- First time epididymal sperm aspiration for men with absent vas or ejaculatory duct block. In the same year, two babies were born after this technique.[61]
- First IVF surrogate born in Australia.
- Successful subzonal insemination (SUZI) performed at the National University of Singapore.[62]
- Successful pregnancy obtained from zona drilling or partial zona dissection mechanically.[63]
- In the same year the pioneer Dr Patrick Steptoe left us forever—March 21, 1988.[64]
- The first preclinical evaluation of pronuclear formation by microinjection of human spermatozoa into human oocytes.[65]

1989

- First report on sexing of embryos by biopsy of human preimplantation embryos by deoxyribonucleic acid (DNA) amplification **(Fig. 33)**.[66]

Fig. 34: Alan Trounson.

Fig. 35: Leeanda Wilton.

- First report on the implementation of laser in the field of assisted reproduction.[67]
- Ultrasound for endometrial quality for thickness and pattern was reported by Gonen and her colleagues in Toronto.[68]
- Embryo biopsy technique was developed in mice by Professor Alan Trounson and Leeanda Wilton **(Figs. 34 and 35)**.[69]

1990

- The first successful human cleavage-stage embryo vitrification followed by a successful delivery.[70]
- Biopsied embryos sexed for Y-chromosome-specific pregnancies.[71]
- First report on the use of assisted hatching on human embryos **(Fig. 36)**.[72]
- The first report on polar body biopsy, transfer of the embryo, and achieving pregnancy **(Fig. 37)**.[73]
- Gonen et al. proposed the use of GnRH agonist in place of hCG as a means to trigger the gonadotropic surge for IVF.[74]

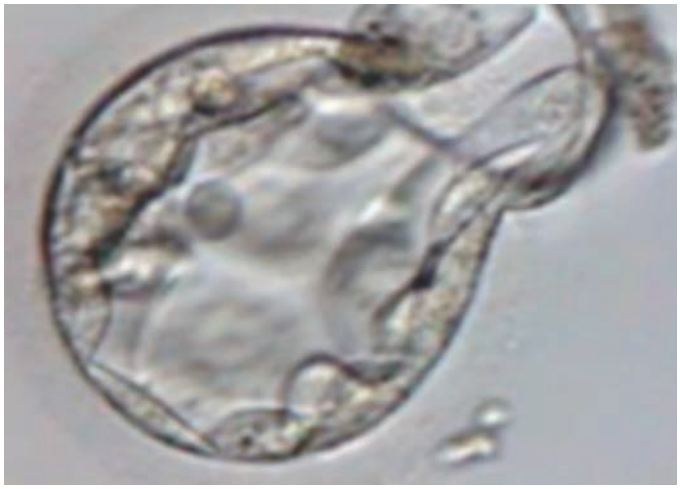

Fig. 36: Hatching of a blastocyst.

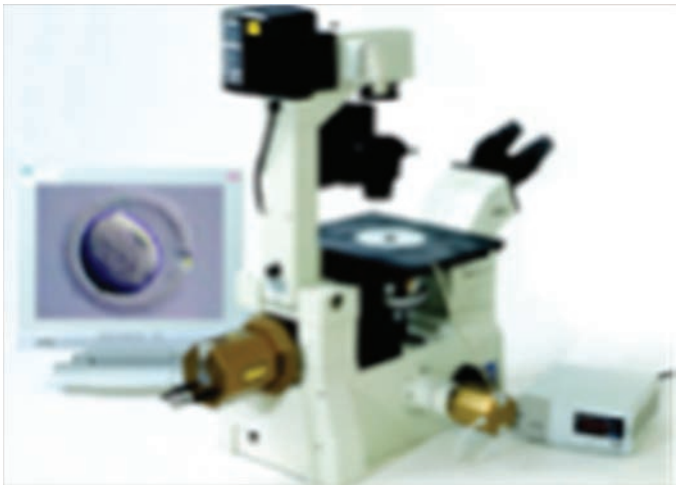

Fig. 37: Microscopic analysis of a blastocyst.

Fig. 38: Jacques Cohen.

- Gonen, Jacobson, and Casper pioneered the use of combined oral contraceptives for follicle synchronization and cycle scheduling in IVF **(Fig. 38)**.[75]
- Fishel et al. reported about twin birth after SUZI.[76]

1991

- IVM in an unstimulated cycle resulted in pregnancy in a donor oocyte program.[77]
- The first report on the prevention of premature LH rise of progesterone in COH treatment by using GnRH antagonist and Nal-Glue **(Fig. 39)**.[78]
- The first report on the use of a laser for zona pellucida drilling.[79]
- Navot et al. confirmed that the age-related decline in female fertility is attributable to oocyte quality.[80]
- ET catheter is visualized by vaginal ultrasound **(Fig. 40)**.[81]

1992

- Two groups simultaneously presented the report on the successful IVF followed by ET after treatment with recombinant human follicle-stimulating hormone (FSH) **(Figs. 41 to 43)**.[82,83]
- Assisted zona hatching was introduced in IVF programs to breach the zona pellucida and promote the natural process of hatching.[84]

Fig. 39: Daniel Palanker.

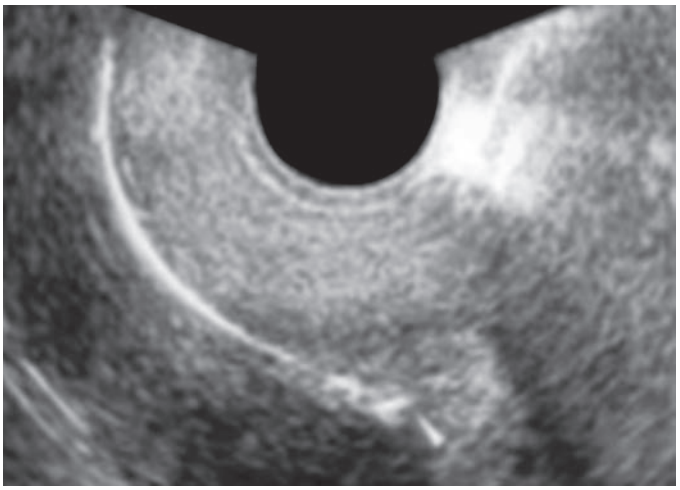

Fig. 40: Embryo transfer catheter.

- Report of the first pregnancy after ICSI by the group in Brussels **(Figs. 44 and 45)**.[85]
- Pregnancy after embryo biopsy and coamplification of DNA from X and Y chromosomes.[86]

Fig. 41: Marc Germond.

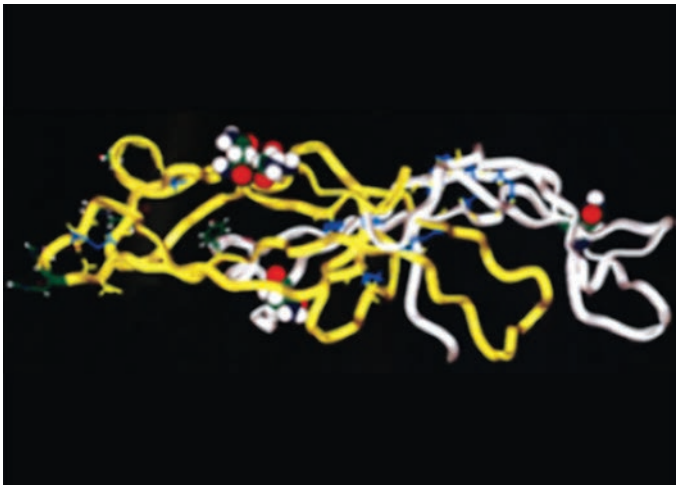

Fig. 42: Three-dimensional model structure of follicle-stimulating hormone (FSH).

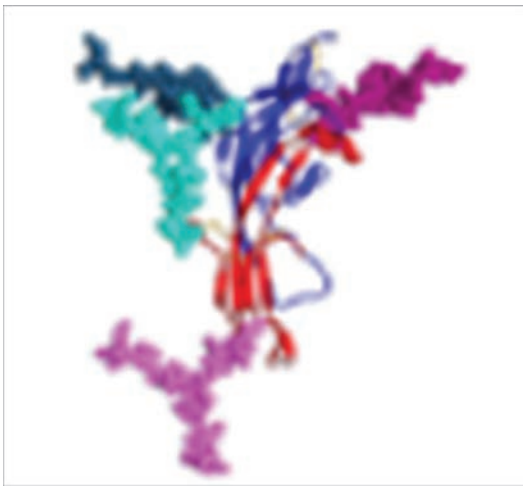

Fig. 43: Recombinant follicle-stimulating hormone (FSH).

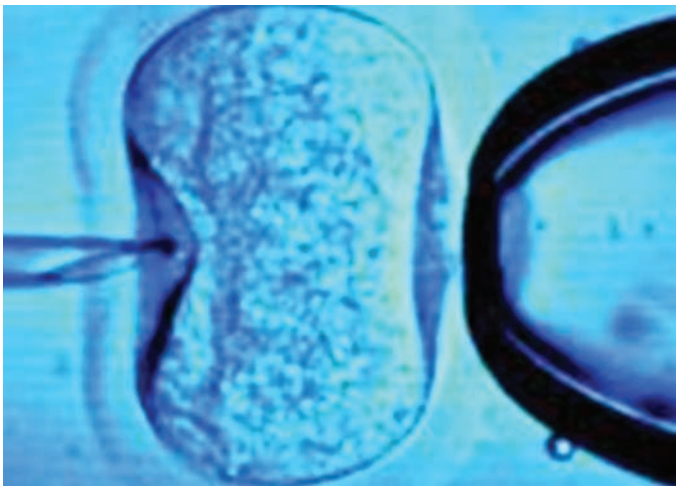

Fig. 44: Intracytoplasmic sperm injection (ICSI) process.

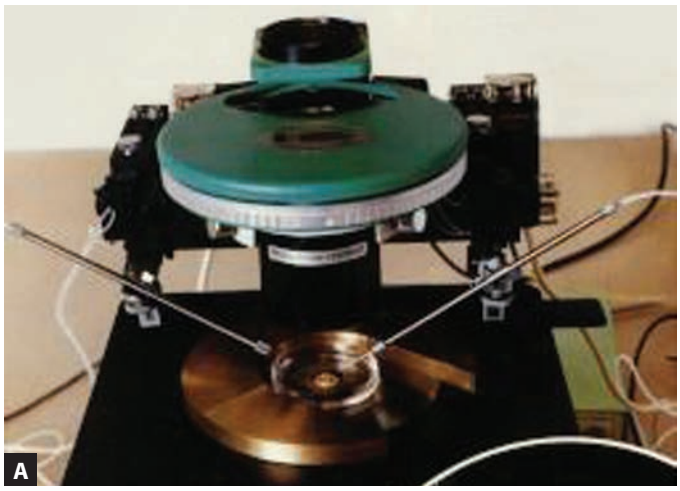

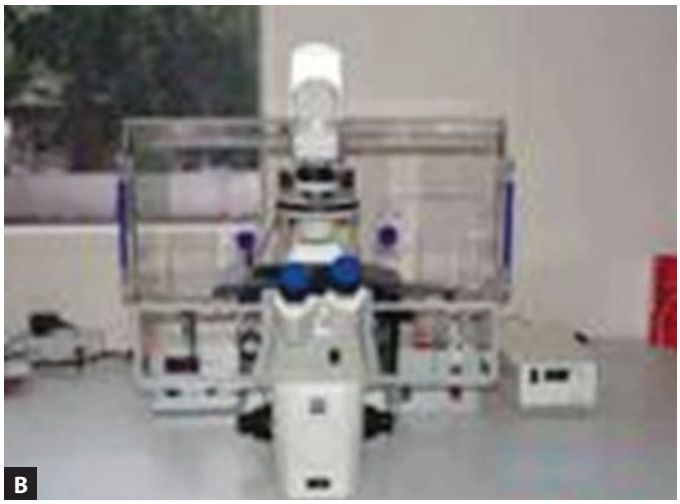

Figs. 45A and B: Intracytoplasmic sperm injection (ICSI) microscope.

- Ovulation induction by endogenous LH released by the administration of a luteinizing hormone-releasing hormone (LHRH) agonist after follicular stimulation for IVF.[87]
- First report on the cumulative conception and live-birth rates after IVF in relation to a patient's age and cause of infertility.[88]

Fig. 46: Herjan JT Coelingh Bennink.

Fig. 47: Sherman Silber.

- First two births from the replacement of frozen embryos produced with epididymal sperm.[89]
- Report on using erbium yttrium aluminum garnet (YAG) laser for micromanipulation of oocytes and spermatozoa.[90]
- Investigating the role of FSH in hypogonadotropic women using the new recombinant FSH drug **(Fig. 46)**.[91]

1993

- The second-term pregnancy after ICSI reported by a group in Sweden.[92]
- Confirmation that men with congenital absence of the vas deferens have cystic fibrosis mutations, which can be transmitted to the offspring **(Fig. 47)**.[93]
- First report on the use of testicular sperm extraction (TESE) and ICSI.[94]
- First pregnancy and birth following treatment with recombinant FSH.[95]

1994

- The first live birth as a result of IVM following transvaginal ultrasound-guided oocyte collection **(Fig. 48)**.[96]

Fig. 48: Colin Howles.

Fig. 49: Frank Barnes.

Fig. 50: Blastocyst.

- Development of the first highly purified FSH preparation for use in IVF.[97]

1995

- Pregnancies after TESE and ICSI in nonobstructive azoospermia.[98]
- Birth after blastocyst development from IVM oocyte plus ICSI plus assisted hatching **(Figs. 49 and 50)**.[99]

Fig. 51: David Gardner.

- The first report of aneuploidy testing.[100]
- The first report in which spermatids were used to achieve pregnancy.[101]
- The largest study was done in the field of IVF comparing urinary FSH with recombinant FSH.[102]

1996

- The Valencia group reported on the first pregnancy employing cryopreserved testicular sperm following IVF–ICSI.[103]
- Discovery that some men with severe oligoasthenospermia have deletions in the Y-chromosome.[104]
- Casper and his colleagues were the first to demonstrate and introduce the use of the hypo-osmotic swelling test for the selection of immotile sperm for ICSI.[105]

1997

- First report on cytoplasmic transfer.[106]
- Sun, Jurisicova, and Casper described the use of Terminal deoxynucleotidyl transferase dUTP Nick-End Labeling (TUNEL) for the detection of DNA fragmentation in sperm and its correlation with IVF outcome. They showed almost uniform presence of DNA fragmentation in round spermatids as the explanation for failure to achieve pregnancy with these immature gametes.[107]
- First births of babies from frozen oocytes following the use of ICSI.[108]

1998

- First established pregnancy using recombinant FSH and GnRH antagonist.[109]
- Gardner introduced sequential media and blastocyst transfer which now greatly assists in the move to single ET **(Fig. 51)**.[110]
- Births after intracytoplasmic injection of sperm obtained by testicular extraction from men with nonmosaic Klinefelter's syndrome.[111]

- The first pregnancies following embryo culture in sequential media and transfer at the blastocyst stage of development.[112]
- First ovum pick-up under three-dimensional (3D) ultrasound vision.[113]

1999

- First unaffected pregnancy using preimplantation genetic diagnosis (PGD) for sickle cell anemia.[114]
- Birth following vitrification of human oocyte[115]
- World's first IVF/ICSI pregnancy and live birth after successful air transport of oocytes reported by the McGill Reproductive Centre, enabling the creation of an air-transport IVF program in large countries with scattered populations or in areas remote from infertility centers.[116]
- *Cryopreserved oocytes and testicular sperm:* First ever birth.[117]

2000

- Oktay and Karlikaya were the first to report on ovarian tissue transplants after frozen storage **(Fig. 52)**.[118]
- The development of a completely chemically defined protein-free embryo culture medium and the births of the first batch of babies generated from the fertilization of eggs collected and inseminated in the said protein-free medium using spermatozoa also prepared in the same protein-free medium in both conventional IVF and ICSI.[119]

2001

- Birth of an infant from cryopreserved embryos (zygotes) produced by IVM oocytes derived from an unstimulated patient with polycystic ovary syndrome (PCOS).[120]
- Ongoing twin pregnancy after ICSI of percutaneous sperm aspiration (PESA)-retrieved spermatozoa into in vitro matured oocytes reported by the McGill group.[121]
- Live birth after sperm retrieval from a moribund man.[122]

2002

- First live birth following blastocyst biopsy and PGD analysis.[123]
- First clinical application of comparative genomic hybridization and polar body testing for PGD of aneuploidy.[124]

2003

- Live births after vitrification of oocytes in a stimulated IVF-ET program[125]
- First live birth after ovarian stimulation using a chimeric long-acting human recombinant follicle-stimulating hormone agonist (recFSH-CTP) for IVF **(Fig. 53)**.[126]
- Dr Barash and Professor Dekel showed an increasing implantation rate following endometrial injury, performed by Pipelle curettage as a simple outpatient procedure.[127]
- Normal birth after microsurgical enucleation of tripronuclear human zygotes.[128]

2004

- Successful pregnancy and delivery following combined treatment of IVM and TESE.[129]
- Jacques Donnez reported on the first live birth after orthotopic transplantation of cryopreserved ovarian tissue.[130]
- Gardner and colleagues performed the world's first prospective single blastocyst trial, which showed the feasibility of single blastocyst transfer (SBT) and in keeping high pregnancy rates.[131]
- First report of fertility preservation for cancer patients using IVM and oocyte vitrification.[132]

Fig. 52: Kutluk Oktay.

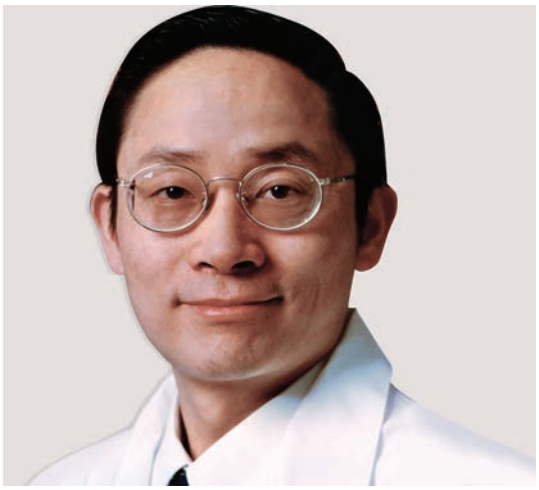

Fig. 53: Ren-He Xu.

- First report on a natural cycle in IVF combined with IVM as a potential approach to infertility treatment.[133]

2005

- Pregnancies and live births after trophectoderm biopsy and preimplantation genetic testing of human blastocysts.[134]
- First birth in Israel from thawed ovarian cortex retransplants.[135]
- The first live birth after trophectoderm biopsy and preimplantation genetic testing of human blastocysts for β-thalassemia **(Fig. 54)**.[136]

2006

- First successful pregnancy after PGD for aneuploidy screening in embryos generated from natural-cycle IVF combined with IVM, achieved at the McGill Reproductive Centre **(Figs. 55 and 56)**.[137]
- Cryopreservation of intact human ovary with its vascular pedicle.[138]

2007

- Introducing the concept of mild treatment strategy for IVF.[139]
- A novel multigradient freezing technique for the cryopreservation of the whole ovary. Thawing the ovary resulted in normal ovarian architecture and no damage to the vascular wall or intima.[140]

2008

- The first report of DNA fingerprinting to identify the blastocyst of origin for live births and that gene expression profiles of biopsied trophectoderm can discriminate between viable and nonviable blastocysts.[141]
- *Cryopreserved oocytes in cancer patients*: First ever birth of healthy twins after oocyte cryopreservation and bilateral ovariectomy.[142]

2009

- Simon Fishel and his group from CARE fertility, Nottingham, reported about a live birth after polar body array comparative genomic hybridization.[143]
- Professor Laufer at the Hadassah Medical Center in Jerusalem reported on a viable pregnancy achieved in a woman who carries the defective *BRCA2* genes after in vitro fertilized embryos were tested and implanted.[144]

LATEST DEVELOPMENTS IN IN VITRO FERTILIZATION TECHNOLOGIES AFTER 2009

Since 1978, numerous advances in fertility science have granted prospective parents an increasing array of options to increase their chances of conception, from IVF to ovarian tissue freezing. Since, this field is rapidly evolving, there are many achievements that have happened after this chapter was last written. So, here is a list of major milestones achieved after the year 2009 in this field.

- *Time-lapse imaging (TLI)*: During the last decade, TLI has emerged as a novel technology that enables continuous evaluation of early embryo development by automated image acquisition every 5–20 minutes and accordingly does not rely on static observations to define a highly dynamic process. Furthermore, it is possible to score embryos without removing them from the incubator, so there is no exposure to changes in light, humidity, temperature, pH, or gas. The world's first embryoscope baby was born in Valencia in June 2010.

  A recent meta-analysis assessed whether TLI resulted in favorable outcomes for embryo incubation and selection compared with conventional methods in clinical IVF. This analysis included 10 randomized controlled studies and concluded that there is insufficient evidence to support TLI as a superior method compared to conventional methods for human embryo incubation and selection. A well-designed randomized controlled trial (RCT) is still needed to evaluate the effectiveness of the clinical use of TLI.
- *Stem cells research*: Ovaries of women in their 20s and early 30s contain a rare population of oogonial stem cells (OSCs) that generate oocytes in defined cultures in vitro and after introduction into human ovarian tissue in xenografts in vivo. The use of stem cell-based strategies as fertility treatment options are often viewed as being clinically applicable only in the distant future; however, these new findings in the area of human ovarian biology bring stem cell-based approaches for treating infertility in women one significant step closer to reality.

  In May 2015, an extension of this theory was used to rejuvenate a woman's old eggs and so-called world's first stem cell baby—Zain Rajani—was born in Canada.

  The idea was that the mitochondria—cellular energy generators—in young, primitive cells function much better than those in the mature eggs collected for IVF. Collecting these mitochondria and injecting them into the prospective mother's mature eggs are supposed to improve their quality. This whole procedure is now known as "autologous mitochondrial transfer."

  Similarly, there have been several cases reported of endometrial regeneration using adult autologous stem cells derived from bone marrow and successful pregnancies thereafter.
- *Endometrial receptivity array (ERA)—molecular test of endometrial receptivity:* Search for an adequate marker of endometrial receptivity led to the development of a molecular diagnostic test—the ERA. ERA consists of a customized microarray based on the transcriptomic signature of human ER, specifically when the human endometrium is receptive to blastocyst adhesion. The test analyses 238 genes that are differentially expressed around the time of implantation. This array is coupled to a computational predictor that can diagnose the personalized endometrial window of implantation (WOI) of a given patient regardless of their endometrial histology.
- *Uterus transplantation:* In 1931 in Germany, Lili Elbe, a Danish transgender woman, died from organ rejection 3 months after receiving one of the world's earliest uterine transplants. With the availability of IVF in 1978, uterine transplantation research was deferred.

  In Saudi Arabia in 2000, a uterine transplant was performed by Dr Wafa Fageeh from a 46-year-old hysterectomy patient into a 26-year-old recipient whose own uterus had hemorrhaged after childbirth. The transplanted uterus functioned for 99 days but ultimately needed to be removed after failure due to blood clotting. Within the medical community, there was some debate as to whether or not the transplant could truly be considered to have been successful.

  In Turkey, on August 9, 2011, the world's first uterus transplant from a deceased donor was conducted by a team of doctors at Akdeniz University Hospital in Antalya. The 21-year-old Turkish woman, Derya Sert, who had been born without a uterus, was the first woman in history to receive a womb from a deceased donor. The operation, performed by Dr Ömer Özkan, Dr Munire Erman Akar, and their team, was the world's first uterus transplant surgery gaining long-term function as evident by the fact that Ms. Sert had six menstrual periods postsurgery and is said to have a fully functioning uterus. The Turkish medical team who performed the delicate surgery, however, is still cautious about declaring the operation a complete success. In April 2013, Akdeniz University announced that Derya Sert was pregnant, but she had to terminate her pregnancy in its 8th week, following a routine examination where doctors failed to detect a fetal heartbeat.

  In October 2014, it was announced that, for the first time, a healthy baby had been born to a uterine transplant recipient, at an undisclosed location in Sweden. The British Medical Journal and The Lancet reported that the baby boy had been born in September, weighing 1.8 kg (3.9 lb). The baby had been delivered prematurely at about 32 weeks, by cesarean section, after the mother had developed preeclampsia. The Swedish woman, aged 36 years, had received a uterus in 2013, from a live 61-year-old donor, in an operation led by Dr Brännström, professor of obstetrics and gynecology at the University of Gothenburg.

  The first uterine transplant performed in India took place on May 18, 2017, at the Galaxy Care Hospital in Pune, Maharashtra. The 26-year-old patient had been born without a uterus and received her mother's womb in the transplant.

THE FUTURE

In this century, it is clear how much the new reproductive technologies have allowed and initiated advances in genetics. The ability to transfer embryos screened for

chromosomal and single-gene defects has reduced the risk of many inherited diseases, while immunoassay technology has provided detailed insight into the cellular processes involved in gene expression. However, such developments, as well as the publicly perceived ability to select embryos for their sex and genetic characteristics, have raised the fear of "designer babies" and a move toward some kind of eugenics under the pressure of parents.

Since the birth of Dolly, the sheep in Scotland in 1996, the issue of reproductive or therapeutic cloning has been exposed. In therapeutics, the transplantation of human embryonic stem cells now holds a great promise for the treatment of diseases such as Parkinson's disease or diabetes, whereas developments in stem cell biology will lead to a better understanding of infertility, implantation failure, genomic imprinting, and meiosis.[15] However, the field poses a huge challenge including inefficient existing protocols for differentiation, epigenetic and genetic changes associated with extensive in vitro manipulation, and also ethical/regulatory constraints.

Although direct correlates between cancer and infertile epigenetic profiles are rare, the general similarities between the two disease processes offer insights into the study of both abnormalities. Foremost among them is the nature of these pathologies, where one disease (cancer) is categorized by an inability to control or inhibit cellular proliferation, and the other (male infertility) is caused by an inability to maintain the normally efficient extreme proliferation of the male germ cell. Based on this similarity alone, the study of epigenetics in both male fertility and cancer has the potential to offer intriguing insights in both fields. The creative application of harmonious studies of both infertility and cancer is likely to yield useful and informative data that may aid in both the understanding and treatment of both pathologies.

So this implies that, still, there is a lot more to explore, and increasingly, this field is becoming superspecialized with a team of doctors, scientists, geneticists, and the researchers aiming toward excellence and improving the outcome in ART.

Hope this collaborative effort keeps on adding more value to the work initiated by our pioneers already.

CONCLUSION

In the 1960s and 1970s, our understanding of the events in human oocyte fertilization grew to the point that in vitro fertilization (IVF) of human oocytes became possible. Ultimately, this knowledge led to the widely acclaimed first live birth of a "test tube baby," Louise Brown, in England in 1978.

CHAPTER 104

In Vitro Fertilization and Embryo Transfer

Alex C Varghese, Shrey Balani, Kannamannadiar Jayaprakasan

INTRODUCTION

Since the birth of Louise Brown at Oldham, Cambridge by the pioneering works of Edwards and Steptoe in vitro fertilization (IVF) and embryo transfer (ET) techniques, many developments in the field have occured and resulted so far, in the birth of >8 million babies worldwide. The active research in both the clinical side (new drugs and regimens for stimulation, advanced ultrasonography, and ET techniques) and the laboratory (preimplantation genetic testing (PGT), sperm selection methods, and novel embryo culture systems) in the last three decades has dramatically increased the take home baby rates. Although newer technologies and methods have definitely improved the pregnancy rate the risks associated with assisted reproductive technologies (ART) have also surfaced concurrently. Current ART practices are trying to minimize the risks by offering mild stimulation protocols, elective single ET (SET), and PGT using high throughput molecular and genetic platforms to select the euploid embryos for transfer, offering donor gametes or embryos in unavoidable conditions. The success of an IVF program should always be measured by the live birth (LB) of healthy babies. To achieve this level of success, many aspects of assisted reproduction play an important role. Artificial intelligence (AI) and machine learning are rapidly changing the practice of medicine. AI has remarkable potential to overcome the barriers of low success rate, cost and accessibility of IVF. There is a huge scope of robotics or automation in IVF lab systems. The IVF laboratory process is very complex and needs high level of accuracy and errors close to zero, along with proper documentation. This chapter tries to give an insight on these areas.

IMPORTANCE OF TOTAL QUALITY

Management in Assisted Reproductive Technologies

The absence of a strict program control can cause potential compromise in the IVF success due to the extreme sensitivity of the gametes and the early embryos to the physical and environmental factors. The attention to the general components of a quality control (QC) and quality assurance program are necessary for a repeatable process and as such the total quality management (TQM) of the program must be stressed. The implementation of TQM involves satisfying customers, controlling the changes in the system or process, managing personnels and quality improvement tools. These are further identified as the five pillars of TQM—(1) Product (service), (2) Process, (3) Organization, (4) Leadership, and (5) Commitment.

Such an undertaking requires an organizational culture change involving a major staff learning and training program followed by pilot quality initiatives in a number of major areas including human, financial, technological, and natural resources.

Quality management is a culture that needs to be implemented at different levels in an organization to yield fruitful results. Merely introducing few QC gadgets does not suffice to obtain the desired. Proper staff training, continuous education, internal and external auditing of the process, implementation of ideal QC strategies, etc., will yield the desired outcomes.

IN VITRO FERTILIZATION LABORATORY AND CULTURE SYSTEMS

In Vitro Fertilization Laboratory

Unlike other pathological, biological, or tissue culture laboratories, the design and layout of IVF laboratories need proper planning since these laboratories are going to deal with human gametes, which are sensitive to external environmental conditions. Sites near significant point sources of contaminants should be avoided or evaluated carefully. A detailed site review is done by environmental firms and includes an onsite inspection, baseline analysis of the prospective location, and a review of public documents. The inspection must include baseline sampling for toxic organics (as listed by the USEPA). The baseline samples

should be done by recognized analytical methods [USEPA toxic organics (TO)15 and USEPA TO11] providing both identity and concentrations at the microgram/cubic meter ($\mu g/m^3$) level by an accredited environmental laboratory. Measurements at milligram/cubic meter (mg/m^3) are not sufficiently rigorous because of the potentially high detection limits. Avoid handheld analysis by photoionization detectors (PIDs) as the investigation tool as PIDs use highenergy photons, typically in the ultraviolet (UV) range. The use of UV light to excite the molecules results in the ionization of gas molecules. The energy of the photons is typically in the range of 10 eV, so that only gases with low ionization energy, e.g., organic vapor, can be ionized. The main air constituents, oxygen and nitrogen, do not form ions at this photon energy. The resulting ions produce an electric current proportional to the signal output of the detector. More molecules are present in the air, more ions are produced, and higher will be the resulting current. Finally, the ions recombine after the detector to reform the original molecules.

The major factor to be taken care while designing such units is the clean room facility especially for the laboratory and the ovum recovery or ET units. These rooms should be maintained at a higher pressure compared to adjacent rooms for exchange of air. A dedicated air handling unit specific for these rooms can definitely be a good investment. These units ideally should have air handling units having prefilters, high efficiency particulate air (HEPA) filters, and activated volatile organic compounds (VOC) filters to trap all chemically active compounds (CAC) sweeping into the rooms or generated in the clean rooms. The existing unit can also opt for standalone VOC filtration units but these are less efficient. Timely changing of filters ensures their optimal functioning. This is also true for the VOC inline filters connected to gas cylinders supplying "medical grade gases" to IVF incubators.

In Vitro Fertilization Culture Systems

The earliest stages of human development, until day 5 or 6 after fertilization, normally occur in the woman's fallopian tube (or oviduct). However, after IVF, much of this period of early development occurs in the laboratory. The conditions under which the preimplantation embryos are cultured have been carefully formulated in the form of culture media and systems to provide an environment that mimics—as closely as possible—that of the fallopian tube.

Commercially prepared culture (sequential or single step) media support embryo development in the laboratory for up to 6 days. By allowing the embryo to reach the blastocyst stage, one can make a more stringent selection of those to be transferred during an IVF cycle. This paves the way for elective single or double ETs. However, the extended culture of preimplantation embryos requires the use of hypoxic conditions. Ideally, the use of benchtop incubators with low oxygen concentration achieves the required gas concentration. In vivo, oocytes and embryos are exposed to a maximum of ~5–8% O_2 in the reproductive system. Atmospheric O_2 may lead to supraphysiologic reactive oxygen species levels, potentially causing oxidative stress [damage to cell organelles, lipids, membranes, deoxyribonucleic acid (DNA), and gene expression] and ultimately poor embryo development.[1]

There are many variables in an IVF laboratory affecting the pregnancy rates, from the air filters to the culture media and the incubators. Only when all the processes are fine-tuned, products of high quality are used, pH and temperature are closely monitored, all equipment are maintained, the results will be optimal. There is a tendency in the running IVF units to procure a single "small" benchtop incubator and culture the embryos from just the zygote stage onward. The preequilibration of culture media, fertilization, and incubation up to zygote stage still performed in the large CO_2 incubators (20% O_2). Hence, gametes and embryos are exposed to 20% O_2 and 5% O_2 consecutively. Data obtained using timelapse incubation strongly supports the notion that at no time during the preimplantation period the embryos should be exposed to 20% oxygen. In a study by Wale, et al., (2010), timelapse microscopy was performed with imaging of individual mouse embryos at 15 minutes intervals. Compared with embryos cultured in 5% oxygen, embryos cultured in 20% oxygen were delayed at the first cleavage by 0.45 hours ($p < 0.05$), at the second cleavage by 0.84 hours ($p < 0.01$), and at the third cleavage by 3.19 hours ($p < 0.001$). Switching from 20 to 5% oxygen after 48 hours did not completely alleviate the earlier induced perturbations. Partial or complete culture in atmospheric oxygen resulted in significantly fewer blastocyst cell numbers compared with control ($p < 0.05$). Oxygen can influence mouse embryo development at both the cleavage and postcompaction stages. This must be true for human embryos too.

The introduction of timelapse imaging (TLI) systems in clinical human IVF, however, has stirred discussions about how new technologies should be implemented in the daily clinical routine. Many reviews and observational studies have discussed the value of timelapse monitoring in routine laboratory practice. It is as yet unclear, however, whether the observed benefits came from the undisturbed culture or improved selection based on continuous timelapse images. In short—what is the weight of these benefits in the added value of timelapse? The recent (Csaba Pribenszky, et al., 2017) metaanalysis of five randomized controlled trials (RCT) (n = 1,637) showed that the application of timelapse monitoring was associated with a significantly higher ongoing clinical pregnancy rate (51.0% versus 39.9%), with a pooled odds ratio of 1.542 ($p < 0.001$), significantly lower early pregnancy loss (15.3% versus 21.3%; or 0.662; $p = 0.019$), and a significantly increased LB rate (44.2% versus 31.3%; or 1.668; $p = 0.009$). Difference in stillbirth was not significant

between groups (4.7% versus 2.4%). Quality of the evidence was moderatetolow owing to inconsistencies across the studies.[2] Comparison of LB rates and the perinatal outcomes after fresh and frozen ET between TLI and standard culture (SC) incubators were done by Mascarenhas, et al., (2018). The fresh ET LB rate was noted to be higher for TLI cycles [TLI 36.8% versus SC 33.9%, adjusted odds ratio (aOR) 1.28, 95% confidence interval (CI) 1.05–1.57], but the frozen ET LB rates were not significantly different. The mean birth weight was higher in the TLI group after both fresh [adjusted mean difference (aMD) 174.78 g, 95% CI 64.80–284.77] and frozen ETs (aMD 175.91 g, 95% CI 16.98–334.84). After a fresh ET, there was a lower risk of early preterm birth (PTB) and very low birth weight (LBW) in the TLI group. Among frozen ETs, there was a lower risk of early PTB and LBW in the TLI group. TLI incubators are associated with improved perinatal outcomes and higher mean birth weight after fresh and frozen ET.[3]

Air quality, particle count, and sterility are extremely important in an IVF laboratory to ensure the best clinical outcomes. Human embryos are extremely sensitive to the presence of any VOC and CAC. Globally, a class 10,000 laboratory is recommended for IVF, that is, 10,000 ppm in air. The best way to achieve this is by building a modular clean room. This is done with a combination of various panels (Steel, Bioclad, etc.), medical grade vinyl flooring, and high efficiency heating, ventilation, and air conditioning (HVAC) air system that control air temperature and particulate matter, as well as filter harmful VOC. Moreover, incorporation of UVC light enables the elimination of the build-up of any fungal or bacterial colonization in the air handling system or ducts. The modular clean room concept facilitates ease in building of partitions, ease of cleaning, curving of joints, and provision for electrical and gas pipelines, with proper esthetic looks. Hence, proper laboratory design and quality assurance and control can prevent compromises. Burnin, validation, and commissioning of new laboratories are very important before starting the new IVF cycles.

Workstations

Tissue handling directives generally recommend the use of laminar air flow workstations whenever cell or tissue material is manipulated. The aim of the laminar filtration is to mitigate the dramatic particle contamination that can be found in any room—even a state of the art clean room—when it has been transformed into a busy laboratory. The first sweep in the room with a high-grade particle counter will astonish most as the particle levels will usually be beyond their wildest expectation. Inside the air curtain of the laminar air flow workstation this is reduced to almost zero.

The challenge with the use of workstations is to integrate them so that their benefits do not become liabilities for the embryos.

The workstation must be equipped with heating systems sophisticated enough to maintain the correct temperature of the specimens during handling under all circumstances. Especially some kind of heated glass stage is vital as the manipulations take place mostly under the microscope.

The most advanced workstations incorporate temporary storing facilities for the dishes where they can be kept in like incubator conditions when they are in between procedures or handling.

The biggest challenge to handle in workstations is open culture conditions as the heat applied below will cause immediate evaporative cool down of the liquid in the dish. There is no way to avoid this other than adding high humidity or some kind of provisions for heat from above to slow down the evaporative cooling. The overall aim is to reduce the total temperature drop during handling. Increasing the heat which seems the logical way to avoid the drop actually have the opposite effect as it increases the evaporative cooling. Only careful testing can reveal what the best method is for keeping the best possible temperature in open culture conditions and what average handling times can be allowed before the temperature drop becomes critical.

Working under oil it is essential to have the correct temperature as oil is not very forgiving for too high temperature.

The laminar air flow can have a cooling effect—but if the workstation has been designed correctly it is possible to maintain a stable and correct temperature in the dish under oil. A possibility that can be utilized successfully with open culture is working in humidified environments. They do, however, have the drawback of risk of contamination or at least being quite difficult to maintain a suitable aseptic state.

A regulatory caused delusion occurred in some countries within IVF when a widespread adoption of Class II (biological safety cabinets) was introduced for IVF work. This type of safety cabinet, designed to protect the operator as well as the specimens being handled, are the least suited laminar air flow workstations for IVF. They are designed to adhere to certain standards as they are meant for biological contaminated work. This means that the mandatory high airflow and design of flow in the tabletop makes it not suited for IVF work. The possible benefit of the operator protection when there is really nothing to protect against is not worth the extra risk to the embryos. Even the best designs of the Class II workstations will never be better than the most average designs of a vertical laminar air flow workstation.

Horizontal laminar air flow workstations offer no benefits over vertical and should be avoided alone because of the extra discomfort they provide for the operator by blowing directly into their face.

The future will surely bring better systems that can offer a more natural environment with both filtration of the air, temperature control, and gas mixture. These systems will

allow for safely working with bicarbonatebuffered media without the risk of rapid pH changes. They will also provide better solutions to the afore-mentioned temperature challenges. Furthermore, they will serve as small clean rooms inside the laboratory so that any moving around in the laboratory does not interfere with the aseptic conditions like it can happen even with good vertical laminar air flow workstations.

Future embodiments might even make it possible to do the complicated procedures such as intracytoplasmic sperm injection (ICSI) and biopsies in a controlled environment instead of manipulations taking place in the open rooms on big microscopes placed on antivibration tables. Thus, offering both a safe environment and also space saving which is so critical in the modern laboratory where space is at a premium.

Ideally a 6 foot cabinet with heated workbench and high-quality stereo zoom microscope is an ideal option anticipating the future workload. One can install a second stereo zoom microscope in these 6 foot cabinets which enables simultaneous work by two embryologists in busy laboratories. Otherwise, an inverted microscope such as Primo Vert (with integrated monitor, Carl Zeiss) can be integrated on the other end which can be used for embryo grading. Using a low magnification stereo microscope can sometimes lead to misleading embryo scoring grades, as the image may not reveal fine details of the embryos. Modern laboratories opt for closed workstations such as Incu chamber (KSystem, Denmark), active IVF (UK), Vitrosafe (UK), or IVF chamber (ORIGIO, Denmark). These workstations offer the ideal physiological environments for gametes and embryos while being manipulated outside the incubator.

The laboratory should also have a dedicated warming incubator (150 L or above, Forma, USA; Binder, Germany or Memert, Germany). This can be of utmost help for warming up the culture dishes and other disposables used in IVF cycles. Moreover, this type of large warming incubators can be used to offgas the VOCs from culture dishes before use. Special care should be done while selecting tissue culture wares or disposables for gamete or embryo culture. The dishes should be IVF or mouse embryo tested.

Since, male factor infertility is becoming increasingly responsible for the couple infertility, the unit should have a dedicated ICSI workstation and a proper training by laboratory personal on micromanipulation techniques. The ICSI workstation requires a vibrationfree heavy table (either commercially available one or a modified heavy table with granite table top). The options are Nikon Narishige (Japan), Olympus Narishige (Japan), Eppendorf (Germany), and Integra (RI, UK). The ICSI workstation should have a dedicated inverted microscope (Leica, Carl Zeiss, Nikon, or Olympus) with optional intracytoplasmic morphology selection (IMSI) attachment for sperm organellar morphology assessment and IMSI. Several sperm selection methods are available which include magnetic activated cell sorting (MACS), microfluidic sperm selection, IMSI, and physiological intracytoplasmic sperm injection (PICSI). Interferometric phase microscopy (IPM), also called digital holographic microscopy, for labelfree sperm imaging in fertility clinics, is also getting explored by Israeli scientists. According to recent studies, epigenetic modifications of sperm could be evaluated by noninvasive Raman spectroscopy by analyzing DNA and ribonucleic acid (RNA), as well as histones and protamines. Label-free optical spectroscopy and imaging techniques, based on the combination of Raman spectroscopy or imaging with holographic imaging, which are able to noninvasively measure the biochemistry and morphology of sperm cells is also being explored.[1]

OOCYTE ABNORMALITIES AND PREGNANCY OUTCOMES

Oocytes retrieved after ovarian stimulation have not undergone the integral process of natural selection. These oocytes may be developmentally defective and would have been pushed to grow by the supraphysiologic gonadotropins. This can have serious impact on the developmental potential of the embryo as well as on the health of the offspring. The morphological examination of the oocyte, documentation of the findings, and segregation of abnormal oocytes which are inseminated is essential. Few important oocyte abnormalities and their pregnancy outcomes are being discussed.

Smooth Endoplasmic Reticulum Oocytes

This abnormality is characterized by disk-like accumulation of the smooth endoplasmic reticulum (SER) due to dilatation and fusion of saccules during maturational process. Since, SER has a major role in calcium homeostasis, it is postulated that the calcium balance in SER + oocytes is abnormal. Studies have shown that SER oocytes are associated with decreased fertilization rates, cleavage rates, and blastulation. Few congenital malformations and genetic abnormalities are also reported. Hence, Alpha Scientists and European Society of Human Reproduction and Embryology (ESHRE) advised against the insemination of SER + oocytes,[4] but there are studies after that reporting delivery of healthy babies.[5,6] Hence, centers inseminating SER oocytes should report their outcomes so that the exact data will be known.

Central Granulation

It is characterized by the appearance of numerous cytoplasmic pits of about 1.5 μ. Studies have divided opinions about the presence of granularity; few suggesting no role in in vitro developmental outcome,[7] while a study suggested that cases of extreme granularity may lead to early pregnancy loss.[8]

Cytoplasmic Vacuolation

This is one of the most common oocyte dysmorphisms. These membrane-bound cytoplasmic inclusions vary in size and number. It had been demonstrated that vacuoles of >14 μ diameter can block fertilization. There are few case reports in the literature showing successful pregnancies in vacuolated oocytes with vacuoles of average diameter of 52.2 μm.[9]

EFFECT OF OVARIAN STIMULATION ON OOCYTE QUALITY

Oocyte quality impacts early embryonic survival, the establishment and maintenance of pregnancy, fetal development, and even adult disease. Quality, or developmental competence, is acquired during folliculogenesis as the oocyte grows and during the period of oocyte maturation.

The interaction between granulosa cells and the oocyte is controlled by gonadotropins and the oocyte itself. Both gonadotropins influence oocyte competence through the two main local growth factor systems—(1) the bone morphogenetic protein system and (2) the insulin-like growth factors (IGF) system.

It has been observed in the animal model that modification of these systems influences ovulation rates, oocyte competence, and resulting embryo quality.[10]

Inevitably, controlled ovarian stimulation (COS) for IVF necessitate variations in theca and granulosa cell functions that may affect oocyte quality. Multiple follicular development causes the growth of follicles of different sizes and functional activity that will contain oocytes at different maturation stages.[11]

On the other hand, success of IVF is clearly dependent on the size and quality of the oocyte cohort.[12-14] Effects of ovarian stimulation on oocyte and embryo quality have been well-characterized in animals, showing that aggressive stimulation leads to poorer embryo development potential and could increase the rate of chromosomal abnormalities.[15-17] Later studies in animals suggested that embryo development seems to be adversely affected in a dose-dependent manner.[18,19]

In humans though, studies are limited and less conclusive. In fact, when natural and stimulated cycles are compared, no differences have been observed in terms of embryo cleavage capacity,[20] oocyte,[21] and embryo aneuploidy rate,[22] or incidence of aneuploidy in aborted fetuses[23] or in chorionic villus sampling in the late first trimester of pregnancy.[24]

A significantly different follicular endocrine milieu has been detected when natural cycle mature follicles and stimulated follicles have been compared,[25] although another group could not detect a relationship between this modification in follicular physiology and embryo morphology or even oocyte meiotic spindle structure.[26]

Most of the studies in humans designed to evaluate the impact of gonadotropins on oocyte quality have compared different doses of gonadotropins. When mild and conventional stimulation are compared, a higher proportion of good morphologic quality embryos is observed in the former.[27,28]

Additionally, a positive relationship between doses of gonadotropins and aneuploidy rate was found, both in the embryo[29] and in granulosa cells.[30]

Another study concluded that ovarian stimulation does not significantly raise the embryo aneuploidy rate in IVF-derived human embryos when compared with an unstimulated cycle and that ovarian response was not positively related to aneuploidy.[31]

The proportion of euploid oocytes is directly related to the number of mature oocytes, and inversely related to the number of units of follicle-stimulating hormone (FSH) per oocyte and per mature oocyte obtained.[32,33]

This is in-line with recent studies, which do not support the idea that ovarian stimulation is so detrimental to oocyte and embryo quality. In fact, it has been shown that high ovarian response to conventional ovarian stimulation does not increase embryo aneuploidy rates in PGT cycles using array comparative genomic hybridization (aCGH), either in infertile patients or in oocyte donors.[34,35]

Moreover, the more euploid blastocysts that are available, the higher the clinical pregnancy rate, even in fresh cycles[36,37] and the higher the ovarian response, the higher the cumulative pregnancy rate after the thawed ETs.[15,38] This is consistent with the recently introduced concept of "ovarian sensitivity index"[39] which is the ratio between the total dose of gonadotropins used during COS and the number of oocytes retrieved. It was shown that the higher this index is, the higher the pregnancy rates, reflecting that healthier ovaries that display a good response with low doses of gonadotropins also provide the best oocyte quality.

A review of a very large series of patients (>650,000) supports this concept. The authors observed that gonadotropin dose, as an independent factor, correlated negatively with the probability of LB.[40]

INDIVIDUALIZED OR PATIENT-TAILORED STIMULATION STRATEGIES

The main objective of individualization of treatment in IVF is to offer every single woman the best treatment tailored to her specific characteristics, thus maximizing success, eliminating iatrogenic risks, such as ovarian hyperstimulation syndrome (OHSS), and minimizing the risk of cycle cancellation.

A key factor determining the outcome of COS and subsequent IVF outcome is selection of the gonadotropin starting dose. The need for individualizing gonadotropin dosage comes from the assumption that variability in the

functional ovarian reserve (the pool of recruitable follicles) is very wide[41-45] and consequently a standard fixed dose of gonadotropin may not be suitable for all women. Correct individualization of the gonadotropin start dose is an extremely important clinical decision.

The correct individualization of treatment protocols in IVF should be based on the correct estimation of ovarian response especially the extremes, namely poor and hyper response. The aim is then to choose the ideal treatment protocol according to this prediction. The prediction of ovarian response allows clinicians to give women more accurate information regarding the likelihood of these scenarios occurring during their IVF cycle.

Patients may receive more accurate information on possible protracted treatment, cycle cancellation OHSS, treatment burden, and reduced success. If personalization is based on the accurate prediction of ovarian response, then the prediction of ovarian response should be based on the most sensitive markers of ovarian reserve.[46,47]

Lan, et al., compared the efficacy and safety of two simple dosing algorithms, one based on anti-Müllerian hormone (AMH) and the other on the antral follicle count (AFC), to determine the starting dose recombinant follicle stimulating hormone (rFSH) for ovarian stimulation in 348 women. This pilot study, concluded that, with subtle differences, both AMH and AFC appear to have the ability to predict poor ovarian response and guide the starting dose of rFSH.[48]

Oliveira, et al., presented a new ovarian response prediction index (ORPI), based on AMH levels, AFC, and age, and set-up a study to verify whether it could be a reliable predictor of the ovarian stimulation response. The ORPI might be used to improve cost-benefit ratio of ovarian stimulation regimens by guiding the selection of medication and by modulating the doses and regimens according to the actual needs of the patients.[49]

The availability of new markers of ovarian reserve, the improvement in methodology for their measurement, and the huge amount of clinical data has supported the view that individualization in IVF is the way forward. The correct measurement of markers of ovarian reserve allows a scientific estimate of the pool of follicles that potentially respond to ovarian stimulation.

Published studies indicate an important role for both AFC and AMH in the prediction of the extremes of ovarian response and for enabling the subsequent individualization of a therapeutic strategy.

This is the basis for the correct selection of women for use of the different GnRH (gonadotropin-releasing hormone) analogs and, for the fine-tuning of the gonadotropin dose.

The ultimate goal would be the selection of an effective protocol for ovarian stimulation which has to be well-balanced between the risk of maximal and suboptimal ovarian response. The benefits of a personalized therapy may include reduced incidence of risks and dropouts as well as a reduced treatment burden.

Mild Stimulation In Vitro Fertilization

In 1996, Edwards, et al., were the first to express concern with regard to contemporary ovarian stimulation approaches for IVF and called for the use of milder stimulation protocols.[50] The aim of mild stimulation is to develop safer and more patient-friendly protocols in which the risks of treatment are minimized.[51-54] The protocols are considered to be patient-friendly as they include fewer injections and days of injections and less monitoring. There is reduced risk of OHSS, discomfort, and stress, all documented in literature.

In addition, there is accumulating evidence that milder stimulation protocols result in better quality embryos and a lower percentage of aneuploid embryos when compared to embryos from conventional or high dose gonadotropin stimulation protocols.

The challenges in mild stimulation remain that cancellation rates are higher and per cycle pregnancy rates are lower with fewer embryos frozen from mild stimulation protocols compared to conventional stimulation. However, if one looks at accumulative cycles over a similar time period the percentage of couples becoming pregnant from the two protocols is similar, with one or more additional IVF cycles required for those couples having low dose protocols.

Studies suggest that ovarian stimulation affects embryo quality as assessed by morphology as well as the chromosomal constitution of the embryos.[29,55]

This phenomenon could be the result of interference with the natural selection of good quality oocytes or the exposure of growing follicles to the potentially negative effects of ovarian stimulation. Supporting this evidence comes from various human and animal studies reporting detrimental effects of ovarian stimulation on oocyte and embryo quality. An increased incidence of morphology and chromosomal abnormalities have been observed in oocytes after exposure to high doses of gonadotropins during in vitro maturation of mouse oocytes.[56,57]

Mild stimulation approaches, aiming at a more physiological response, might therefore improve embryo quality. A randomized trial concerning the chromosomal competence of human embryos as assessed by preimplantation aneuploidy screening by fluorescence in situ hybridization (FISH) showed a significantly higher proportion of euploid embryos following mild ovarian stimulation compared with conventional stimulation, suggesting that through maximal stimulation the surplus of obtained oocytes and embryos are of lower quality.[29]

A meta-analysis combining the results of three separate RCTs suggests that the retrieval of a modest number of oocytes following mild stimulation is associated with a distinctly higher implantation rate compared with patients

where the same number of oocytes is retrieved following conventional stimulation.[58]

These observations have led to the contention that when few oocytes are obtained following mild ovarian stimulation, they are more likely to represent a more homogenous group of good quality oocytes instead of a pathological reduction in the ovarian response.

These findings suggest that the fear of obtaining low numbers of oocytes following mild ovarian stimulation is unjustified thereby contradicting the assumption that an increased quantity of oocytes leads to better outcomes.[59]

In fact, in most of the studies investigating the relationship between oocyte numbers and pregnancy rates, the positive effect on pregnancy rates with a growing number of oocytes eventually levels off.[59,60] A potential disadvantage of the development of lower numbers of oocytes might be the reduction of supernumerary embryos for cryopreservation to transfer in subsequent cycles.

The number of good quality embryos resulting from mild ovarian stimulation was found to be similar to that following a conventional stimulation protocol and should therefore lead to equal total number of pregnancies.[29]

Evidence in favor of mild ovarian stimulation for IVF is accumulating in recent literature. Young, poor responders, estrogen sensitive cancer patients, and hyper responders to conventional IVF may benefit from mild stimulation.

However, an important concern regarding the use of a mild treatment strategy remains the reduction in the per cycle chance of pregnancy. Again, chances for IVF success should be balanced against patient discomfort, chances for complications, and costs.

Mc Donald, et al., designed a computer algorithm for day-to-day decision making in IVF. It shows that the use of AI technology in day-to-day IVF decision making is feasible, at least as an adjunct tool, and it should be explored further with big data. The authors conclude that as new data and images are added to the repository, metadata, and outcomes can be extended to improve algorithm precision. Ultimately, it would be interesting to see if machine learning platforms outperform physicians in decision making during ovarian stimulation.

OOCYTE RETRIEVAL

Oocyte retrieval is performed 36 hours after the trigger injection of human chorionic gonadotropin (hCG) or GnRH agonist. Methods of egg collection have improved considerably since the introduction of ART. At first, all egg collections were performed laparoscopically. This is now rarely used and is reserved for women if their ovaries are inaccessible through the transvaginal route. With the introduction of endovaginal transducers, the transvaginal ultrasound-guided approach became the predominant method for egg collection. In this, the specially designed transducer is used to visualize the follicles and the aspirating needle is passed alongside it. This method is generally well-tolerated when carried out under light intravenous sedation, can be learnt by clinicians very quickly and is associated with minimal morbidity.

Several designs of aspiration needles are available. They may have a single or double lumen to enable aspiration and flushing through different routes. The needle is usually 16-gauge and must have a very sharp tip to enable easy puncture of mobile ovaries and its distal 2 cm should be roughened to enhance ultrasound visualization **(Fig. 1)**. The needle is connected to a test tube by tubing and suction is applied either from a foot-operated pump **(Fig. 2)** or manually. The ultrasound transducer **(Fig. 3)** is enclosed in a special sterile condom and plastic sleeve prior to insertion into the vagina and should be thoroughly cleaned with a damp cloth after each procedure.

It is important to provide effective anesthesia and analgesia for transvaginal oocyte recovery as they are painful. No technique of anesthesia, analgesia, or sedation is free from side effects. Whatever technique is used, recognized standards of practice should be adhered to and all IVF professionals should follow the safe practice of administering sedative drugs. Conscious sedation should be offered to all women having the procedure as it is safe and acceptable method of providing analgesia.

Generally, very few technical difficulties are encountered during vaginal egg collections. The main risks of transvaginal oocyte recovery are pelvic infection (0.6%) and bleeding (>100 mL in 0.8% cases) (Bennett, et al., 1993), which may be serious, sometimes even fatal. Appropriate preoperative vaginal preparation and minimizing the number of repeated vaginal penetrations may serve to lower the risk of infection. While there is no evidence that routine antibiotics reduce the risk of infection, the administration of an intravenous bolus of antibiotics is generally recommended to women

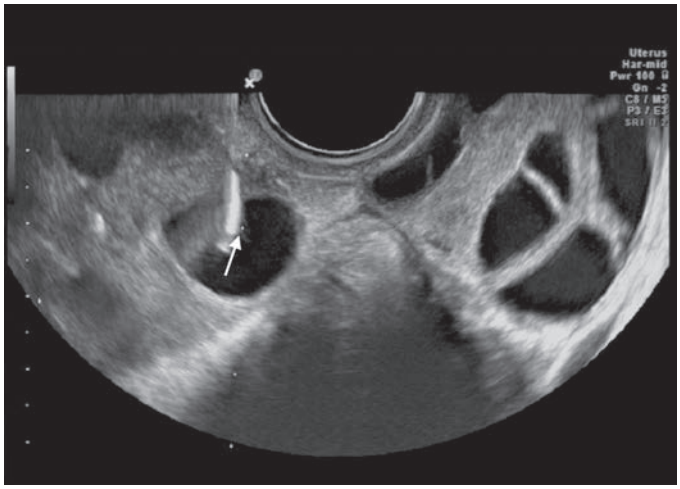

Fig. 1: Ultrasound picture during vaginal egg recovery. The tip of the needle (arrow) is seen within the follicle (F).

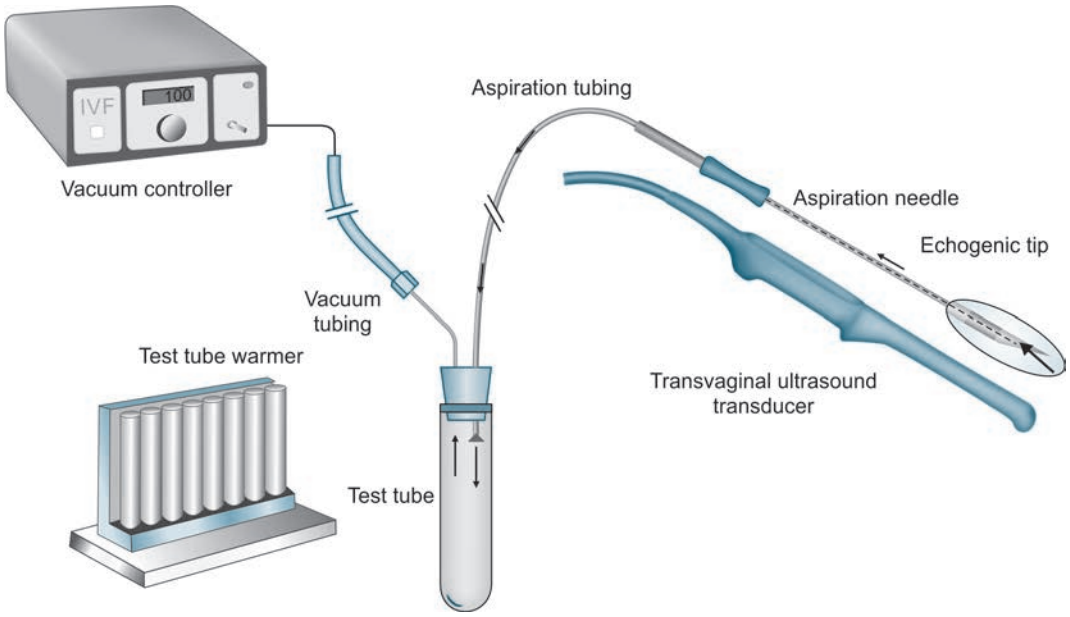

Fig. 2: Follicle aspiration equipment. An assembled follicle aspiration single lumen needle connected to a test tube. The test tube is in turn connected to a suction pump. The needle is attached to the transvaginal ultrasound transducer through needle guide and bracket.

with history of severe pelvic inflammatory disease or if an endometrioma is punctured. Intestinal, vascular, uterine, and tubal injuries with the aspiration needle have also been reported. Bleeding and infections may be serious, sometimes even fatal complications.[61]

IN VITRO FERTILIZATION VERSUS INTRACYTOPLASMIC SPERM INJECTION INSEMINATION

The editor-in-chief of human reproduction has criticized the overuse of ICSI, following a world report into the use of ART.

The report, published in the same journal, finds that ICSI—a technique used during IVF for men with very low sperm counts—is used in almost 100% of IVF cycles in the middle East and some parts of Latin America. This is not different in India where an increase trend in ICSI practice is noted (based on a survey done by lifeinvitro.com).

In an editorial in the journal, Professor Hans Evers of Maastricht University wrote: "Unless the majority of couples" infertility in the world today is determined by severe male causes, the report offers a sobering confrontation with modern reproductive medicine practice".

He added that there has been "unjustified enthusiasm for ICSI on the part of patients and doctors" and that "we have arrived in a situation of therapeutic illusion on a grand scale".

The oldest ICSI offspring cohort worldwide has recently reached adulthood. In a large follow-up project at UZ Brussels focused on reproductive and metabolic health of young adults, between 18 and 22 years, conceived after ICSI with ejaculated sperm. Results of both physical examination and semen analysis were compared between young ICSI men being part of a longitudinally followed cohort and spontaneously conceived controls who were recruited cross-sectionally. Young ICSI adults had a lower median sperm concentration (17.7 million/mL), lower median total sperm count (31.9 million), and lower median total motile sperm count (12.7 million) in comparison to spontaneously conceived peers (37.0 million/mL; 86.8 million; 38.6 million, respectively). The median percentage progressive and total motility, median percentage normal morphology, and median semen volume were not significantly different between these groups. These first results in a small group of ICSI men indicate a lower semen quantity and quality in young adults born after ICSI for male infertility in their fathers.

Many studies have compared the efficacy of conventional insemination versus ICSI—for all. The results from a similar study by Eftekhar, et al., (2012) show that in IVF group, fertilization and implantation rates were significantly higher than ICSI group (66.22 and 16.67% in IVF group versus 57.46% and 11.17% in ICSI group, respectively). Chemical and clinical pregnancy rates were statistically higher in IVF group as compared with the ICSI group (42.9% versus 27.3% and 35.7% versus 21.5%, respectively). According to these authors, the routine use of ICSI is not improved fertilization, implantation, and chemical pregnancy rates and is not recommended in nonmale factor, normozoospermic patients.[62]

A recent study aimed to compare the clinical outcomes between IVF and ICSI in sibling oocytes. A total of 571 cycles in 555 couples undergoing split insemination cycles were included in this study. The clinical outcomes did not differ between IVF and ICSI in split insemination cycles. Split insemination can decrease the risk of total fertilization failure. However, the authors conclude that unnecessary ICSI is carried out in most split insemination cycles and the use of split insemination might make ICSI more common.[63]

In a study by Hershlaq, et al., (2002) found superiority of ICSI over conventional insemination in cases of unexplained infertility cases. In couples with unexplained infertility, a higher fertilization rate was achieved through ICSI compared with conventional IVF. No such benefit could be demonstrated for couples with borderline semen parameters. The use of ICSI rescued 12 of 110 cycles (10.9%) where IVF failed. Adoption of the ICSI–IVF insemination split in cases of unexplained infertility may help eliminate fertilization failures.[64]

A recent meta-analysis looked as if ICSI, compared with conventional insemination, improves fertilization rates, and prevents total failed fertilization (TFF) in couples with unexplained infertility. The pooled relative risk (RR) of TFF was significantly higher with conventional insemination than with ICSI (RR 8.22, 95% CI 4.44–15.23). The number of subjects needed to treat with ICSI to prevent one case of TFF was five. This meta-analysis favors the use of ICSI to increase fertilization rates and decrease the risk of TFF in couples with well-defined unexplained infertility.[65]

Some studies show preference of ICSI over conventional inseminations in cases such as endometriosis-associated infertility, unexplained infertility, with regard to better fertilization status. A recent study provides strong evidences that the conventional IVF exhibits advantages over the ICSI method in non-male factor infertility for advanced age patients with five or fewer oocytes retrieved.[66] Studies have shown that in the USA there is an increasing usage of ICSI for non-male factor infertility despite a lack of evidence-based benefit. The study by Grimstad, et al., (2016) corroborates this increasing use over the last 8 years, specifically in the tubal ligation only patient population. Even after adjusting for multiple confounders, the patients who underwent ICSI had no statistically significant improvement in fertilization rate and actually had a lower likelihood of achieving a clinical pregnancy and LB. Therefore, their data suggest that the use of ICSI in tubal ligation patients has no overall benefit. This study contributes to the body of evidence that the use of ICSI for non-male factor diagnosis does not improve ART outcomes over conventional IVF.[67]

American Society for Reproductive Medicine (ASRM) committee concludes that ICSI without male factor infertility may be of benefit for selected patients undergoing IVF such as with PGT and cryopreserved oocytes. In other conditions additional cost-burden of ICSI must be considered.[68]

Transfer of Euploid Embryos by Preimplantation Genetic Testing–Next-generation Sequencing

Embryonic aneuploidy is one of the most common cause attributed for IVF failures. The quoted rates of aneuploidy being 40% in younger women and 80% in women older than 43. PGT was proposed as a method to screen the embryos and to select for transfer only the chromosomally normal ones. Also, this strategy would ease the selection of embryos for single ET. The PGS version 1 used FISH to screen polar body and day 3 embryos. FISH could screen 3–12 chromosomes with a specificity of ~90% in detecting aneuploidy when compared to the newer comprehensive chromosome screening. A meta-analysis of PGS version 1 by Mastenbroek, et al., showed that there is no benefit in younger women and in older women it may actually reduce the pregnancy rates attributed to the fact that the loss of genetic material from a lesser cell stage of day 3 embryo may reduce the implantation potential.

Comprehensive chromosome screening technologies which can assess all 24 chromosomes and advances in embryo culture systems led to the introduction of PGS version 2. This is characterized by blastocyst culture and biopsy of the trophectoderm after breaching zona pellucida and in most cases followed by frozen ET. Single nucleotide polymorphism microarrays (SNP arrays), micro aCGH, and quantitative polymerase chain reaction (qPCR) were the earlier used and validated methods. Advantages of next-generation sequencing (NGS) over these methods are—it allows the analysis of chromosomes for aneuploidies, inversions, deletions, the detections of point mutations, copy number variations, and even the mitotic chromosomal abnormalities in a single run. NGS can also evaluate the mitochondrial genome in the same sample.[69]

Next-generation sequencing uses massive parallel sequencing of small DNA fragments until required depth of reads to analyze the copy numbers of the chromosome. The advantage in NGS is that the read depth can be increased even to cover the whole genome. SNP arrays and microarray

CGH are also equipped for processing high sample volumes but as the volume of sample increases the number of array slides required and the cost also increase.

Criticisms on PGS version 2 are that the standards of a day 5 biopsy itself can lead to a lot of embryo wastage considering the blastulation rates to be around 50% even in ideal scenarios. Given the higher degree of prevalence of mosaicism in trophectoderm and the lesser representation of inner cell mass by trophectoderm biopsy the accuracy of PGS in determining the embryo ploidy is questioned. The evidence of benefits for the indications which PGS was initially proposed—indications such as recurrent implantation failures, recurrent pregnancy loss, and advanced maternal age are still lacking.[70]

Preimplantation genetic screening—NGS have given promising results.[71-73] The results of the ongoing trials and more well-conducted studies would clear the controversies and PGS would make its way to standard of care in ART. Several RCTs have demonstrated an improvement in implantation rates and pregnancy rates with reduced time to conception

FREEZE ALL STRATEGY

The routine procedure after IVF or ICSI is the transfer of embryo in the same cycle and freezing the available embryos. With the advent of advanced laboratory techniques and improved embryo survival rate postvitrification, the pregnancy rate following frozen ET also improved. One of the lessons learned from donor oocyte programs is that the pregnancy rates were better when compared to the fresh transfer counterparts. This led to the identification of the causes for lesser implantation in a fresh transfer cycle: (1) exposure to the supraphysiological doses of estrogen and (2) premature elevation of progesterone in the late follicular phase—both these leading to functional dysregulation of the endometrium. Also, the GnRH antagonist cycle with agonist trigger have been increasingly used in the predicted hyper responders to prevent OHSS. The GnRH agonist trigger causes significant luteal phase defect due to the intense luteolysis. Freeze all strategy refers to electively freezing all the available embryos and transfer later on in an unstimulated cycle, thereby bypassing the untoward effect of elevated hormones and allowing segmentation of IVF procedure thereby reducing the OHSS risk. Also, in the need for embryo accumulation for preimplantation genetic diagnosis (PGD) or PGS and in cases of embryo endometrial asynchrony as in the case of a day 6 blastocyst, freeze all strategy is of utmost benefit.

Chen, et al., in a RCT of 1,508 polycystic ovary syndrome (PCOS) patients demonstrated that freeze all strategy helped in achieving significantly better pregnancy rates, lower risk of OHSS, and reduced miscarriage rates. The 2017 Cochrane review on fresh versus frozen ET in ART suggested a moderate quality evidence that there is no significant increase in the LB rate and a low-quality evidence in reducing the OHSS risk.[74] The recent meta-analysis done by Dieamant, et al., 2017 concluded that freeze all strategy is not helpful when the mean number of retrieved oocytes is <15 but it may be advantageous when there is an increased response.[75]

In the absence of a grade A evidence to adopt freeze all strategy, Blockeel, et al., 2017, conducted a SWOT analysis and the increased pregnancy rates, better perinatal out-comes, reduced ectopic pregnancy, and very importantly OHSS free clinics were identified as the strengths of this strategy. The weaknesses highlighted were the lack of robust evidence and the cost increment. The birth of large for gestational age babies and the need for optimization of cryopreservation techniques were cited as weaknesses. However, this strategy provided the opportunity for scheduling and any day start of stimulation.[76]

The recent multicenter randomized controlled trial in the UK (E-Freeze) although limited by sample size, provides no evidence to support the adoption of a routine policy of elective freeze in preference to fresh ET in order to improve IVF effectiveness in obtaining a healthy baby.[77] No significant increase in the LB rates or the miscarriage rates between fresh or frozen cycles were noted in properly chosen patients. The decision for freeze all or to go ahead with fresh transfer should ideally be patient or cycle oriented, limiting freeze all policy to hyper responders. The one important complication which can be prevented by freeze all strategy is late OHSS.

EMBRYO TRANSFER

Embryo transfer is a critical step in determining the final outcome of the treatment. The convention has been to replace embryos on the second or third day postinsemination, when the embryos are usually 2–8 cell stage of cleavage. With improvements in culture media, there is an increasing tendency for delaying ET with an aim to improve the implantation rates. While there is no improvement in LB rates (1.07, 95% CI 0.84–1.37) with delaying ET from day 2 to day 3 (Oatway, et al., 2004), transfer of embryos at blastocyst stage (day 5/6) has shown significant increase in LB rate (OR 1.35, 95% CI 1.05–1.74) when compared with day 2–3 transfers (Blake, et al., 2007). It is a more physiological approach, allowing synchronization of the embryo with the endometrium and the selection of viable embryos for transfer will be more efficient. However, the rates of embryos freezing are lower and the treatment cancellation rates are higher with blastocyst transfer. But in selected group of couples, the practice of blastocyst transfer has the potential to favor single ET without compromising the overall success rates but can significantly reduce the occurrence of multiple pregnancies. The most favored group for blastocyst transfer are those having high numbers of eight cell embryos on day 3, in whom the cycle cancellation is not increased.

Fig. 4: Embryo transfer: The echogenic tip of the catheter is placed approximately 1–1.5 cm from the uterine fundus so that the embryo/s are expelled gently into the midcavity of the uterus.

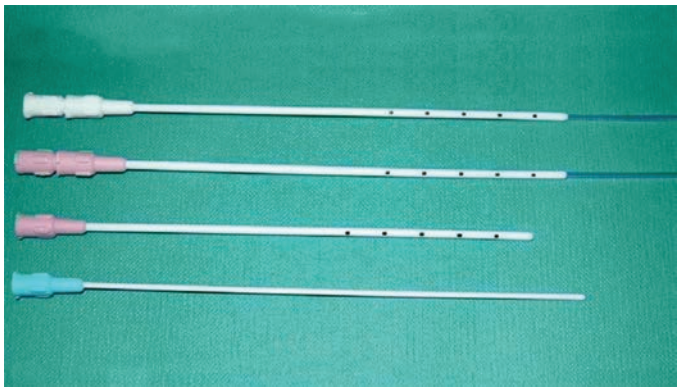

Fig. 5: Embryo transfer catheters. From top to bottom—Trial Wallace (no lumen), Wallace, outer sheath, and stylet of malleable catheter.

Transcervical embryo replacement into the uterine cavity is a relatively simple procedure, which must be carried out meticulously to ensure appropriate placement of the embryos. Variations among clinicians in the technique of ET may influence the pregnancy rate. Avoidance of blood, mucus, bacterial contamination, excessive uterine contractions, and trauma to the endometrium is associated with optimal pregnancy and implantation rates after transcervical ET. Transabdominal ultrasonographic guidance to determine the precise depth of embryo placement within the uterus appears to facilitate successful ET and is preferred (Brown, et al., 2010). The tip of the catheter is placed approximately 1–1.5 cm from the uterine fundus **(Fig. 4)** so that the embryo/s are expelled gently into the midcavity of the uterus. Soft catheters are preferred over rigid ones as they are less likely to traumatize the cervix and endometrium and to invoke any uterine contractions. The commonly used soft catheters (Wallace) **(Fig. 5)** have a softer inner cannula and a stiffer outer sheath. Occasionally, resistance to pass the soft inner cannula into the uterus usually at the level of internal OS is encountered and in these cases the stiffer outer sheath is advanced in the cervical canal to negotiate the resistance with the inner cannula can now be advanced into the uterine cavity. A firmer malleable catheter with a stylet and an outer sheath is another option in difficult cases, where the catheter is advanced up to the level of the internal OS. The inner stylet is then removed and the softer cannula with embryos loaded in and it is fed through the outer sheath to advance into the uterine cavity for transfer. The outer sheath or the malleable catheter should never be advanced beyond the internal OS.[78]

Following ET, women are often advised to continue their normal daily activities as prolonged bed rest has not shown to improve the IVF outcome. Luteal support is usually required as ART is associated with inadequate luteal function, possibly because of the feedback inhibition of LH due to the supraphysiological hormonal milieu, the removal of the granulosa cells surrounding the oocytes while performing the oocyte retrieval and of the use of GnRH agonists. hCG or progesterone is traditionally used to provide luteal support during conventional IVF cycles. However, the routine use of hCG is not recommended because of the increased likelihood of OHSS and no benefit over progesterone in terms of IVF success. The progesterone can be administered either 200–800 mg/day vaginally or 50–100 mg/day intramuscularly and is continued for 14–16 days, when pregnancy test is performed.

TRAINING IN OPU AND ET BY SIMULATORS

The value of training and certification in fellowship programs in reproductive medicine is most evident in the remarkable and consistent improvement in the success of ART procedures, particularly IVF. For both patient and physician, the final step of IVF—the transfer of the embryo into the uterine cavity for implantation— is often stressful. This anxiety is often attributed to the high-cost and time-associated with IVF treatment, the potential difficulty of the transfer due to individual patient anatomy, and the delicate nature of the embryo itself. It is said that nearly 50% of fellows training to be IVF specialists have historically received little or no training in ET because of the importance of this final step in the IVF process and the difficulty in allowing trainees to perform it on patients for the first time. The simulator provides in training physicians the opportunity to practice simulated transfers with varying degrees of difficulty in a safe, risk-free environment, and with unlimited repetitions under supervision by experts. They receive real-time simulation feedback of their metrics that, when combined with structured debriefing with expert faculty, further facilitates development of motor and cognitive skills required to attain proficiency in ET.

TABLE 1: Innovative/AI based platforms currently introduced in in-vitro fertilization.

Company name	*Website*	*Overview*
Preconception		
Ovaterra	https://myovaterra.com/	Ovaterra is the the first intelligent fertility content and commerce platform focused on optimizing fertility naturally
IMMA health	https://www.imma.health/	At home ovarian stimulation monitoring system for IVF
Hertility health	https://hertilityhealth.com/	At-home hormone and fertility testing
Béa fertility	https://beafertility.com/	The first intracervical insemination kit designed for home use
Apricity	https://www.apricity.life/	Fertility prediction
Infertility workflow		
MIM solutions	https://www.mim-solutions.ai/en/	FOLLISCAN: Intelligent algorithms supporting the doctor in the ultrasound diagnosis of a woman's ovarian reserve
Ferty U	https://www.f6s.com/assistant-in-human-reproduction-and-ivf	Service for ovarian response prediction in IVF infertility treatment
FertilAI	https://fertilai.com/	AI and big data-based platform for automating protocol management in the IVF clinic
Improving stimulation		
OptIVF		A software package for predicting optimal drug dosage customized for each patient for IVF cycles, marketed by Stochastic Research Technologies LLC., USA
Choosing the best oocyte		
Future fertility	https://futurefertility.com/	A novel, non-invasive oocyte scoring system using AI applied to 2D images
AIVF	https://www.aivf.co/	provide the IVF clinic with a proprietary fertility OS™ platform that changes the "art" of IVF into a more data-driven and predictable science
Choosing the best embryo		
Life whisperer	https://www.lifewhisperer.com/	Using deep learning and computer vision, it identifies embryo features for selection
Amplexa genetics	https://amplexa.dk/	Noninvasive PGT-A and NGS for optimizing IVF treatments
Fairtility	https://fairtility.com/	Novel AI and computer vision algorithms enabling accurate classification and prediction of the best embryos
Embryonics	https://www.embryonics.me/	Ubar: Next generation Embryo selection
iDAScore	https://www.vitrolife.com/our-products/idascore-intelligent-data-analysis-for-embryo-evaluation/	Intelligent data analysis for embryo evaluation-vitrolife
Choosing the best sperm for fertilization		
QART medical	https://www.qart-medical.com/	Quantitative, morphometric sperm cell selection in ICSI
Baibys	https://www.baibys.com/	Artificial intelligence system for autonomous sperm selection before ICSI
IVF 2.0 Ltd	https://www.ivf20.ai/	SiD: AI enabled real-time sperm selection based on morphology, speed, and motility patterns

(AI: artificial intelligence; ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization; NGS: nextgeneration sequencing)

ARTIFICIAL INTELLIGENCE AND AUTOMATION

Many innovative systems and products are in either clinical trial/developmental phase for ART **(Table 1)**. In recent times, the use of AI has gained popularity in its ability to predict clinical outcomes using routinely obtained information, such as patient attributes, medical images, and blood results. AI may help embryologists in selecting the best oocyte and sperm combination as well as predicting embryo quality. Furthermore, AI may assist the infertility specialists in

developing an optimal patient-specific treatment regimen to improve treatment success.

Recent studies using AI to predict embryo developmental competence are on the rise and show promise in improving the accuracy of manual grading and predicting development to blastocyst and pregnancy.[79] Interestingly, AI is able to use cellular textures to accurately discern between the inner cell mass and trophectoderm of the blastocyst. The use of AI to accurately identify cell lineages may lead to improved embryo classification and IVF success. AI will likely aid clinicians in devising patient-specific treatment regimens, before and after oocyte collection, as well as improving gamete and embryo selection.

Even though medical/tissue culture laboratories embraced advanced automation workflow systems, the IVF laboratories still lag behind in introducing new technologies. Unlike any other clinical/cell culture laboratories, IVF labs need an error-free system as it deals with creation of human embryos.[80]

Microfluidics platforms hold high promise for embryo culture. Integration of microfluidics into the ART laboratory may give rise to several foreseeable advantages: (1) precisely controlled fluidic manipulations of gametes/embryos; (2) contribute biomimetic environments for in vitro culture; (3) facilitating genetic and molecular bioassays at microscale level; and (4) making miniaturization and automation a reality. The basic utility and advantages of individual microfluidic devices/systems for gamete and preimplantation embryo isolation, manipulation, and assessment have been demonstrated by many research groups. Current efforts are focused on integrating individualized microfluidic procedural components into a future IVF lab-on-a-chip. Presently, two startups are doing the clinical trials—one in Europe (https://www.overture.life/) and another one in Australia (https://www.fertil.is/).

The IVF embryo culture has already been partially automated with use of time-lapse incubators which helps continuous monitoring of embryo development in a closed environment. Data generated from time-lapse incubators can be analyzed with machine learning/AI to aid in the selection of embryos with the highest implantation potential. Additional information about embryo viability may be gleaned from other omics technologies which can either sample the embryo directly or indirectly via its culture media.

Vitrification has become the dominant method for oocyte and embryo cryopreservation. While semiautomated/automated systems for oocyte/embryo vitrification have been reported and are now in early stages of clinical adoption.

Furthermore, automation will likely significantly decrease the staffing requirements and alter the type of skills required to operate fertility centers.[81] It is likely that the technical aspects of IVF will be gradually assumed by machines.

Intracytoplasmic Sperm Injection

Alex C Varghese, Kenichiro Hiraoka

INTRODUCTION

In the 1980s, several micromanipulation procedures were adopted from animal husbandry to facilitate gamete interaction, and this resulted in the development of intracytoplasmic sperm injection (ICSI), a procedure through which an oocyte can be fertilized independent of the morphology and/or motility of the single spermatozoon injected. The procedure was first used in cases of fertilization failure after standard in vitro fertilization (IVF) or when an inadequate number of sperm cells were available. The consistency of fertilization independent of the functional quality of the spermatozoon has extended the application of ICSI to immature spermatozoa retrieved surgically from the epididymis and testis.[1] Moreover, the need to denude the oocyte has allowed assessment of the nuclear maturity of the oocyte. ICSI **(Fig. 1)** is also preferred in conjunction with preimplantation genetic diagnosis (PGT) and recently has been used to treat human immunodeficiency virus (HIV) discordant couples, where there is a pressing need to minimize the exposure of the oocyte to a large number of spermatozoa. For all ages and with all the different sperm types used, fertilization after ICSI is at approximately 70–80% and it ensures a clinical pregnancy rate of up to 45%. These results have made ICSI a procedure comparable in popularity with conventional IVF and have minimized the need for couples suffering from all forms of male infertility to resort to adoption or the use of donor sperm.[2]

Fig. 1: Two intracytoplasmic sperm injection (ICSI) workstations in opposite direction—a space-saving placement in a busy laboratory. *Courtesy:* Giles Palmer, Mitera Hospital, Greece.

The first gamete micromanipulation techniques date back to the late 1990s. In Rome, in 1990, there was the first birth by injection of the sperm into the perivitelline space [subzonal insemination (SUZI)] obtained by the team Simon Fishel, Severino Antinori, and Franco Lisi. The technique was developed by Gianpiero Palermo in 1991 at the Vrije Universiteit Brussel in the Center for Reproductive Medicine headed by Paul Devroey and Andre Van Steirteghem.[3] It has been estimated that approximately 40% of sterility in couples can be attributed to male subfertility. ICSI has raised hopes that these couples can have children of their own. This method of treating predominantly male-factor patients has achieved a breakthrough, and it has established itself as the preferred method of treatment in the field of assisted reproduction.

In recent years, researchers have been working to produce a more effective ICSI protocol, from introducing novel sperm selection techniques to evaluating how appropriate ICSI may be for an infertile couple. These include techniques such as physiological ICSI (PICSI) and intracytoplasmic morphologically selected sperm injection (IMSI).[4] Moreover, oocyte activation has also been tried to alleviate failed fertilization cases in ICSI cycles.[5]

INDICATIONS FOR INTRACYTOPLASMIC SPERM INJECTION

The indications for ICSI are:

- Oligozoospermia
- Severe asthenozoospermia
- Teratozoospermia (≤4% normal morphology)
- Fertilization failure in previous cycles
- Surgically retrieved spermatozoa

- High titers of antisperm antibodies
- Frozen–thawed spermatozoa with compromised motility
- Unexplained infertility
- Patients with immotile cilia syndrome
- PGT/noninvasive PGT (niPGT) cases.

INDICATIONS FOR INTRACYTOPLASMIC SPERM INJECTION WITH SURGICALLY RETRIEVED SPERMATOZOA

Intracytoplasmic Sperm Injection with Epididymal Sperms

- Congenital bilateral absence of the vas deferens (CBAVD)
- Failed vasoepididymostomy
- Failed vasectomy reversal
- Obstruction of ejaculatory duct
- An ejaculation due to spinal cord injuries
- Young syndrome.

Intracytoplasmic Sperm Injection with Testicular Sperms

- Hypospermatogenesis
- Sertoli cell-only syndrome
- Incomplete maturation arrest
- Klinefelter syndrome.

Factors Influencing Intracytoplasmic Sperm Injection Results

- Intrinsic changes in oocyte
- Fragmentation of deoxyribonucleic acid (DNA) in sperm.

LOCATION OF INTRACYTOPLASMIC SPERM INJECTION SETUP

The ICSI workstation should preferably be near a structural frame or wall to minimize vibration interference and must be kept dust free. The equipment must be installed on a substantial bench top, away from distractions of traffic such as people or trolleys. Any vibration will seriously interfere with the injection procedure, and it is essential to make sure that the equipment is completely stable, using antivibration equipment if necessary, situated on a stable floor. Subdued lighting is helpful for microscopy. The proper visibility of specimens in the inverted microscope should be checked well in advance of any ICSI procedures. Ensure that the tool holders and all other parts of the micromanipulation system are correctly fitted and adjusted for optimal range of movement and that the microtools can be accurately aligned (the angle of the tool holder to the microscope stage should be set at 30–35°).

INTRACYTOPLASMIC SPERM INJECTION

Intracytoplasmic sperm injection involves several micromanipulation procedures that involve delicate maneuvers using glass microtools operated by joysticks. The operator has control over movements in three dimensions (X, Y, and Z directions) with a resolution of up to 1 μm. Common hurdles to be overcome when using micromanipulators include long setup times, visualizing the tip of the microtool under the microscope, and moving the tools without inadvertently breaking them in the dish. Most suppliers provide a "home" function where microtools are returned to their setup position to enable faster changeover of culture dishes and to allow users to locate pipette tips if they should "lose" them in the field of view. With such delicate instruments and the need for precise positioning, the microscope used for micromanipulation procedures should be protected from any vibration which could disturb the system and/or compromise focus. Magnifications of 200–400× are generally required to visualize procedures. Quality optics with high numerical apertures and long working distances are also essential. Contrast optics, such as Nomarski differential interference contrast (DIC) (with glass culture dishes) or Hoffman modulation contrast (suitable for both glass and plastic), are commonly used. Apodized phase contrast objectives can help to overcome the halo effects common in phase contrast techniques to provide sharper edges, enhanced specimen detail, and a greater apparent depth of field. A correction collar that compensates for the effects of working at physiological temperatures is also useful. The warming stage should be calibrated and frequently checked. Traditionally, many laboratories use the ones with hole but nowadays many embryologists prefer thin glass warming stages which give a better and uniform heating of ICSI dishes. The configuration of the ICSI setup may vary from laboratory to laboratory.

Materials

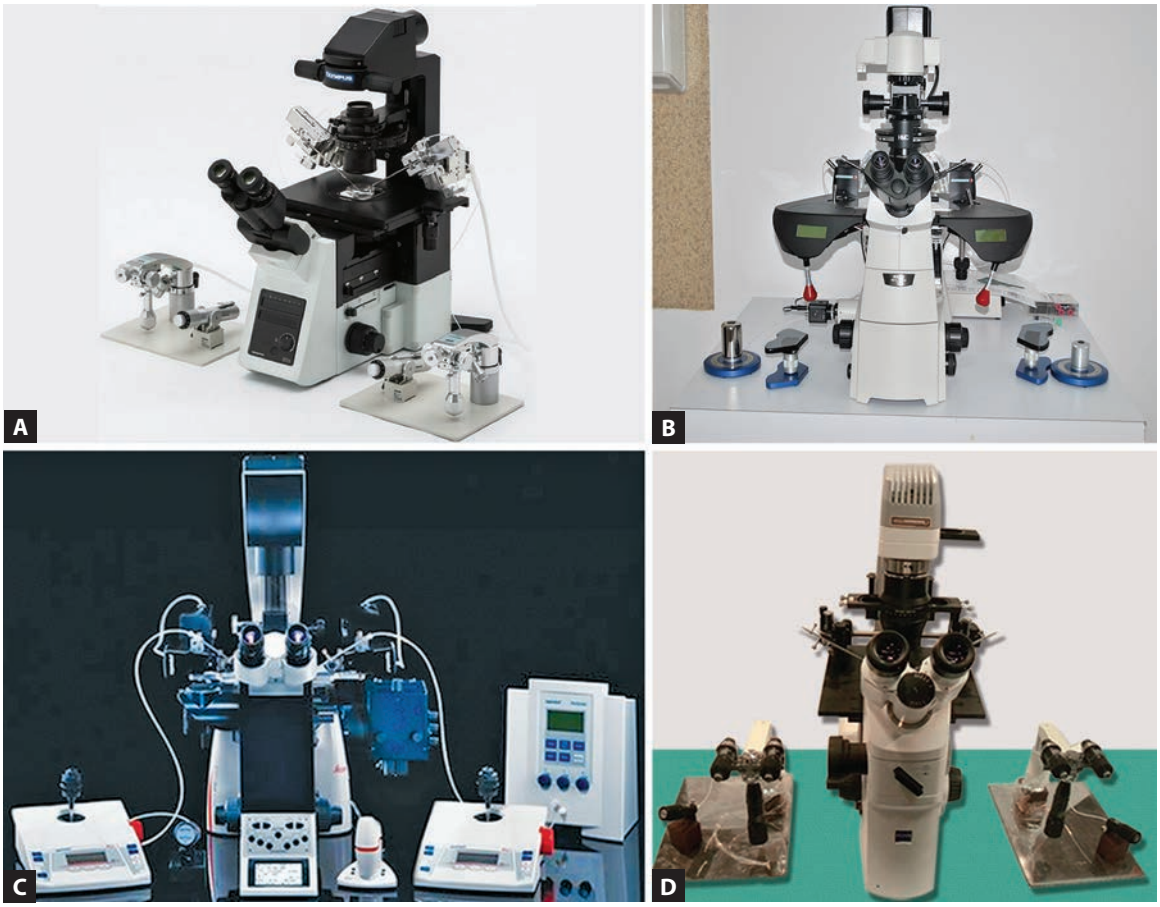
Equipment

Intracytoplasmic sperm injection demands a high level of skill and careful manipulation of cells under a microscope. An important determining factor to the success of this procedure is the performance of the manipulation set. Each micromanipulation set consists of the following equipment:

- Inverted microscope equipped with Hoffman modulation contrast or DIC and 4×, 10×, 20×, and 40× objectives
- Two micromanipulators (one for moving the holding capillary and another for transferring the sperm)
- Adapter for inverted microscope
- Air microinjector for holding the oocyte
- Oil microinjector for transferring the sperm.

There are many systems available in the market. **Figures 2A to D** show different models of ICSI work station.

Inverted microscope equipped with heated stage allows work to be carried out without fluctuation in temperature. Consistency of temperature is important as transient cooling



Figs. 2A to D: Different models of intracytoplasmic sperm injection (ICSI) workstations. (A) Olympus inverted microscope with Narishige (Takanome) micromanipulator; (B) Integra workstation (ORIGIO, CooperSurgical); (C) Leica microscope with Eppendorf micromanipulator; (D) Carl Zeiss microscope with S-micromanipulator.

can cause irreversible spindle damage. Narishige, Olympus, Integra, Leica, and Carl Zeiss are different types of inverted microscopes.

Micromanipulators are devices intended to translate macroscopic movement of human hand into microscopic movement of a fine tool held in its grasp. Two identical sets of two manipulators are mounted on the microscope: One set for coarse movements and another set for fine movements. One on the left side is for manipulation of the holding side and one on the right side is for manipulation of the injection side.

Each manipulation set is completed with a microinjector. Microinjectors are used either to fix or to release the oocyte with holding pipette or to aspirate and inject a spermatozoon with injection pipette. The injectors consist of airtight glass syringes which are connected to the steel pipette holders with Teflon tubing. They are filled with mineral oil or air. The plunger of the syringe is controlled by micrometer. Since movements in oil-filled syringes are fine, they are usually used for the injection side. But it has drawbacks such as oil leakage, oil breakdown due to ultraviolet (UV) exposure, and air bubble entrapment. Pneumatic injector, on the other hand, can be used on the holding side owing to its robust control. Upright pneumatic injector is referred to as mushroom due to its upright handle and large base design. The positioning of the injectors is up to the embryologist.

Some prefer both on the left side while some prefer injection on left and holding on right side.

Consumables

- Shallow Petri dishes, tissue culture grade (e.g., 351006 Petri dishes: BD Falcon, NUNC 0150265, Oosafe ICSI dish, Vitrolife ICSI dish 16006)
- Holding pipettes
- ICSI injection needles (either 30 or 35° bevel tips).

In the early years, each unit used to make its own microtools from capillary tubes with the use of commercially available microtool pullers, grinders, and forges. Nowadays, there are many companies making microtools, many with computer-generated automation. ICSI pipettes may differ in ways of packaging to facilitate the handling before installation on the microscope, some with spike or non-spike and differences in the bevel (angle) at the tip (30–21°). The choice is entirely up to the preference of the operator and

the procedure. For procedures such as spermatid injection, wider bore needles can be used (Humagen MIC-9-35).

Media

- 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES)/3-(N-morpholino) propanesulfonic acid (MOPS)/HEPES–MOPS combination
- Polyvinylpyrrolidone (PVP) or SpermCatch
- Light mineral oil/paraffin oil (Vitrolife, Vitromed, LifeGlobal, Lite Oil).

Many laboratories use flushing medium (HEPES-buffered, supplemented with antibiotics and protein) or sperm preparation media to make the ICSI droplets. Some laboratories even use the cleavage media as the oocyte holding droplets. However, there is a chance of drastic shift of pH while using such bicarbonate buffered media, especially when the injection process takes longer duration. Currently, there are many commercially available formulations having the chemical composition of cleavage stage media, but buffered by HEPES (global total HEPES). Since oocytes are stripped off the cumulus mass, the gamete is prone to changes in the surrounding microenvironment including the pH and osmolarity.

Polyvinylpyrrolidone is used as a medium to reduce motility prior to immobilization before ICSI. Since PVP contains synthetic plastic which cannot be digested by the lysosomal enzymes in the oocyte, it can cause a deleterious effect on post-zygote development. Another physiologic alternative is "sperm catch" [current Good Manufacturing Practice (cGMP), Nidacon International AB], which contains hyaluronate-containing product.

Microinjection Preparation and Procedure

- Microinjection dish preparation
- Setting up and alignment of microinjection pipettes
- Transfer of gametes to injection dish
- Sperm selection and immobilization.

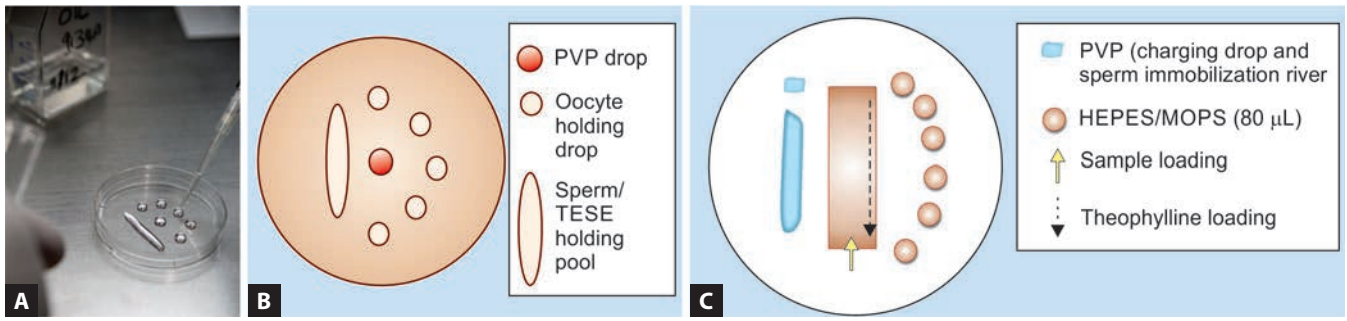
Microinjection Dish Preparation

It is essential to heat all media and oil to 37°C prior to use.

Prepare injection dishes with 4–8 droplets of 5–10 µL of HEPES-buffered culture medium (global total with HEPES) for each individual oocyte and a 5 µL droplet of PVP for the sperm. The droplets can be arranged in a circle with sperm or PVP in the center or in parallel groups, but must be positioned so that they are not too close to the edge of the dish, where manipulation will be difficult. Some embryologists make river-like flat and long spreads of PVP which makes the sperm tail immobilization easier **(Figs. 3A to C)**. The oocyte droplets should not be too close to the sperm or PVP in order to avoid mixing—use an arrangement that allows quick and easy distinction between sperm and oocyte droplets, with numbers etched on the bottom of the dish. Small volumes of media evaporate very quickly and they should be covered immediately with a layer of oil. Light mineral oil also maintains the stability of droplets as well as the temperature and osmolarity. Equilibrate the dishes in the incubator for at least 20–30 minutes and keep them in the incubator until you are ready to begin the procedure. If Falcon 1006 dishes are being used with HEPES-buffered medium, the lid must be tightly fixed if they are to equilibrate in a CO_2 incubator. Dishes with HEPES medium and no lids should be warmed to 37°C without CO_2 atmosphere.

A prepared and preequilibrated traditional culture dish should be available to transfer and further culture the oocytes after injection **(Figs. 3A and B)**.

For surgically retrieved samples which will have sperms mixed with red blood cells (RBC) and tissue and for samples with very poor count and motility (no motility in PVP), conventional ICSI dish will pose a technical problem. In such cases "sperm fishing dish can be prepared," wherein the sample will be loaded in the HEPES river in the middle from where the sperms can be picked and moved to adjacent PVP drop where it can be immobilized and subsequently proceed with oocyte injection. Additionally, in this dish, one



Figs. 3A to C: Two different types of fishing dish preparation for surgically retrieved samples (A and B) polyvinylpyrrolidone (PVP) in drop form (C) PVP spread like a river. Prepared testicular sperm extraction (TESE) suspension is placed in 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES)/3-(N-morpholino)propanesulfonic acid (MOPS) pool having added theophylline (GM501 SpermMobil, Gynemed, Germany). The intracytoplasmic sperm injection (ICSI) pipette is slightly raised from dish floor to avoid debris. Spermatozoa wakes up and swims through the edges which can be picked, placed in PVP for immobilization (tail crushing). TESE/micro-TESE (mTESE)/SOAT sample loading dish.

also has a provision to add sperm motility adjuvants such as pentoxifylline or theophylline in the HEPES river.

Setting Up and Alignment of the Microinjection Pipettes

The micropipettes have to be fitted, aligned, and equilibrated (charges) before starting the ICSI procedure. Since the holding pipette is much bigger than the injection pipette, it can be used as a guide for positioning and equilibrating. First, the micropipettes have to be fitted into the universal capillary holder, which is connected to the microinjector via a tube. When working with oil-filled systems, please make sure that no air bubbles are in the system. Gently push the pipettes past the sealing rings inside the tool holder. After attaching the universal capillary holder, check the alignment. The injection angle can be adjusted independently.

To align the capillary in the vertical position, the universal capillary holder can be rotated, even when the pipette is tightly gripped in place. Both pipettes have to appear straight in the field of view. The end of the holding pipette should be flat, that is, at 90° **(Fig. 4)**.

The alignment in the horizontal plane has to be done with great care. The following points must be taken into account—the holding pipette has to be aligned without tilt as it needs to lie flat on the bottom of the dish in order to aspirate the oocyte in a controlled manner. In contrast, the injection pipette needs to tilt downward slightly so that the tail of the spermatozoon can be broken properly. It is also necessary to prime micropipettes with medium (ideally PVP) before use so that the manipulated gametes never come into contact with air or oil.

Cumulus–corona removal (denudation): There are many hyaluronidase solutions in the market—Cumulase, Syn-VitroHyadase, etc.; the preferred one is 80 IU.

1. Prepare a culture dish containing one drop of hyaluronidase solution and five wash drops of a HEPES-buffered medium (global total HEPES), covered with an overlay of equilibrated mineral oil (denudation may also be carried out in BD, center-well organ culture dishes). Incubate at 37°C for 30–60 minutes. *Note:* HEPES-buffered medium has been adjusted to pH 7.4 and usually 5 mM bicarbonate, and exposure to a CO_2 atmosphere will cause the pH to drop; therefore, culture dishes that contain HEPES-buffered media should be warmed to 37°C in a warming oven and not in a CO_2 incubator.
2. Prepare a thin glass probe and select denudation pipettes or use the commercially available denuding pipettes (140/150 µm diameter, 175 µm to start with).
3. Remove the oocyte and hyaluronidase dishes from the incubator. Place 1–4 oocytes together into the enzyme drop, agitating gently until the cells start to dissociate. Do not leave them in the enzyme for >1 minute. Carefully aspirate the oocytes, leaving as much cumulus as possible behind. Wash by transferring them through at least five drops of culture medium and change to a fine-bore tip for aspiration in order to remove all of the coronal cells. The remaining coronal cells may help in getting better-quality embryos or blastocysts.[6]
4. Assess the quality and maturity of each oocyte under an inverted microscope. Use the glass probe to roll the oocytes around gently in order to identify the polar body and examine the ooplasm.[7]

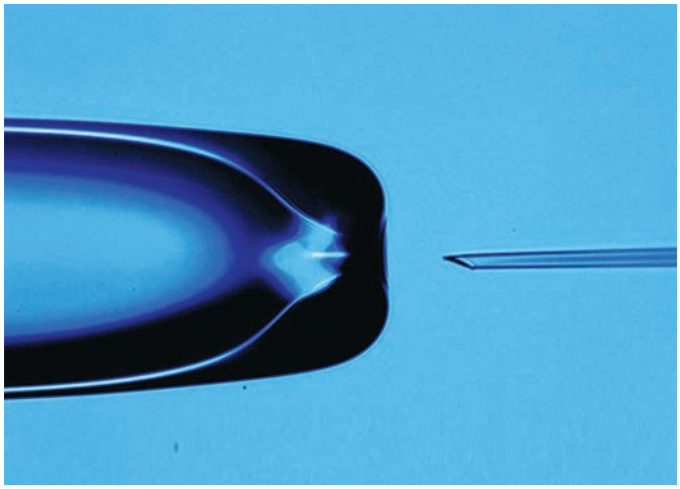


Fig. 4: Alignment of micropipettes.

Micromanipulator

1. Make sure that the microscope heating stage is at a temperature that will maintain droplet temperature in the dishes at 37°C and ensure that all controls are set to neutral (adjusted to zero in Narishige system) and can be comfortably operated and that you are confident that all parts function smoothly before you begin. It is essential to check that you can smoothly carry out very small movements. Ensure that the pipettes are operating smoothly and are in field of view. This involves not only the equipment itself, but also its position on the bench in relation to your (comfortable) seating position.
2. Insert holding and injection pipettes into the pipette holders, tighten well, and if an oil-filled system is being used, make sure that there are no air bubbles in the tubing system. Bubbles interfere with sensitivity when attempting to control movement with fine precision.
3. Align the pipettes so that the working tips are parallel to the microscope stage. First, align the holding pipette under low magnification and then at high magnification. Check the position of both under high magnification. It is important to begin with pipettes in accurate alignment, with both working tips sharply in focus. If a part of the length is out of focus, the pipette is probably not parallel to the stage, but pointing upward or downward.

4. *Adjust the injection controls:* If using an oil system, the oil should just reach the distal end of the pipette, do not try to fill the needle with oil; this will work only if you leave a tiny 5 mm gap of air between the oil and the medium. Briefly touch the tips of both pipettes in oil and then in medium (ideally PVP drop, which gives better control) so that the ends fill by capillary action (a drop of oil behind the drop of medium/PVP will act as a buffer). The injection dish is still in the incubator, so you should be using a "blank" dish for this. Align the injection pipette again under low magnification.

Transfer of Gametes to the Injection Dish

1. Carefully add a small aliquot of sperm suspension (3–4 μL, depending on the concentration of prepared sperm) to the edge of the central PVP droplet. The viscous solution should facilitate sperm handling by slowing down their motility and also prevents the sperm cells from sticking to the injection pipette during the procedure. Be careful of sperm density—too many sperm will make selection and immobilization more difficult.
2. After the sperm droplet has been carefully examined for the presence of debris or any other factors that might cause technical difficulties, examine all the denuded oocytes again for the presence of a first polar body; wash them gently with HEPES-buffered medium and transfer one oocyte into each oocyte dropleton the injection dish, taking care to avoid too much handling or cooling of the oocytes. Keep the oocytes in the incubator until you are confident that the injection procedure can proceed smoothly. Until sufficient experience of the procedure has been gained, it may be advisable to keep sperm and oocyte dishes separate, avoiding overexposure of the oocytes while selecting and immobilizing sperm.
3. Place the injection dish with central sperm droplet on the microscope stage. Using the coarse controls of the manipulator, lower the injection pipette into the drop.
4. In case of samples with very low motility and surgically retrieved samples, the sample can be loaded in the HEPES river (80 μL). Before loading, remove 40 μL of HEPES from the river. This will prevent bulging of the edge of the river, thus making visualization of sperm easy. To the HEPES river, one can add sperm motility enhancers such as theophylline (1:3 ratio theophylline: HEPES + sample) or pentoxifylline (1:1 ratio) half an hour before fishing for sperms.

Sperm Selection and Immobilization

1. Select sperm that appears morphologically normal. Sperm can be selected and stored in the PVP drop for a limited period of time (be aware that prolonged exposure to PVP can cause damage to sperm membranes) before starting the injection procedure; this is an advantage in cases of extreme cryptozoospermia, and reduces oocyte exposure time. If SpermSlow is being used for immobilization, the sperm becomes rigid and sticks to the dish after approximately 30 minutes.
2. At 200× magnification, immobilize motile spermatozoa by crushing their tails: select the sperm to be aspirated and lower the tip of the injection needle (by mechanical joystick) onto the mid-piece of the sperm, striking down and across, and crushing the tail against the bottom of the dish. This "tail crushing" impairs motility and destabilizes the cell membrane; the latter may be required for sperm head decondensation. If the resulting sperm has a "bent" tail, it will be difficult to aspirate into the needle and will stick inside it. When this happens, abandon that sperm and repeat the procedure with another sperm. Do not strike too hard, or the sperm will stick to the bottom of the dish, also making aspiration into the needle difficult and sometimes causes sperm head decapitation, especially in testicular sperm. After some practice, sperm immobilization in routine ICSI cases can be carried out quite quickly. If the preparation contains only a few sperm with barely recognizable movement and a large amount of debris, this part of the procedure can be very tedious and require great patience. Do not hesitate to change the injection needle if you find that it is blocked. There is no hard and fast rule that one has to use only a single set of needle for each patient. The patient always comes before the price of a pipette. Increased disruption of sperm plasma membrane at sperm immobilization promotes dissociation of perinuclear theca from sperm chromatin after ICSI as shown in some animal models.
3. Aspirate the selected immobilized sperm into the injection pipette by rotating the knob of the injector anticlockwise. Sperm were traditionally aspirated into the pipette tailfirst, but they can be aspirated headfirst.[8] Position the sperm approximately 20 μm from the tip.
4. Lift the injection needle slightly. If the sperm moves up the pipette (due to the difference in density between culture medium and PVP), bring it back near the tip before beginning the injection procedure. If ever the sperm sticks to the pipette, better choose another sperm as it has a tendency to stick during injection. Before injection, when the injection pipette is ready to inject into the oocyte, try to move up and down the sperm inside the pipette. This "flushing" might help dispel any PVP around the sperm.

Microinjection

1. Move the Petri dish until you can see an oocyte in one of the surrounding drops and bring it into focus. Move the holding capillary to the oocyte droplet. The oocyte is attached gently but firmly to the holding capillary with

the help of negative pressure created by the air device. The pressure should be great enough to hold the oocyte in place but not so strong that it causes the oolemma to bulge outward. Occasionally, embryologists experience a kinking in the oocyte during injection due to improper angle of injection. This can be avoided by slight upward or downward rotation of joystick (oocyte holding side) knob so as to allow the injection pipette to go smoothly into the oocyte. Polar body positioning at 6 or 12 o'clock in order to minimize the possibility of damaging the meiotic spindle was thought to be important, but later evidence using polarized microscopy to visualize the spindle itself suggests that polar body positioning is of less benefit than minimizing the duration of the ICSI procedure.[8] Some embryologists keep the position of polar bodies at either 7 or 11 o'clock position to avoid the damage to spindle.

2. Make sure that the oocyte is slightly elevated from the bottom of the Petri dish to facilitate the easy injection process. Otherwise, one may find difficulty while the injection needle is penetrated to the oocyte and it may slide away from the direction of the injection needle.
3. Then, focusing on the ICSI pipette and the oocyte, move the spermatozoon along the capillary and bring it to rest at its very tip by rotating the knob of the injector. Move the injection pipette close to the oocyte, and check that it is in the same plane as the right outer border of the oolemma on the equatorial plane at the 3 o'clock position. Check that the sperm can be moved smoothly within the injection needle and position it near the beveled tip.
4. By moving the joystick slightly, carefully push the injection pipette through the zona pellucida (ZP) and the oolemma into the ooplasm at 3 o'clock. The oocyte should be pricked in the middle so that the oolemma membrane is gently and atraumatically broken. Advance the injection pipette to the ooplasm into the injection capillary to be sure that the membrane is ruptured. Deposit the aspirated ooplasm and the spermatozoon toward the center of the oocyte. To introduce a minimal volume of the medium and PVP solution into the cytoplasm, gently withdraw the injection pipette after the head of the sperm cell has left the pipette tip. Release the injected oocyte from the holding capillary and raise both pipettes by pressing the joystick button.

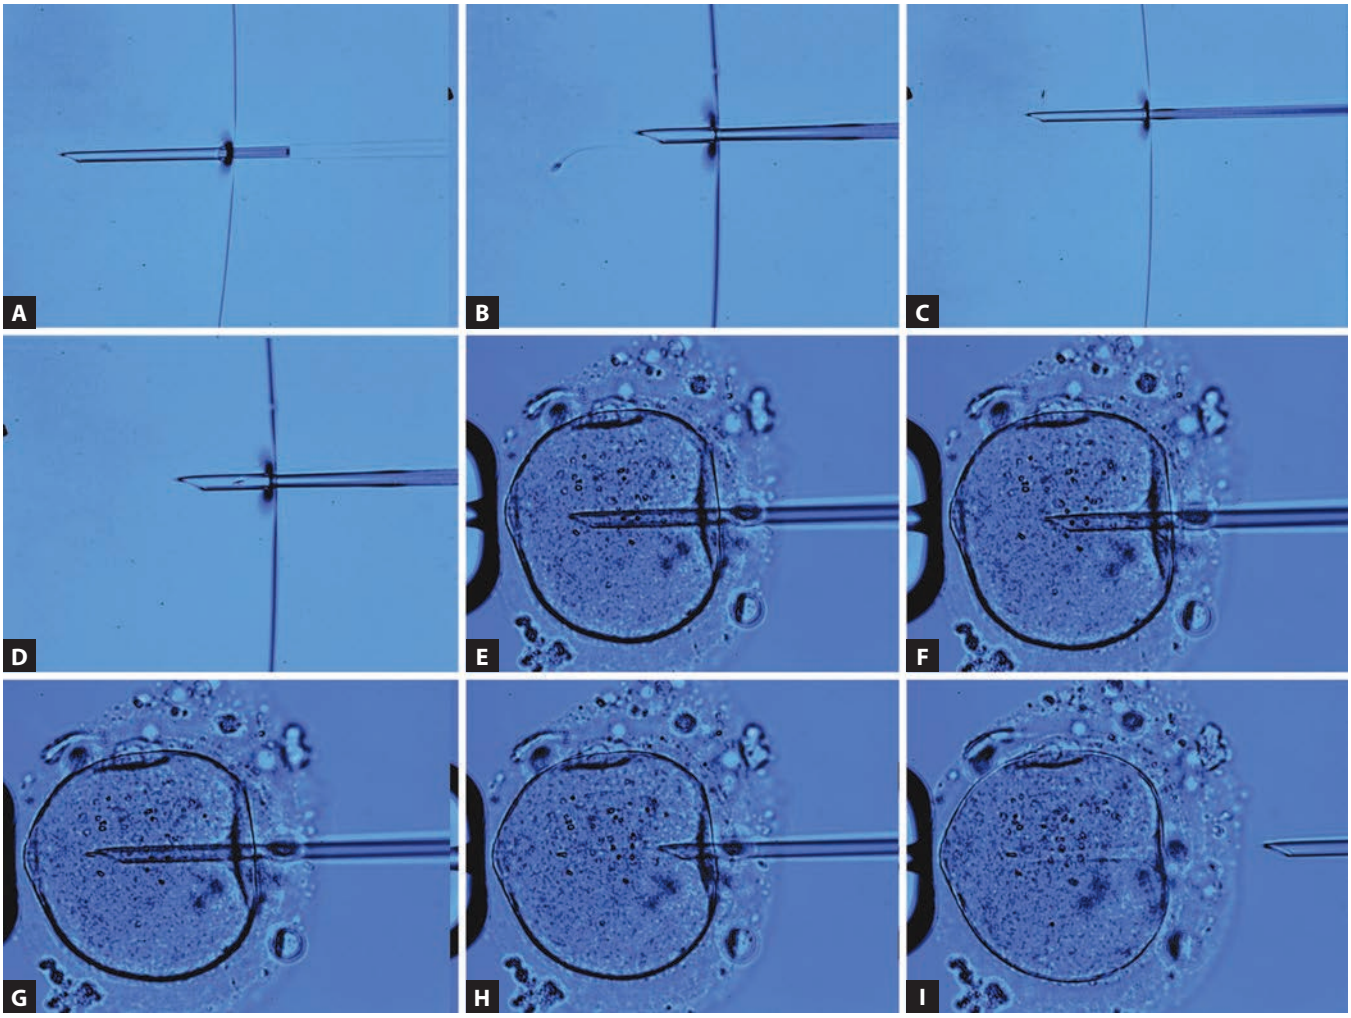
If the pipette is in the wrong plane, entry into the cell will be difficult. The membrane may rupture spontaneously or may require negative pressure, sucking the membrane into the pipette before expelling the sperm. When it breaks, there will be a sudden flux of cytoplasm into the pipette. For many embryologists, failed fertilization in ICSI happens in their early days of ICSI practice just because of improper cytoplasmic aspiration and lack of proper membrane rupture while injection. Many times, it has been observed that sperm gets ejected once the pipette is withdrawn from the oocyte. To avoid this, make sure that there is a sudden flux of ooplasm into the injection needle. However, care should be exercised not to aspirate too much ooplasm. This happens if the injection needle is not properly installed or if there are air columns in the oil tubing, which causes abrupt movement of fluid in the ICSI needle. Inject the sperm slowly into the oocyte with a minimal amount of fluid (1–2 pL). The sperm should be ejected past the tip of the pipette, to ensure a tight insertion among the organelles, which will hold it in place while the pipette is withdrawn. Some surplus medium may be reaspirated to reduce the size of the breach created during perforation. If the plasma membrane is elastic and difficult to break, it may be necessary to withdraw the pipette from the first membrane invagination and slowly repeat the procedure **(Figs. 5A to I)**. Occasionally, some maneuvering of pipette tip (to different directions inside the ooplasm) may be required in cases of ooplasm which are viscous and prevent the smooth entry into the pipette.

Yanaihara et al.[9] studied sperm retention site and its influence on cleavage rate and early development following ICSI cases involving 336 ICSI patients (age 27–44 years; average 37.4), where 1,545 oocytes were observed. An oocyte was divided into nine sites and the sperm retention site was observed microscopically after injection. The polar body was placed at either the 12 or the 6 o'clock position. The injection pipette was introduced at the 3 o'clock position and oolemma rupture was ascertained by mild suction. The main outcome measures were the relationship of sperm remaining in position in the oocyte to fertilization rate and embryo quality.

When the injection pipette was introduced at the 3 o'clock position, about 80% of the sperm remained in the center or left of center. The fertilization rate was significantly lower ($p < 0.05$) when the sperm remained near the site of introduction. Embryo quality was not significantly affected by the sperm retention site. About 12–14% of the spermatozoa remained near the introducing position, and in these cases, the fertilization rate was low. However, once fertilization occurred, the sperm retention site had minimal impact on embryo quality. The study indicates that injecting sperm near the spindle site may improve embryo quality.

5. Gently remove the injection pipette, and examine the breach area. The membrane should be funnel-shaped, pointing in toward the center. If the border of the oolemma is everted, cytoplasm may leak out and the oocyte may subsequently cytolyze. Release the oocyte from the holding pipette.

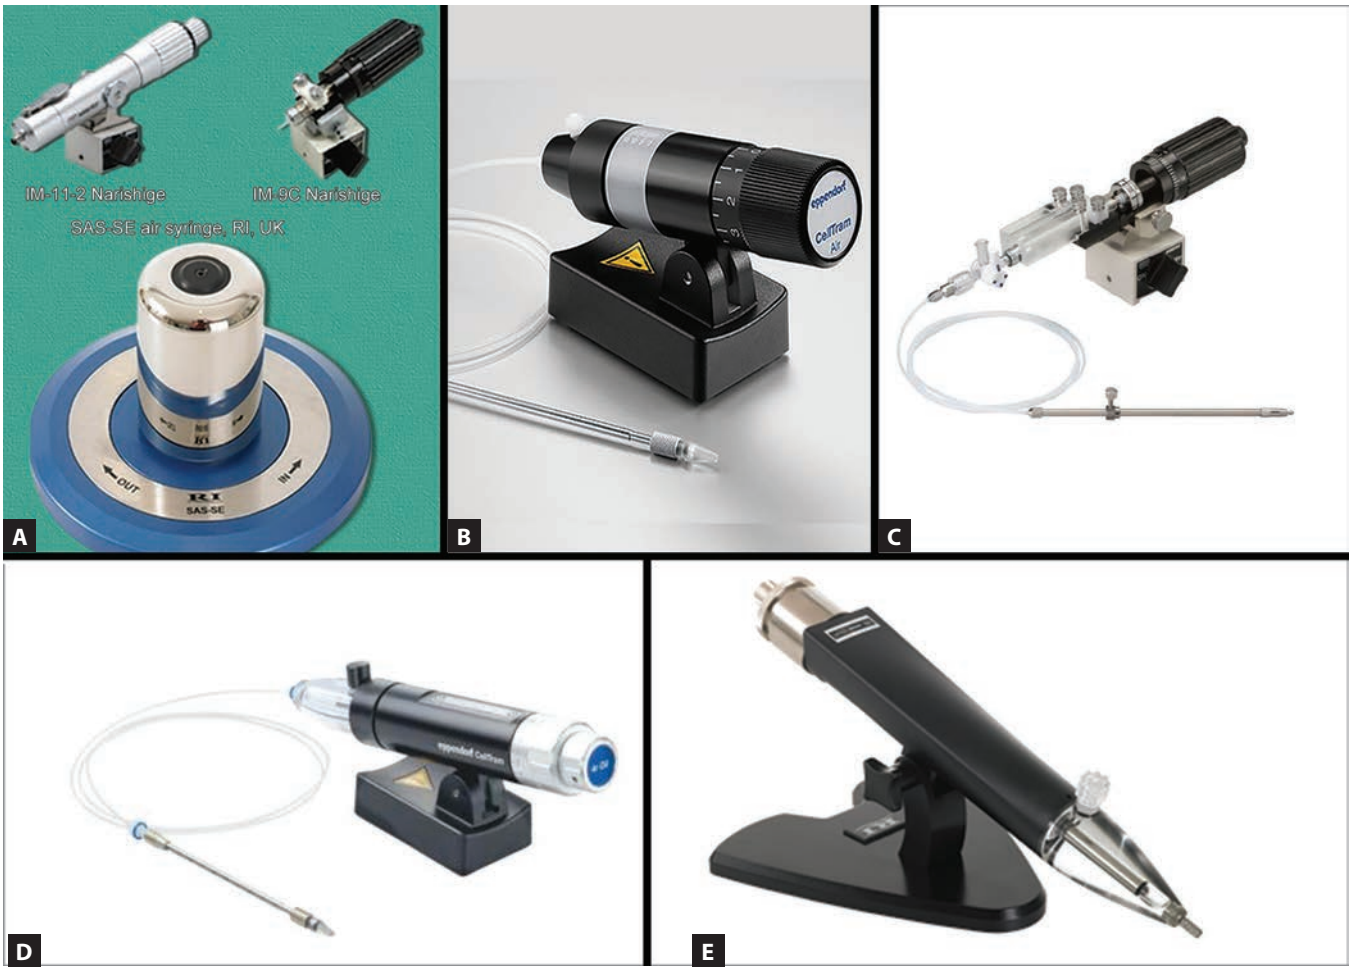
If several oocytes are obtained, only three to four oocytes are injected as a rule. They are first washed in cleavage medium and placed there for long-term culture, and the remaining oocytes are then injected.



Figs. 5A to I: Intracytoplasmic sperm injection procedure stepwise.

Injection Procedure: Important Points

1. *All conditions must be stable*: Temperature, pH, equipment properly set up, adjusted, aligned, and checked for leaks and air bubbles. Check everything, including secure and comfortable operating position, before you begin.
2. Correct immobilization of sperm.
3. Advance far enough into the ooplasm with the injection pipette.
4. Ensure that the plasma membrane is broken (immediate membrane rupture after introducing the injection needle results in a lower probability of fertilization). Fertilization failure in many cases is due to improper aspiration (confirmation of a sudden gushing in of ooplasm) of cytoplasm and thereby deposition of sperm outside.
5. Inject a minimal volume.
6. If the sperm comes out of the ooplasm into the perivitelline space, reinject.
7. If there is debris sticking to the injection pipette surface, move the microscope stage so that injection needle passes through the media droplet–oil interface to wipe out the debris.
8. After injection, if pressure builds up in the holding pipette making it difficult to dislodge the egg, move the holding pipette along with the attached egg to the media–oil interface by moving the microscope stage (not into oil). It automatically gets dislodged from the pipette.
9. There is a tendency by some embryologists to pick up 10 or even more sperms into injection pipettes and do the consecutive injection of multiple oocytes. Sometimes, this can lead to injection of more than one spermatozoa into oocytes.
10. Make sure that one changes the injection and holding pipettes after each patient's injection cycles. It has been noticed that some embryologists retain the holding pipette, some do not change the either needle to save time and simply clean it before the next injection process. Both these practices should be avoided and should not be encouraged.
11. Pneumatic syringe is ideal for the holding side of the micromanipulator and hassle-free compared to the oil syringes (IM-11-2, Narishige) **(Figs. 6A to E)**.



Figs. 6A to E: Narishige, ORIGIO (A) and Eppendorf (B), pneumatic syringes and oil syringes from Narishige (C), Eppendorf (D), and ORIGIO (E).

12. Four-axis hanging joystick oil hydraulic micromanipulator (Narishige) spares the laborious work of pipette alignment with optical axis ***(see* Fig. 2A)**. The injection holder is provided with a special clamp which memorizes the length of the pipette from injection holder, thus exchanging and repositioning the pipette more accurately at a shorter time **(Fig. 7)**.
13. The newly launched TrakJector micromanipulators **(Fig. 8)** from Hamilton Thorne offer a new standard in smooth, fine control, and precision (tolerance <1 μm), and this allows one-handed operation using the all-in-one trackball (AIO^{trackball}) in conjunction with the motorized oil injection unit (MIU^{mot}Oil). The system can easily control both the injection holding pressure and the motorized movement using the trackball and the two buttons. The integrated, ergonomic gel pillow allows hands to stay relaxed during extended operating sessions. An adjustable velocity setting permits balancing between operators and different magnifications.

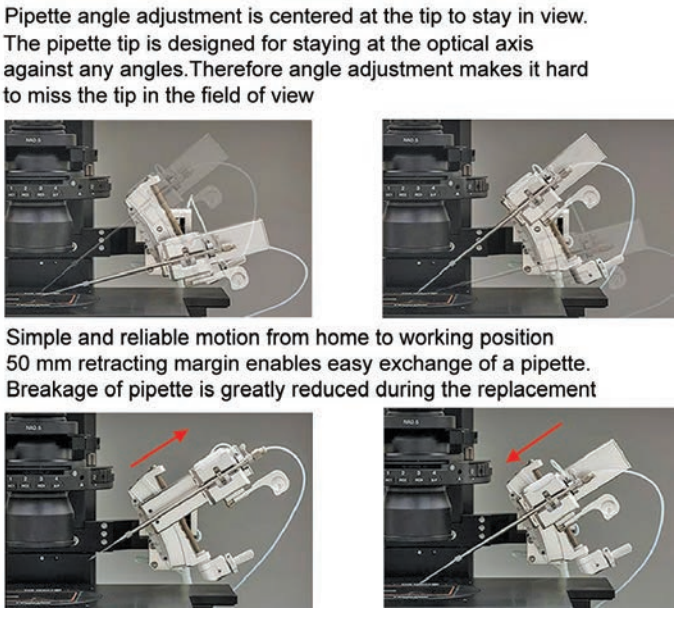


Fig. 7: Home positioning function in Takanome (Narishige).

Assessment of Fertilization

About 16–18 hours after microinjection, check the oocytes for the presence of pronuclei and polar bodies. After another 24 hours, score the embryos (e.g., equal size of blastomeres) and transfer them into the uterus.

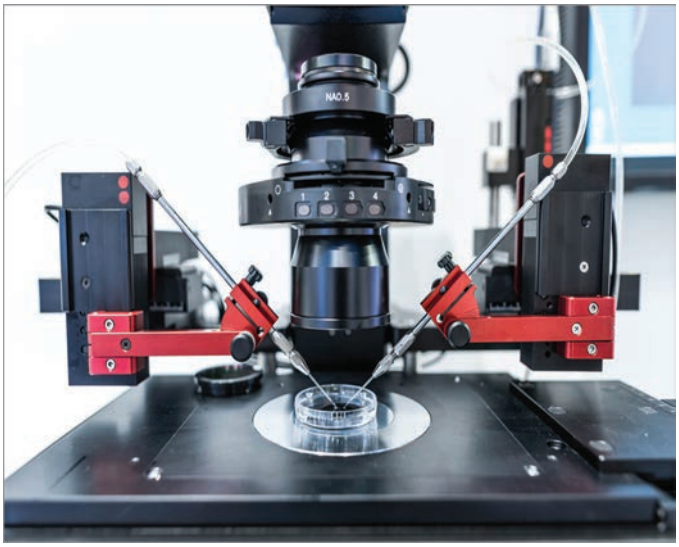

Fig. 8: TrakJector micromanipulators from Hamilton Thorne (USA).

CONVENTIONAL INSEMINATION VERSUS INTRACYTOPLASMIC SPERM INJECTION

Though many clinics opt for 100% ICSI for insemination of oocytes irrespective of semen quality, the debate is on for the risks associated with this invasive procedure. Recent studies show that assessment of sperm function prior to actual cycles can discriminate the mode of insemination required for each couple.

Wiser et al.,[10] in a prospective study, analyzed if hyperactivated motility (HAM) and acrosome reaction (AR) can be useful tests for evaluating semen quality during male infertility evaluations and to help the clinician decide whether regular insemination or ICSI is preferable during IVF. Patients with normal sperm, according to World Health Organization guidelines, who underwent IVF treatment and planned regular insemination were asked to participate and a portion of sperm sample was evaluated for HAM and AR on the day of ovum pickup. In HAM assessment, 93.3% of patients with increased HAM had a high fertilization rate compared with 64% in the group without increased HAM ($p = 0.059$). For the AR evaluation, 91.7% of samples with a low rate of spontaneous AR had a high fertilization rate compared with 39.3% in the group with a high rate of spontaneous AR ($p = 0.004$).

The same group in another study evaluated the post-wash sperm characteristics as a tool to discriminate the insemination procedure by either conventional method or ICSI. They evaluated 112 cycles fertilized with both regular and ICSI insemination during the same cycle. In 62 cycles, fertilization was obtained with both ICSI and IVF, and in 50 cycles, fertilization was obtained by ICSI alone. The sperm samples were reevaluated after the preparation process. The mean initial total motile sperm count (TMSC) was 66.3 × 106 ± 47.5 in the group that underwent both methods and $23.1 \times 10^6 \pm 20.4$ in the ICSI-only group ($p < 0.05$). After sperm preparation, the mean post-wash TMSC was $4.4 \times 10^6 \pm 3.4$ and $1.06 \times 10^6 \pm 0.9$, respectively ($p < 0.05$). They found a cutoff of 1.5×10^6 or fewer sperm after preparation as an indicator for ICSI has a sensitivity of 80% and a specificity of 77%. Reevaluation of TMSC can prevent unexpected fertilization failure. The study shows that fewer than 1.5 million TMSC after wash should be considered an indication for ICSI fertilization.[11]

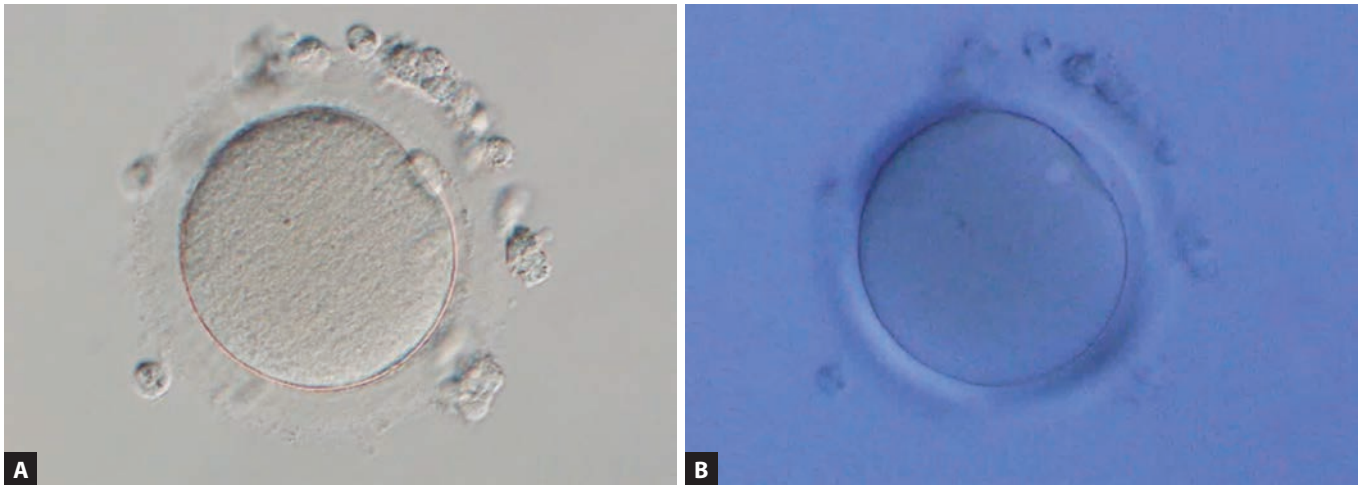
Breznik et al.[12] studied the diagnostic value of the following sperm function tests in predicting the fertilizing ability of spermatozoa in conventional IVF and ICSI—hyaluronan binding assay (HBA), DNA fragmentation (Halosperm), and hyperactivity. Both fertilization rate and embryo quality in IVF cycles negatively correlated with sperm DNA fragmentation. Furthermore, a positive correlation was observed between fertilization rate and hyaluronan-binding ability or induced hyperactivity. The semen samples from the IVF cycles with low fertilization rate (group 1) were characterized by statistically significantly higher sperm DNA fragmentation and lower hyaluronan-binding ability in comparison with semen samples from the group with high levels of fertilization (group 2). In ICSI cycles, no relationship was found between sperm function tests and fertilization rate or embryo quality. This study also proves that the Halosperm test, the HBA test, and induced hyperactivity are useful in predicting the ability of spermatozoa to fertilize oocytes in IVF and are helpful in distinguishing semen samples suitable for IVF or ICSI.

Key Performance Indicators For Intracytoplasmic Sperm Injection

Key performance indicators (KPIs) are essential for evaluating the introduction of a process in the IVF laboratory, establishing minimum standards for proficiency, monitoring ongoing performance within a quality management system, benchmarking, and quality improvement. The Vienna consensus jointly developed by European Society of Human Reproduction and Embryology (ESHRE) and Alpha Society of Reproductive Scientists focuses on the four most important performance indicators: (1) normal fertilization rate, (2) oocyte degeneration rate, (3) poor fertilization rate, and (4) failed fertilization rate in ICSI.[13] The definition used most often for the ICSI normal fertilization rate is the proportion of injected oocytes with 2 pronuclei (2PN) the day after injection. ICSI damage rate is defined as the number of oocytes damaged during ICSI and/or observed at fertilization check over the number of injected oocytes. It is useful to monitor this indicator for operator competence, oocyte quality, and laboratory performance. The damage rate can also be indicative of technical problems (e.g., cumulus cell removal stress, vibration) **(Table 1)**.

TABLE 1: PI and KPI for the ICSI

Performance indicator (PI)	*Calculation*	*Competence (%)*	*Benchmark value (%)*
1 PN rate (ICSI)	$\frac{\text{no. 1 PN oocytes} \times 100}{\text{no. MII oocytes injected}}$	<3	
KPI			
ICSI damage rate	$\frac{\text{no. damaged or degenerated} \times 100}{\text{all oocytes injected}}$	≤ 10	≤ 5
ICSI normal fertilization rate	$\frac{\text{no. oocytes with 2 PN and 2 PB} \times 100}{\text{no. MII oocytes injected}}$	≤ 65	≤ 80



Figs. 9A and B: Oocyte with a visible meiotic spindle. (A) Oocyte positioned with polar body located at 1.5 o'clock position for better facilitating spindle observation under the bright-field; (B) Meiotic spindle appears bright white in the oocyte under the polarized light microscopy.

Oocyte degeneration is a common phenomenon experienced by all embryologists who perform ICSI. Generally observed after withdrawal of the injection needle, it is characterized by lysis of the oocyte but also may follow normal injection, being noted the following day by a darkened ooplasm. In severe cases, the degeneration rate may be as high as 30–50% and the potential implications are concerning to both the physician and the embryologist. Data suggest that oocyte degeneration is not technician- or physician-dependent. Some reports suggested that the rate of oocyte degeneration is operator-dependent and a smaller injection needle can minimize the incidence of degeneration.

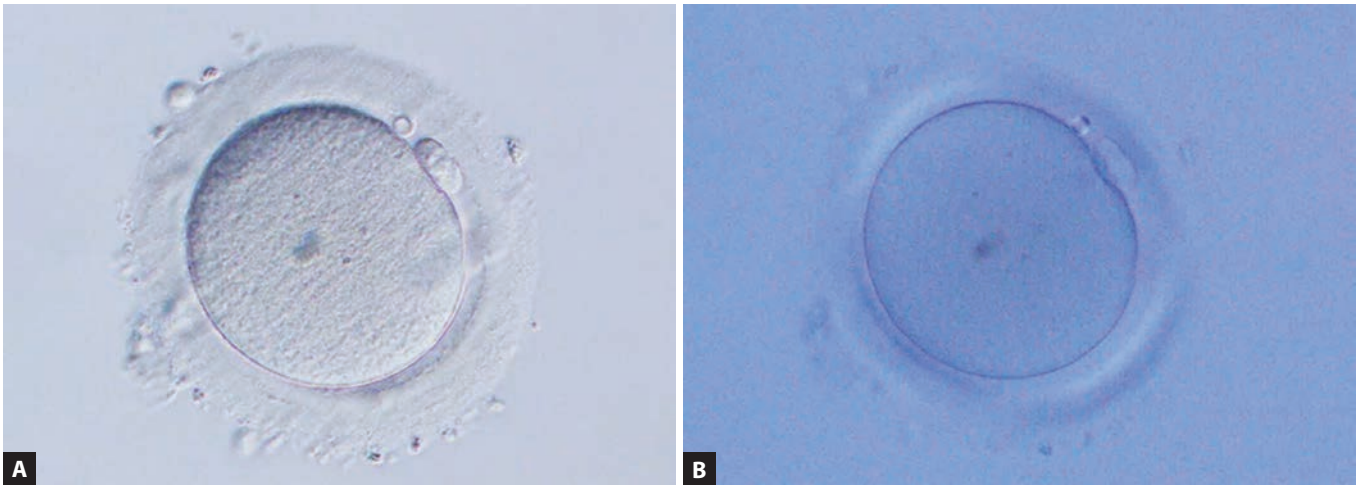
Degeneration is likely a function of the inherent oocyte quality in women who underwent ovarian stimulation. However, the remaining cohort of retrieved oocytes appears to be unaffected by virtue of an uncompromised implantation rate. The first author of this manuscript has noted higher ICSI degeneration in centers where higher recombinant gonadotropin is used for controlled ovarian stimulation (COS) without any human menopausal gonadotropin (hMG), hence less luteinizing hormone (LH).

AUTOMATION OF INTRACYTOPLASMIC SPERM INJECTION

Gamete micromanipulation requires an experienced and highly skilled embryologist and the process is labor-intensive. The laboratory outcomes of this manual operation are susceptible to human factors such as volume of work, stress, and fatigue as well as variations in performance between operators. Is it possible for this most sophisticated of all assisted reproductive technologies (ART) to ultimately be automated? In the first report of robotic ICSI (RICSI), using a hamster oocyte or human sperm model, the robotic system demonstrated a high (90%) survival rate.[14] Human trials are already under way for RICSI (Yu Sun personal communication), and it may only be a matter of time before automation, in some form, gains confidence among the IVF community.

Meiotic Spindle Imaging by Using a Polarized Microscope

The presence of the first polar body is a sign of oocyte maturation **(Figs. 9A and 10A)**. However, actual nuclear



Figs. 10A and B: Oocyte with not observed meiotic spindle. (A) Oocyte positioned with polar body located at 1.5 o'clock position for better facilitating spindle observation under the bright-field; (B) Meiotic spindle does not appear in the oocyte under the polarized light microscopy.

maturity is unclear. The technique of assessing the actual nuclear maturity of oocytes before sperm injection is meiotic spindle imaging. A polarized microscope combined with a glass bottom dish enables one to observe the status of the meiotic spindle. The oocyte with a visible meiotic spindle **(Fig. 9B)** means the oocyte is metaphase II and is ready for sperm injection. But the oocyte with no visible meiotic spindle **(Fig. 10B)** means the oocyte is telophase I (immature) or overmatured.[16,17] The visible or no visibility of the meiotic spindle affects oocyte fertilization and embryo development. Petersen et al. compared fertilization and embryo development after standard ICSI between oocytes with visible meiotic spindle and oocytes with no visible meiotic spindle in a meta-analysis.[18] The fertilization rate of spindle-positive oocytes was significantly higher (75.6%) as compared with that of spindle-negative oocytes (61.5%). The blastocyst rate of spindle-positive oocytes was also significantly higher (50.7%) as compared with that of spindle-negative oocytes (28.6%). Recently, Hiraoka et al. assessed the effect of meiotic spindle visuality on ICSI results after Piezo-ICSI.[19] The authors used polarized light microscopy (Olympus IX73 inverted microscope equipped with IX3 ICSI/IMSI, Olympus, Life Science Solutions, Tokyo, Japan) and a glass bottom dish (87-453, NIPRO, Osaka, Japan), and then first positioned with the polar body located at 1.5 o'clock positions because this position facilitates better spindle observation under the bright field **(*see* Figs. 1 and 2A)**. The fertilization rate of spindle-positive oocytes **(*see* Fig. 1)** was significantly higher (92.0%) as compared with that of spindle-negative oocytes **(*see* Fig. 2B)** (70.0%). The blastocyst rate of spindle-positive oocytes was significantly higher (53.7%) as compared with that of spindle-negative oocytes (32.1%). These results show the importance of meiotic spindle imaging for better timing of sperm injection and predicting embryo development.

Piezo-Intracytoplasmic Sperm Injection

Piezo-ICSI is one of the ICSI techniques that uses a piezo actuator. A piezo actuator can make it possible to do sperm immobilization, zona opening, and membrane breakage semiautomatically. Therefore, Piezo-ICSI can contribute to standardizing the ICSI technique. In this section, we describe the equipment, preparation, and procedures.

Equipment

- Piezo-ICSI system (operation box, controller, footswitch, and drive unit)
- Inverted microscope
- Air injectors.

Microtool

- Glass bottom dish
- Operation liquid
- Flat tip micropipette
- Holding pipette.

Media

- 7% PVP
- MOPS-buffered medium
- Mineral oil.

Preparation

Piezo-ICSI system is composed of an operation box **(Fig. 11A)**, controller **(Fig. 11B)**, footswitch **(Fig. 11C)**, and drive unit **(Fig. 11D)**. Attach the drive unit to the pipette holder **(Fig. 11D)** and put the footswitch on the floor **(Fig. 12)**. Footswitch drives the piezo pulse. Put an operation box and controller inside the clean bench appropriately **(Fig. 12)**.

Place three drops (two PVP drops and one MOPS-buffered medium drop) on the glass bottom dish and cover

Figs. 11A to D: Four types of equipment of Piezo-ICSI. (A) Operation box; (B) Controller; (C) Footswitch; (D) Drive unit.

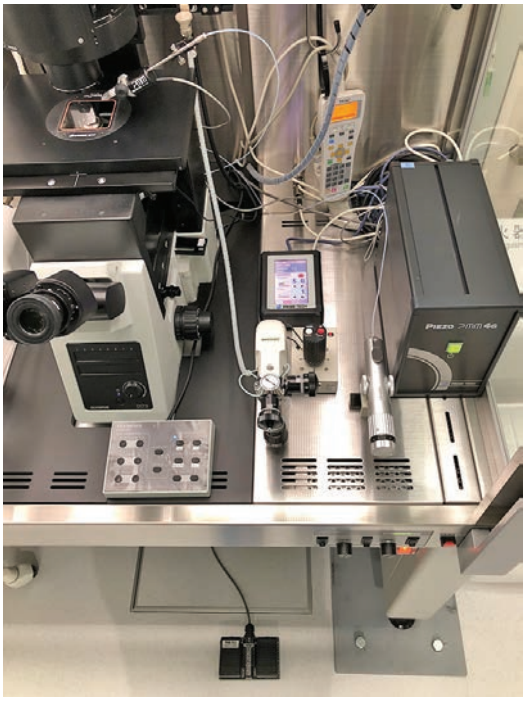


Fig. 12: Piezo-ICSI system.

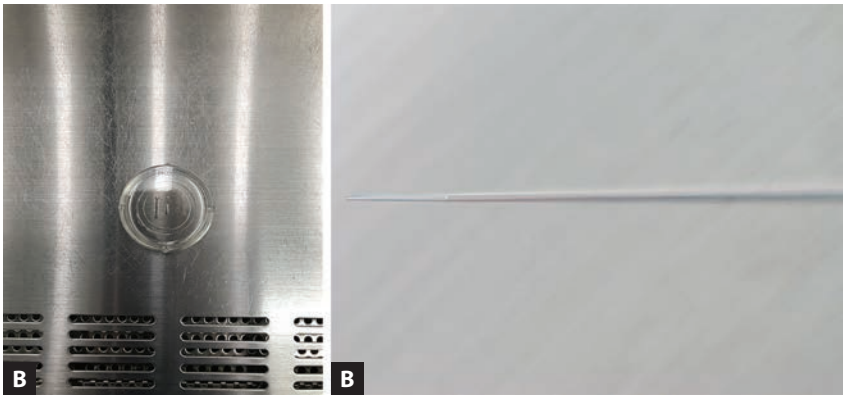


Figs. 13A and B: ICSI dish and micropipette preparation for Piezo-ICSI. (A) Place three drops (two PVP drops and one MOPS buffered medium drop) on the glass bottom dish and cover these drops with the mineral oil; (B) PVP is aspirated at the tip of the micropipette next to the operation liquid.

these drops with the mineral oil **(Fig. 13A)**. Inject the sperm suspension into the lower of the longer PVP drop.

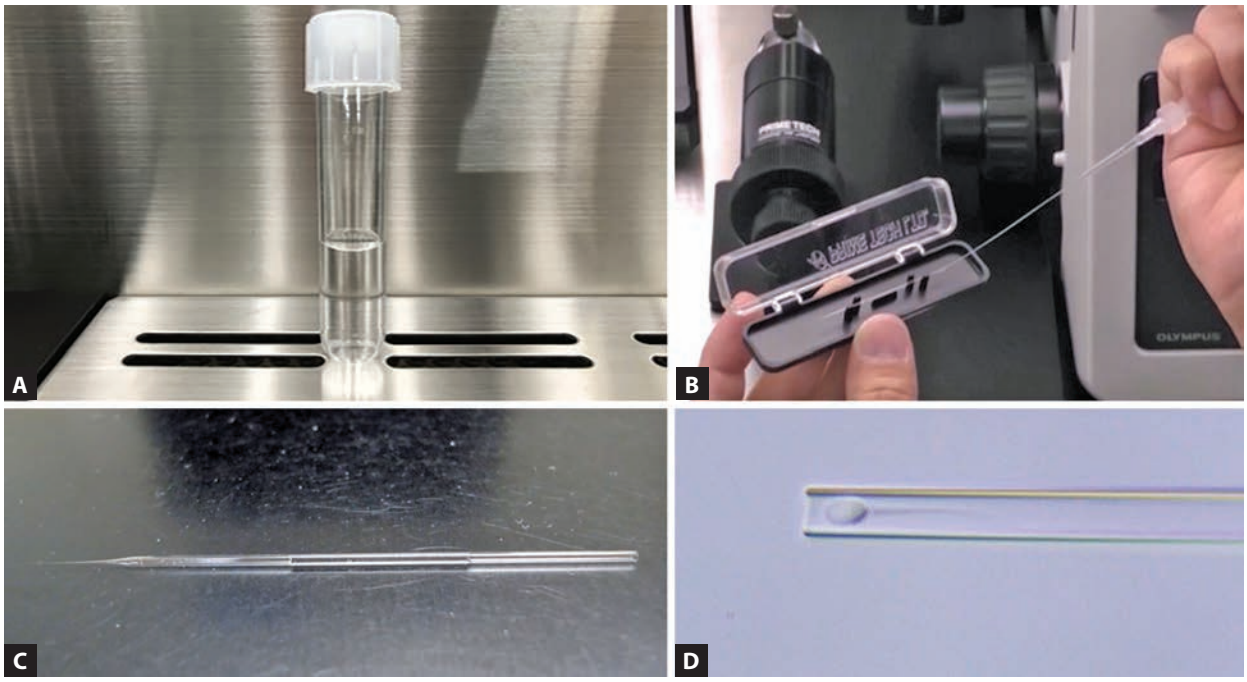
Inject the operation liquid **(Fig. 14A)** inside the micropipette 2.0 cm **(Figs. 14B and C)**. Avoid the air getting mixed in the line of operation liquid. The specific gravity of operation liquid is about 1.8, colorless, transparent, and nonwater soluble. Attach the micropipette to the pipette holder and twist the holder cap firmly. The micropipette used for Piezo-ICSI has a flat tip **(Fig. 14D)**. Expel the operation liquid inside the micropipette toward the micropipette tip. Immerse the micropipette tip into the smaller PVP drop and aspirate PVP into the micropipette. Try to keep the volume aspirated into the micropipette 300 μm during procedures for stable operation **(Fig. 13B)**.

Sperm Immobilization

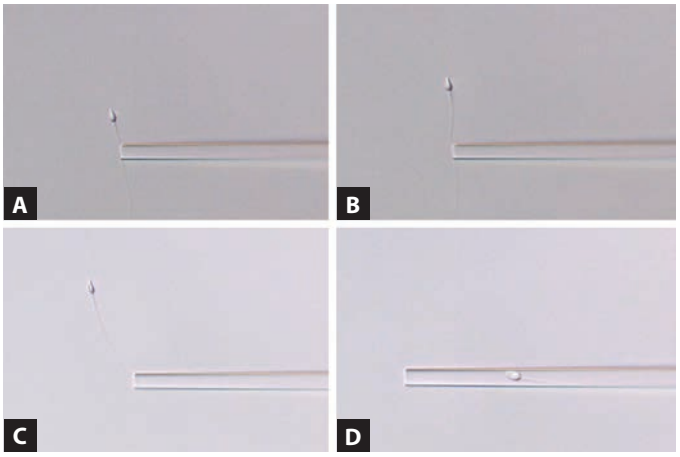
After selecting the sperm upper of longer PVP drop **(Fig. 13A)**, attach the micropipette tip to the sperm's tail and apply a piezo pulse **(Figs. 15A and B)**. Repeat this procedure one to two times until the complete stopping of the tail motion is confirmed. Then aspirate the immobilized sperm into the micropipette tailfirst **(Figs. 15C and D)**.

Microinjection

Transfer the oocyte to the MOPS-buffered medium drop **(Fig. 13A)**. Observe the spindle by polarized microscope and rotate the oocyte as avoiding the spindle is at 3 o'clock. Hold the oocyte keeping the spindle location away at



Figs. 14A to D: Micropipette preparation for Piezo-ICSI. (A) Operation liquid. The specific gravity of operation liquid is about 1.8, colorless, transparent, and non-water soluble; (B) Inject the operation liquid inside the micropipette; (C) The operation liquid is injected inside the micropipette 2.0 centimeters; (D) The micropipette used for Piezo-ICSI has a flat tip.



Figs. 15A to D: Sperm immobilization. (A and B) Attaching the micropipette tip to the sperm's tail and applying a piezo pulse; (C and D) Aspirating the immobilized sperm into the micropipette tail first.

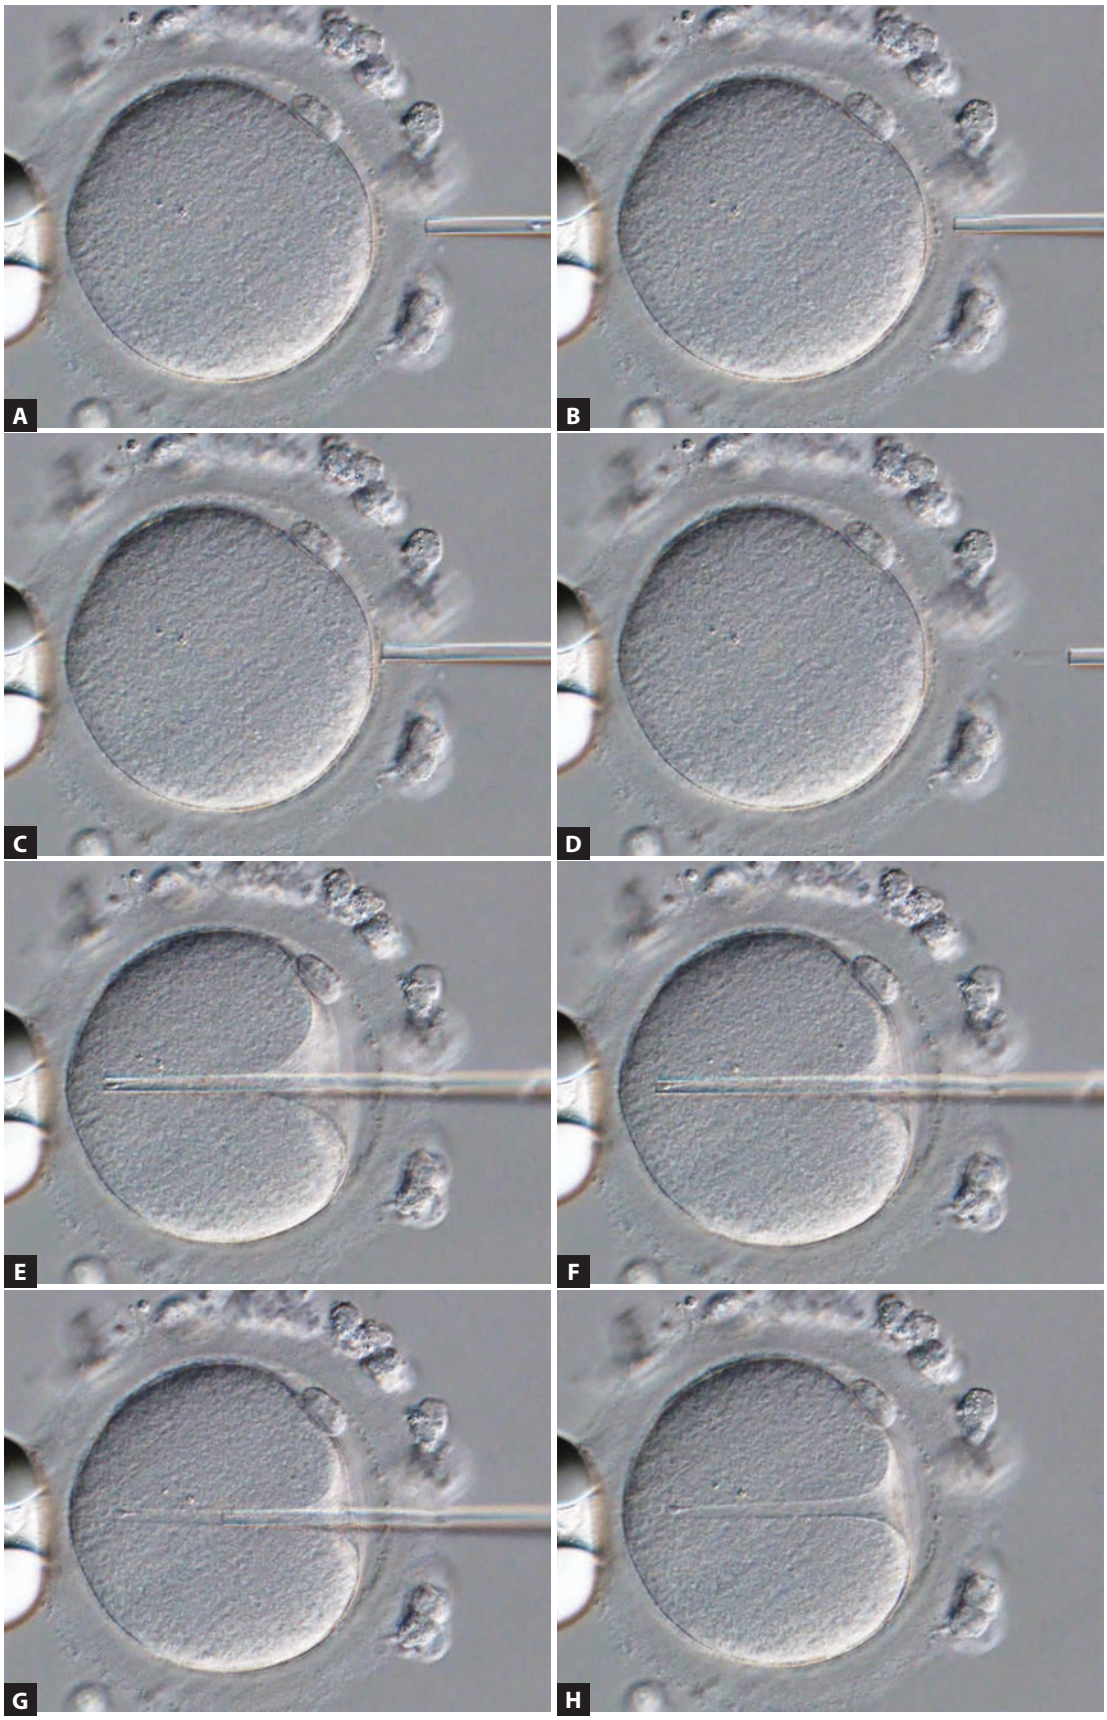
3 o'clock. Attach the micropipette tip to the surface of ZP **(Fig. 16A)**. While applying the piezo pulses, move the micropipette tip slowly toward the oocyte without zona deformation **(Fig. 16B)**. When the micropipette tip reaches the inner layer of the ZP, aspirate the piece of ZP **(Fig. 16C)**. Remove the micropipette tip outside of the ZP and expel the ZP piece from the micropipette **(Fig. 16D)**. Pass through the micropipette tip via opened ZP and move deep inside the oocyte (about 90% of oocyte diameter) **(Fig. 16E)**. After stopping the movement of the micropipette, apply one piezo pulse to break the membrane. After confirming the membrane breakage by observing the rebounding of the membrane **(Fig. 16F)**, inject the sperm head into the oocyte **(Fig. 16G)**. Remove the micropipette tip outside of the ZP **(Fig. 16H)**.

Standard-Intracytoplasmic Sperm Injection Versus Piezo-Intracytoplasmic Sperm Injection

To the best of our knowledge, seven papers compared the clinical results between Standard-ICSI and Piezo-ICSI. All of the seven papers reported higher fertilization rates of Piezo-ICSI than the Standard-ICSI.[15,20-25] Hiraoka and Kitamura assessed the average volume of aspirated cytoplasm into the micropipette at membrane breakage. These authors reported significantly more volume of Standard-ICSI (2746 ± 940 μm^3) than the Piezo-ICSI (0 ± 0 μm^3).[15] Cytoplasmic aspiration procedure might cause damage to the cytoplasm. Piezo-ICSI could avoid this damage by getting rid of cytoplasmic aspiration. More studies would be needed to assess the clinical efficiency of Piezo-ICSI.

KEY POINTS

- Currently, however, ICSI is also being performed for infertile couples with normozoospermic males, even if the less-invasive IVF would likely produce a similar outcome. Some clinics even utilize ICSI in all instances of treatment with IVF. This could be problematic since several studies have advised against routinely using ICSI for all cases of IVF treatment. ICSI undoubtedly can be a



Figs. 16A to H: Piezo-ICSI procedure stepwise. (A to C) During opening and aspirating the piece of the zona pellucida into the micropipette; (D) Expelling the piece of the zona pellucida. (E) Moving the micropipette tip deep inside the oocyte (about 90% of oocyte diameter); (F) After applying the piezo pulse to break the membrane; (G) Injecting the sperm head into the oocyte; (H) Removing the micropipette outside the zona pellucida.

blessing for those men suffering from severe male factor infertility. However, due to the invasive nature of the procedure, there is great potential for complications of all degrees of severity.

- Additionally, the long-term consequences of this procedure on the resulting embryos and children remain largely unknown since the first successful ICSI-conceived child was born in 1992, and most long-term ICSI studies have not yet completed data collection. A number of factors could affect the ICSI outcome, including poor embryonic genetic health and failure of germ cells to properly execute vital biological events such as fertilization.
- In some instances, success with ICSI is compromised because of the technical limitations of ICSI instruments, clinicians, and laboratory technicians. In other failed cases, solutions cannot be proposed until more knowledge is gained about the underlying pathology of infertility.
- Proposed techniques which need more dedicated work and extensive studies are:
  - Use of round spermatid (ROSI) from men with no elongated spermatid or spermatozoa in testes
  - In vitro culture of immature germ cells to more mature stages
  - But the possibility of genetic and epigenetic risks to offspring cannot be ruled out in these cases.
- As new studies on the subject, especially on sperm physiology and molecular biology, continue to be published, it is important that the established protocol for ICSI is revised on a regular basis and that its role in infertility therapy is continually reevaluated.

CHAPTER 106

Analysis of Fertilization

Shailaja Gada Saxena, Ritu Gada, Dhiraj Gada

INTRODUCTION

History was created on July 25th 1978, when Louise Brown was born to John and Lesley Brown in United Kingdom through in vitro fertilization (IVF). Since then, the field of assisted reproductive technology (ART) has witnessed huge stride toward finding suitable, cost-effective, and easily acceptable treatment options for infertile couples. There have been several technological advances in the stimulation protocols, oocyte retrieval procedure, embryo culture, and transfer technique to improve the success rate in ART. Despite all these technological advances, the success of IVF still faces many obstacles, especially recurrent implantation failure and multiple pregnancies and its associated complications, which are mainly related to selection of appropriate embryos for implantation. There are many different techniques and approaches used worldwide for evaluation of fertilization and selection of best embryo for transfer. Most commonly used method is to assess the developmental potential and morphological characteristics of the gametes and the embryos. In addition, morphokinetic evaluation and time-lapse imaging have also been attempted by various IVF centers. However, studies have revealed that genetic studies of gametes and embryos reveal chromosomal aberrations, which in turn are an important factor in developmental arrest of preimplantation embryos and the concomitant higher implantation failures, and early first-trimester pregnancy losses. Genetic evaluation of the embryos can be done through preimplantation genetic diagnosis/screening (PGD/PGS). However, these studies are invasive in nature. Apart from these, evaluation of embryo metabolism through metabolomic profiling to assess the growth and viability potential of the embryo is another method, which has been attempted. This chapter focuses on various techniques used for analysis of fertilization and embryo selection.

MORPHOLOGICAL EVALUATION OF GAMETES AND EMBRYOS

Morphological evaluation of gametes and embryos currently is the most easily available and widely used method for embryo selection, with the advantage that it is cost-effective and can be easily implemented in all ART laboratories. However, this technique has its inherent drawbacks. The visual grading of embryos is static and requires training and is best carried out by experienced embryologists. Being a subjective assessment, accuracy is always questionable. The morphological evaluation can be carried out at various stages of embryo development right from the gamete stage to the blastocyst stage.

Evaluation of the Quality of Gametes

The impact of assessment of the gamete quality and the success of the treatment has not been well established. However, oocyte quality affects the pronucleus (PN) stage and early cleavage-stage embryo development. Abnormalities in the form of shape, color of cytoplasm, size of polar body (PB), and perivitelline space affect the viability and developmental potential of embryos.[1] Recent studies have shown that the morphology and structure of the zona pellucida can also be considered as a predictor of oocyte quality and embryos.[2] Likewise, sperm quality also affects the early 4–8-cell stage embryo development when the embryonic genome is activated.[3]

Evaluation of Pronucleus-stage Embryos

Scott and Smith (1998) and Tessarik et al. (2000) had developed assessment of pronuclear morphology, a pronuclear scoring system, Embryo development markers as well as patients status determine the number of resulting good quality embryos. Successful fertilization is visible as early as 4–5 hours post insemination. Various groups have attempted various scoring system. Pronuclear stage embryos are evaluated at 16–18 hours after fertilization. The key parameters monitored at this stage include pronuclei (size and symmetry), nucleoli (size, number, and distribution), and cytoplasmic appearance.[4-7] Presence of two fully formed PN, two PB and an intact zona pellucida is an indicator of proper fertilization. Fertilization failure is when there is

absence of pronuclei and presence of only one PB, whereas presence of two or more pronuclei and two PB suggest polyspermy.[8] Pronuclear morphology is also considered as an indicator of embryo development. Failure of the two pronuclei to become completely opposed is an abnormality. Other features such as position of the second PB in relation to the first as well as the position of the polar bodies in relation to axis of the pronuclei has also been evaluated as an indicator for embryo quality.[9] In a retrospective study carried out by Balaban et al. (2001), they concluded that ideal pronuclear score was associated with better quality embryos both at cleavage stage and blastocyst stage, which are demonstrated by higher implantation potential.[10]

Evaluation of Cleavage Stage Embryos

The second criterion of assessment is the cleavage stage at 23–27 hours after insemination. The criteria evaluated at this stage of embryo development include the rate of cell division in blastomeres, their shape and size, the cytoplasmic features in terms of vacuoles and granularity, the thickness of the zona pellucida, etc. If the embryo has two blastomeres present at this stage, it is labeled as an early cleavage embryo.

Giorgetti et al. (1995) suggest evaluation of embryo morphology 48 hours after insemination, when the embryos that have cleaved, have no fragmentation or irregularities, and have reached the 4-cell stage are considered to have the best potential for implantation.[11] On the other hand, Lucinda Veeck has laid down embryo grading on day 3 based on the size of the blastomere and fragmentation. **Table 1** gives the details of the scoring pattern as per Veeck et al. (1991).[12] Several other scoring systems have been proposed by different groups.

Fisch et al. (2001) introduced the concept of graduated embryo score (GES).[13] They recommended scoring of the embryos successively at 16–18 hours, 25–27 hours, and 64–67 hours postinsemination, respectively. They are given an aggregate score out of 100 as detailed in **Table 2**. An aggregate score >70 was found to be associated with 30% implantation rate, whereas the implantation rate dropped down to 24%, if the total score was <65.

TABLE 1: Cleavage stage embryo scoring (Day 3).

Grade	*Description*
Grade 1	Embryo with blastomeres of equal size, no cytoplasmic fragments
Grade 2	Embryo with blastomeres of equal size, minor cytoplasmic fragments or blebs
Grade 3	Embryo with blastomeres of distinctly equal size, none or few cytoplasmic fragments
Grade 4	Embryo with blastomeres of equal or unequal size, significant cytoplasmic fragmentation
Grade 5	Embryo with blastomeres of any size, severe or complete fragmentation

Evaluation of Blastocyst (Figs. 1 to 6)

From the morula, the embryo develops into a blastocyst and undergoes the first cell-fate division forming two layers the trophoblast and inner cell mass. Blastocyst stage embryo transfer has been shown to be associated with improved pregnancy rate, as it helps in natural selection of embryo, eliminating cleavage stage embryos without implantation potential. However, some studies have reported that the success of blastocyst transfer depends on the quality of early cleavage-stage embryos.[14] In addition, growing embryos in

TABLE 2: Graduated embryo score.

Evaluation	*Hours after insemination*	*Developmental milestone*	*Score*
1	16–18	Nucleoli aligned	20
2	25–27	Cleavage regular and symmetrical	30
		Fragmentation absent	30
		Fragmentation <20%	25

vitro to blastocyst stage may be associated with inherent problem of cancelled cycles due to nonavailability of embryo for transfer.

A method for grading embryos at the blastocyst stage was devised by Gardner et al. (2000), which is based on the stage of blastocyst development, quality of inner cell mass, and trophectoderm as detailed in **Table 3**.[15] In their study, each patient received transfer of two blastocyst. When the embryo grade of both the embryos was more than 3AA, they have better implantation and clinical pregnancy rate (72.8% and 86.5%, respectively). When the score of only one of the two blastomeres was more than 3AA, the implantation and clinical pregnancy rate dropped to 54.3% and 69.6%, respectively. Similarly, when both the blastocysts had a score <3AA, the implantation and clinical pregnancy rate dropped further to 28.1% and 43%, respectively.

TIME-LAPSE IMAGING

Time-lapse monitoring (TLM) helps in identification the morphokinetics of cultured oocytes as well as embryos, and it can majorly prevent missed PN observations by enabling the continuous observation of the oocyte morphology as well as PN appearance. The above listed methods of embryos selection are based on observing the embryo morphology at different time points, which is subjective and static evaluation. The training of the embryologist and interpersonal variations in grading are likely to be present. In addition, embryos thus chosen are based on the growth at various fixed time points of development, which may not necessarily always be informative of various cellular events and kinetic events occurring between any two observations. This is likely to be one important reason that the technological developments for assessing embryo competence have not been able to translate into corresponding increase in implantation and pregnancy rates. In addition, removing the embryos from the incubators once per day or at fixed time intervals to assess the morphology and development, disturbs the embryo development as there is change in the temperature, pH, and carbon dioxide levels, which may be harmful.

Time-lapse technology offers a solution to many of problem listed earlier, as it allows embryos to be monitored dynamically in their controlled culture environment.[16] This newly developed technology allows monitoring of the embryos throughout the developmental stages without removing them from the incubator repeatedly. This automated technology eases the work of the embryologist and also aids in selection of embryo with maximum implantation potential, as it provides more information on the correlation of morphological development to embryo viability. Various time-lapse techniques are currently used of which the three available systems currently used in the clinical practice include Primo Vision, EmbryoScope, and Eeva. These systems take image of the embryo at fixed time intervals, which can then be converted to a video for the ease of viewing. The EmbryoScope is compact incubator with an in-built camera, while the Eeva and Primo Vision systems consist of only the camera, which is placed in the regular incubator. Since, EmbryoScope and Primo Vision use bright-field imaging, they are useful for assessing both the morphology of the embryo and the associated kinetic event.

On the other hand, Eeva uses dark-field imaging and is thus, not good for assessing the embryo morphology. All systems need the embryos to be cultured in microwell dishes and necessarily require an oil overlay.[17] The advantage of this technique is that the embryos are not exposed to repeat changes in the environmental milieu in terms of gas composition, pH, or temperature shifts, or to the movements as needed for periodic embryo evaluated.[18] Another major advantage is that this technique gives information about additional developmental morphokinetic changes, i.e,. by analyzing their complex patterns of cell division and cell

movement and phenotypic markers as against the standard and static morphological grading.

It has known earlier cleaving embryos have a better chance of developing into blastocysts.[19] In a retrospective time-lapse video observational study conducted by Meseguer et al. (2011), they observed that direct cleavage from 1 to 3 cells, presence of unequal sized blastomeres at the 2-cell stage and multinucleation at the 4-cell stage were associated with low implantation potential and they suggest to exclude these embryos from the selection process for embryo transfer.[20] On the other hand, embryos reaching 5-cell stage by 48.8–56.6 hours, time for 3–4- cell division of <76 hours and that of two to three division of <11.9 hours, have maximum chance of implantation and hence should be included in the selection criteria for embryo transfer. A randomized controlled trial (RCT) conducted by Rubio et al. (2014) that monitoring of embryo using time-lapse monitoring was associated with an improved the implantation potential and ongoing pregnancy rates and reduced abortion rate.[21]

METABOLOMICS

Another method of embryo selection is based on metabolomic profiling of embryo. This involves testing of the culture media using various techniques. Alteration in pyruvate and/or glucose concentration in the culture medium has been attempted to predict the energy metabolism of the embryo.[22,23] It is believed that oxygen consumption and amino acid turnover may be more accurate indicators of viability of the embryo. Many metabolic parameters of developing embryos have been studied using a variety of noninvasive methods.[24] Various studies have been conducted to evaluate the differences in metabolomics profile of embryos that result in a pregnancy in contrast to the embryos that do not result in pregnancy, with a focus on studying the pyruvate, carbohydrate, and amino acid metabolism. Gardner et al. (2001) suggested that better pyruvate uptake on day 4 is associated with more chances that the embryo will develop to blastocyst. Studies have also demonstrated that similar to pyruvate, the capacity of embryo to metabolize glucose increases significantly, as the embryo progresses to blastocyst from the morula stage. Thus, increased glucose metabolism capacity also reflects better developmental potential and viability. However, other studies have not been able to conclusively prove correlation between glucose uptake or the role of pyruvate uptake to blastocyst development or as a predictor for embryo development and viability.[25] Brison et al. (2004) evaluated the changes in concentration of amino acids (glycine, leucine, and asparagine) and noted that embryos with greater viability have a lower amino acid metabolism compared to the embryos that arrest.[26]

Various different technologies have been tried to evaluate the different analytes in the culture medium. However, widespread use of metabolomics in clinical setting has remained limited due to need of complex equipment and dedicated staff to carry out the assay trained in using the special equipment. Also in some cases, the testing is cumbersome and results may not be available in the limited timeframe of an IVF cycle to allow fresh embryo transfer.

PREIMPLANTATION GENETIC DIAGNOSIS/SCREENING

Morphological evaluation of embryos requires expertise. Yet, as discussed earlier, it is not always accurate as many times embryos labeled as low grade on morphological evaluation have shown to have high-developmental potential. Chromosomal aberrations occur due to errors in meiosis and mitosis both at the time of formation of the gamete and during embryonic development. These chromosomal aberrations are a major obstacle to achieving a healthy pregnancy. Preimplantation genetic diagnosis (PGD) involves testing the embryo for a specific genetic condition likely to be inherited from the parents to the offspring, while preimplantation genetic screening (PGS) is used to screen the embryo prior to implantation for any chromosomal aberrations, i.e., for establishing chromosomal normalcy. PGS, thus, seems to be a logical step for evaluating the embryo quality. For PGS, the embryos are subjected to biopsy, which can be performed at different stages of embryo development. The commonly used techniques include PB biopsy from unfertilized and fertilized oocytes,[27-29] blastomere biopsy from day 3 cleavage-stage embryos[30,31] and trophectoderm biopsy from blastocyst stage embryos.[32,33] The genetic testing can then be performed on the cell thus obtained. Fluorescence in situ hybridization (FISH) and polymerase chain reaction (PCR) are the two commonly used first-generation technologies in PGD. Generally, PCR-based methods are used for DNA-based analysis for monogenic disorders and FISH is used for numerical and structural chromosomal aberrations. In recent times, these first generation tests are being replaced by more advanced tests such as comparative genomic hybridization (CGH), microarrays, array CGH (a-CGH), next generation sequencing (NGS), single nucleotide polymorphism (SNP) array, etc.

The classical form of PGS involved removal of one or two blastomeres from day 3 embryo and analysis of this cell by FISH for aneuploidies, for a limited number of chromosomes helping in selection of euploid embryos.[34] Initial studies using FISH testing on cleavage stage embryos revealed favorable ongoing pregnancy rate with PGS, but the later studies could not reproduce the results.[35] The increase in the number of chromosomes analyzed using FISH from routine 9 chromosomes to 15 aneuploid embryos, however, it showed

a marked increase in the number of mosaic embryos.[36] The reason for low success using single-cell preimplantation FISH testing includes technical limitations like overlapping FISH signals, hybridization failure, nonspecific hybridization, and errors in interpretation. Other problems associated with FISH include mosaicism. Additionally in routine FISH testing, only 33% of chromosomes are tested, thus missing out on aneuploidy for the remaining chromosomes.

In an attempt to overcome the pitfalls associated with FISH based using carried on day 3 embryos, newer methods to determine the ploidy status of a single cell are developed, such as CGH, a-CGH, and SNP arrays.[37] In addition, to avoid the confounding effects of chromosomal mosaicism, PB biopsy and blastocyst biopsy have gained popularity.[38] CGH and a-CGH have gained more popularity in testing of all 24 chromosomes simultaneously in the same assay. The technique reveals gains or losses of genome segments, which may be related to a chromosomal segment or the entire chromosome by picking up changes in the hybridization ratio of target to control.[39,40] The advantage of the a-CGH over FISH is that preclinical validation is not required.[41] Like any technique, this technique is also associated with some inherent drawbacks. a-CGH fails to detect balanced chromosomal rearrangements or the ploidy status of the embryo.[42] SNP arrays and NGS are also commonly used for PGS.

The cost-effectiveness of PGS has always been a topic of controversy, as the technologies used for establishing the diagnosis are currently expensive. However, we need to keep in mind that the technique overall has cost-effective result, as it potentially helps to reduce the number of ART cycles plus it enables single embryo transfer[43-46] and helps to lower miscarriage rates.

CONCLUSION

The test for a successful IVF cycle is successful implantation and pregnancy. In IVF, the selection of embryos for transfer is generally based on the morphology of the available embryos, which has been attempted at various stages of embryo development starting with assessing the quality of gamete and going up to the blastocyst stage. Each laboratory has their own algorithms for the same. Time-lapse imaging holds promise for aiding the embryologist in determining which embryos are most suitable for transfer, as it gives dynamic information about the embryo through various stages of cell division. Various groups have tried this technique with variable success. Hence, the adoption any new technique for selection of embryo or to analyze fertilization should be based on thorough scientific evaluation and validation in clinical scenario. Evaluation of numerous metabolic markers at various stages of embryo development to evaluate their development and implantation potential has also been attempted by many groups with limited success in clinical scenario in view of the time required for reporting of the results. Testing methodologies, which are less cumbersome and have better turnaround time, can help to improve the area of metabolomics. Apart from these noninvasive methods of embryo selection, the quest for selection on chromosomally normal embryo has led to introduction of PGS. This technology has seen various advances in the form of better test modalities. Hence, analysis of fertilization in selection of the best embryo continues to remain a challenging task with more and more ongoing research in this area to improve the success rate with IVF.

CHAPTER 107

Morphological Assessment of Oocyte and Embryo

Vijay Mangoli, Ranjana Mangoli

INTRODUCTION

It is really fascinating to observe how male and female gametes unite together, transform themselves into beautiful embryos and one day, they come to you as a complete human being. While performing assisted reproductive technology (ART) procedures, these preimplanting embryos are with us for only 3–5 days. But even at this early stage, they are as unpredictable as toddlers. We have to pamper them with all their demands and day-to-day requirements to get best out of them. It is a period of rapid transition where foundations of all further embryonic growth are established. And apart from different stimulation protocols and laboratory techniques adapted, selecting best embryos plays crucial role in getting optimum results.[1]

Now, the million dollar question is—how to select an implantable embryo? And as of today, even after 44 years of human in vitro fertilization (IVF), there is no straight answer to this. The situation is complicated because even if the laboratory creates and selects a viable embryo, it requires an equally competent and receptive endometrium for a successful implantation. An embryo which is not implanted in one uterus might have implanted in another uterus but obviously one cannot transfer a single embryo in different uteri to test its implantation potential. We generally do not have choice of uterus, but we can select oocytes and embryos based upon certain morphological assessment and nuclear criteria.

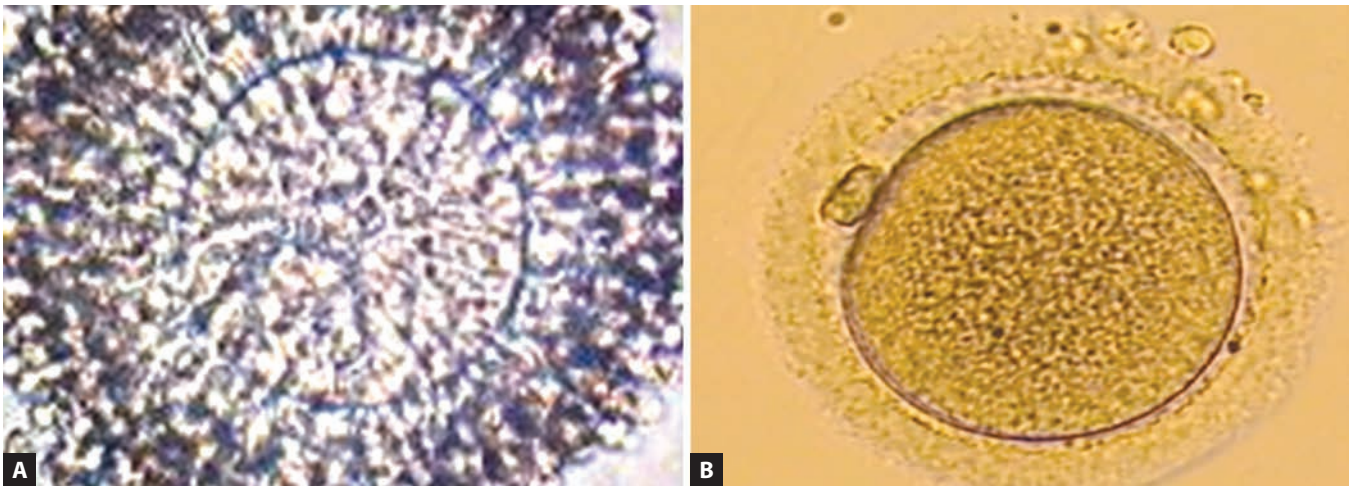
Most commonly applied evaluation method is morphological selection because it is noninvasive, does not require any additional instruments, takes less time, and often—though not always—correlates with outcome. Recent times have seen methods of assessing oocytes and embryos through technical advances such as time-lapse monitoring, proteomics, and through genetic evaluation of blastomeres or trophectoderm cells as discussed in Section 17.

OOCYTE

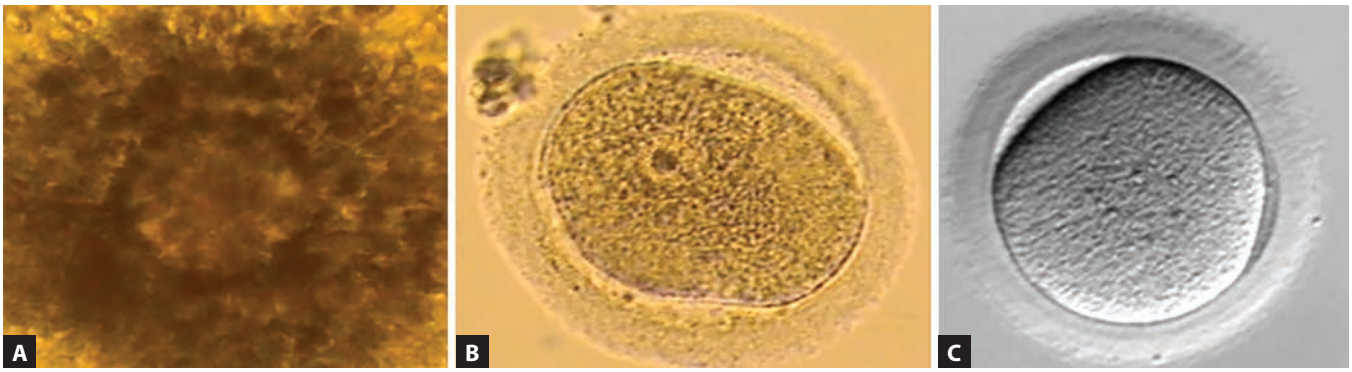
At birth, a baby girl has about two million oocytes in her ovaries. All these oocytes are arrested at the prophase of first meiotic division and they remain dormant until onset of puberty. During each menstrual cycle, one of these "sleeping beauties" is being kissed by "Prince" luteinizing hormone (LH), awakening it to continue its meiotic division. After completion of maturation, the oocyte is released into the fallopian tube and if it meets with the sperm, fertilization may occur. Though the whole process appears romantically simple, practically, not all the oocytes released are capable of getting fertilized. A large variation is seen in the sibling oocyte quality when retrieved after controlled ovarian stimulation.

These are some of the morphological aspects deciding potential of an oocyte to become a viable embryo:

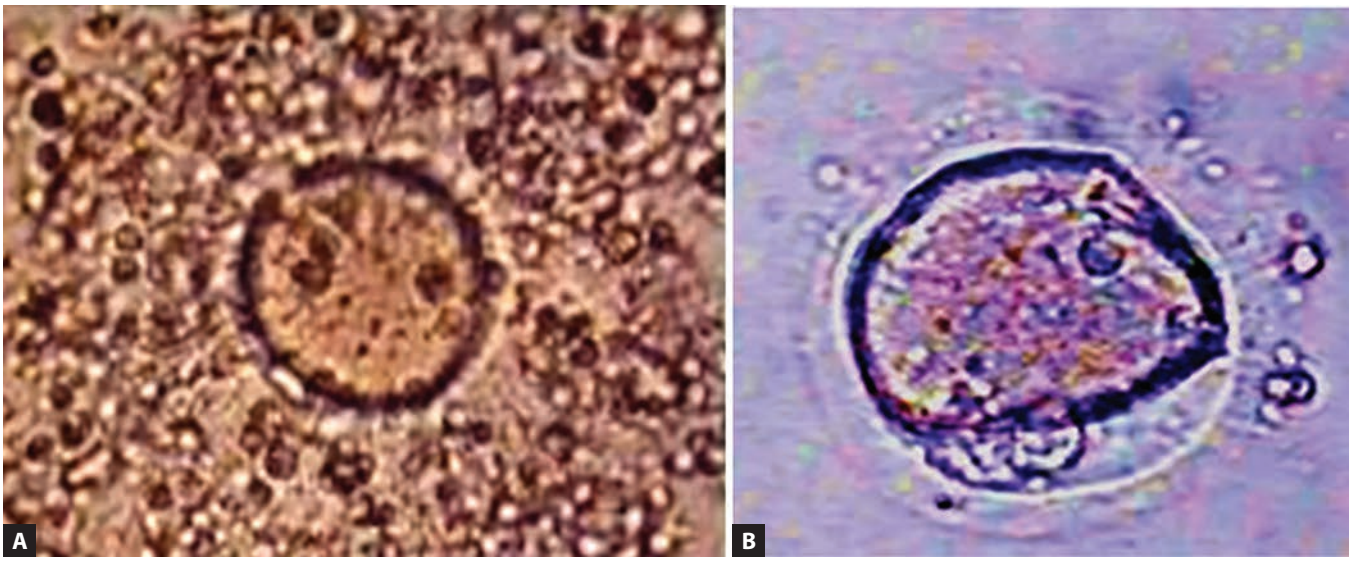
- *Cellular and nuclear assessment:* Immediately after ovum pickup (OPU), oocyte can be grossly categorized as mature, immature, postmature, or atretic on the basis of cellular investments around it. A mature oocyte typically displays expanded cumulus with radiant or "sunburst" corona **(Figs. 1A and B)**. A densely packed cumulus-corona complex is generally associated with immaturity **(Figs. 2A to C)**. Loosely spreaded layers of cumulus with scanty corona indicate post maturity **(Figs. 3A and B)**, and one without any cellular investments indicates atretic oocyte **(Figs. 4A and B)**. Though this assessment closely approximates maturity status of oocytes, it can be imprecise and therefore it has to be co-assessed with nuclear status.
- *Size and shape of oocytes:* A mature, healthy meiosis II (MII) oocyte is spherical having diameter of about 120 µm. Rarely giant oocytes of >200 µm diameter with multiple polar bodies are observed which are generally associated with markedly reduced viability **(Fig. 5)**. Most giant oocytes are reported to be associated with aneuploidy.[2] Occasionally, elongated oocytes are retrieved which are usually result of increased aspiration pressure during OPU and do not exhibit altered fertilization, cleavage, or pregnancy rate **(Fig. 6)**.[3] Rarely, oocytes without zona are reported. Even such oocytes have potential to get



Figs. 1A and B: Mature oocyte.



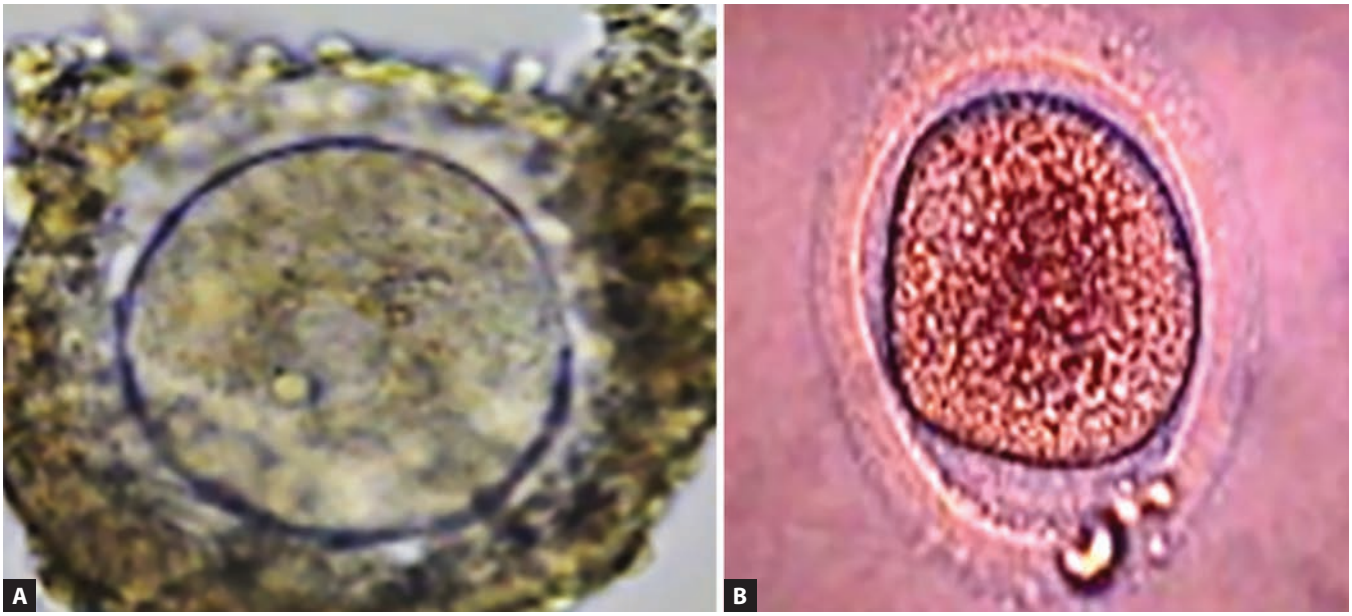
Figs. 2A to C: Immature oocyte. (A and B) Germinal vesicle; (C) Metaphase I oocyte.



Figs. 3A and B: Postmature oocyte.

fertilized. They may display 2PN or polyploidy and are usually associated with hampered further embryonic growth.[4]

- *Zona pellucida (ZP):* It is a matrix of three intermediate filament proteins, ZP1, ZP2, and ZP3, laid down during folliculogenesis. ZP is a dynamic multifunctional structure at different stages of embryogenesis. At oocyte stage, it prevents polyspermy; at cleavage stage, it promotes selective permeability to maintain optimum concentration of nutrients; and at blastocyst stage, it thins out to facilitate hatching. A healthy zona is about 16–18 μm in width with a smooth, even, spongy, and



Figs. 4A and B: Atretic oocyte.

Fig. 5: Normal and giant oocytes.

Fig. 6: Elongated oocyte.

flexible texture. Makiko et al. reported that the zona thickness in the range of 15–17 μm gives good fertilization rate with normal IVF using normozoospermic sample whereas, those with zona thickness between 17 and 21 μm results in drastically low fertilization rate. Those oocytes having zona thickness of >22 μm certainly requires intracytoplasmic sperm injection (ICSI). Such papers give us an idea about selecting mode of insemination to get good fertilization.[5] ZPs 2 and 3 also serve as receptors for sperm binding and help activate the sperm acrosome reaction **(Fig. 7)**. Sometimes oocytes with uneven zona are observed with controversial reports about their viability **(Fig. 8)**.

- *Cytoplasm:* A healthy oocyte displays translucent cytoplasm with evenly distributed fine granularity. It contains mitochondria, peroxisomes, endoplasmic reticulum, Golgi complex, vacuoles, and other organelles.

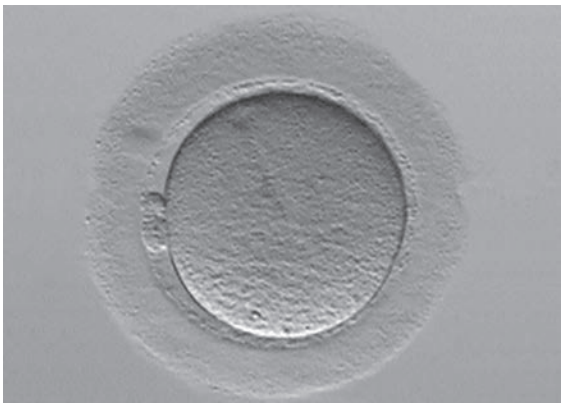


Fig. 7: Oocyte with thick zona.

Patchy or localized dark and granular cytoplasm has been associated with decreased fertilization, particularly in IVF, presumably related to atresia[6] **(Fig. 9)**.

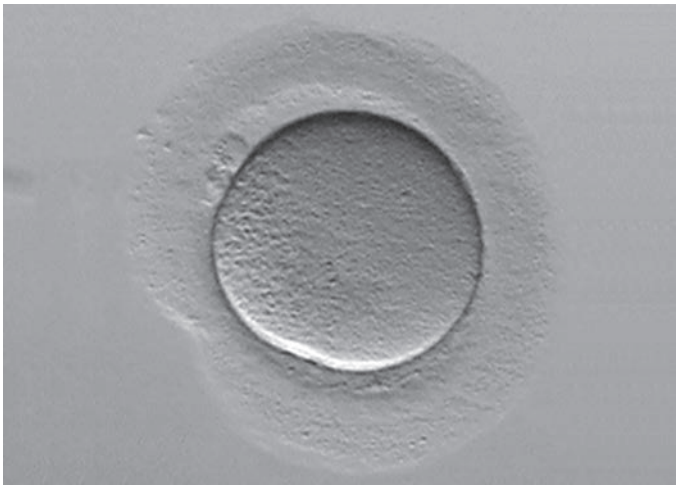

Fig. 8: Oocyte with uneven zona.

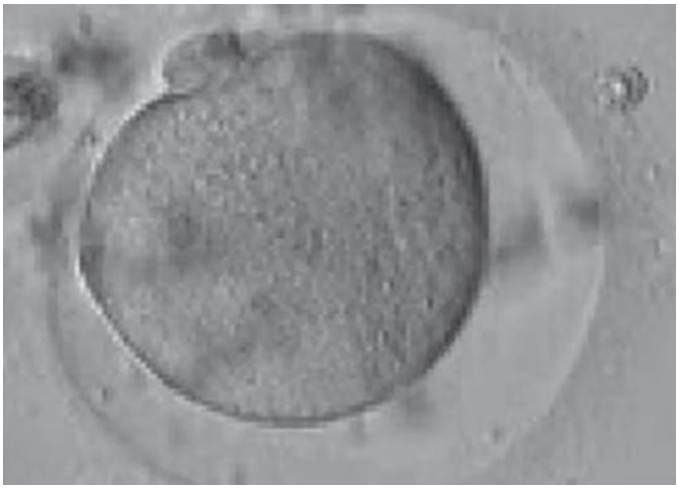

Fig. 11: Oocyte with large perivitelline space.

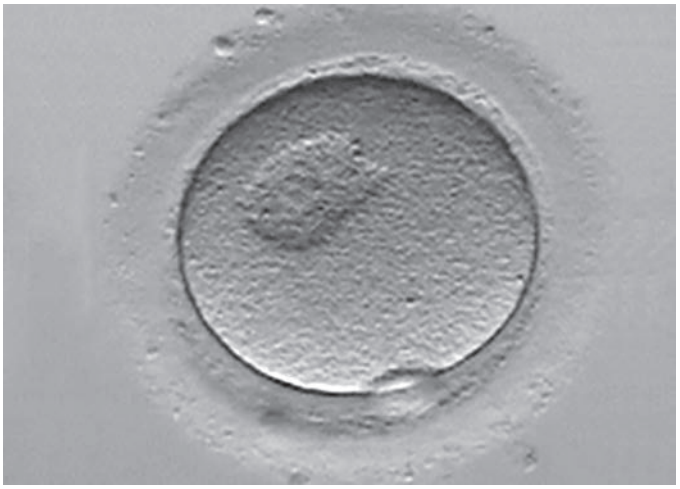

Fig. 9: Oocyte with eccentric granular ooplasm.

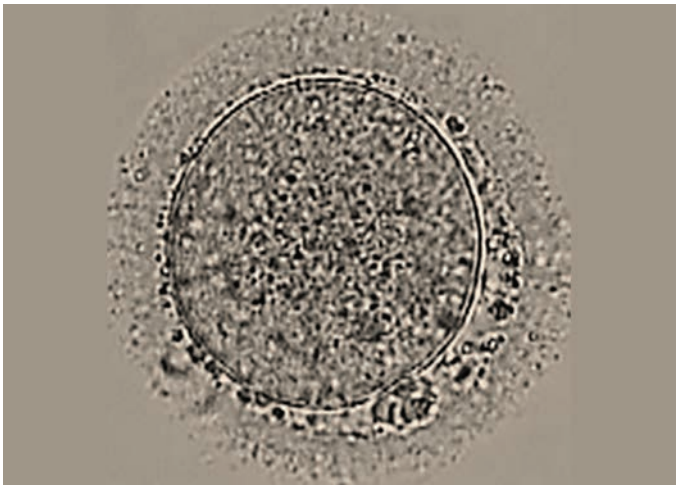

Fig. 12: Granules in perivitelline space.

Fig. 10: Oocyte with two germinal vesicles.

Very rarely, an oocyte may display two germinal vesicles. Possible explanation for this is fusion of two primordial follicles during oogenesis resulting in creating single oocyte that shares common cytoplasm. Such oocytes do not have potential to continue maturation **(Fig. 10)**.

- *Perivitelline space:* It is the space between the oolemma and ZP. Normally, the gap is almost invisible throughout the contact area, except near polar body. Occasionally, varying degree of gaps between the two is observed **(Fig. 11)**. Effect of such gap space has unclear effects on fertilization, preimplantation embryo development, and pregnancy rates. Granules may appear within this space, but they also do not appear to influence oocyte or embryo development.[7] Stimulation protocol can influence oocyte quality, e.g., exposure to high dosage of human menopausal gonadotropin (hMG) has been shown to be associated with granularity of the perivitelline space[8] **(Fig. 12)**.
- *Polar body:* Human chorionic gonadotropin (hCG) or the LH surge resumes meiosis, resulting in extrusion of the first polar body. The second polar body separates only after fertilization or activation. The timing of the first polar body extrusion varies among aspirated oocytes, presumably because of variations in the timing of meiotic maturation.[9]

Oocytes with incomplete cytokinesis, which leave the polar body attached to the oocyte, exhibit low fertilization

Fig. 13: Oocyte with large polar body.

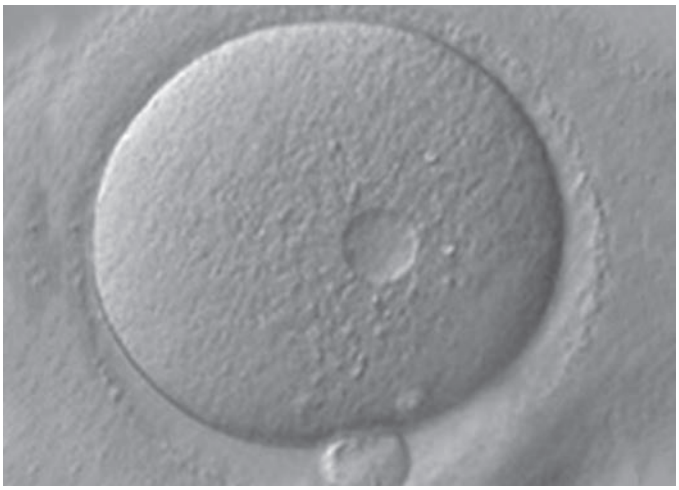

Fig. 15: Oocyte with vacuole.

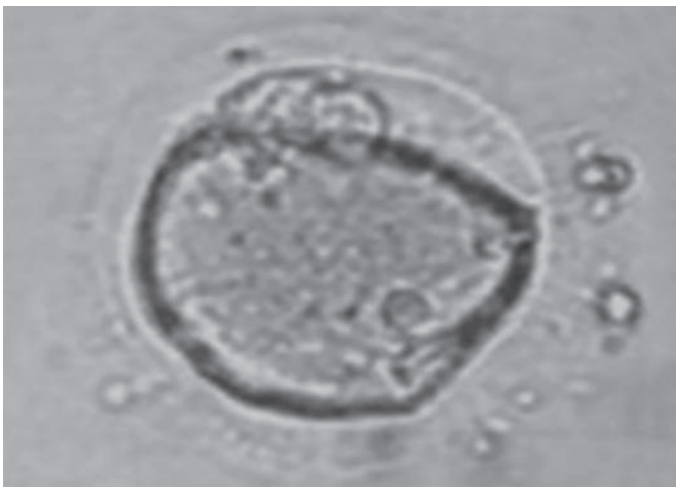

Fig. 14: Fragmented polar body.

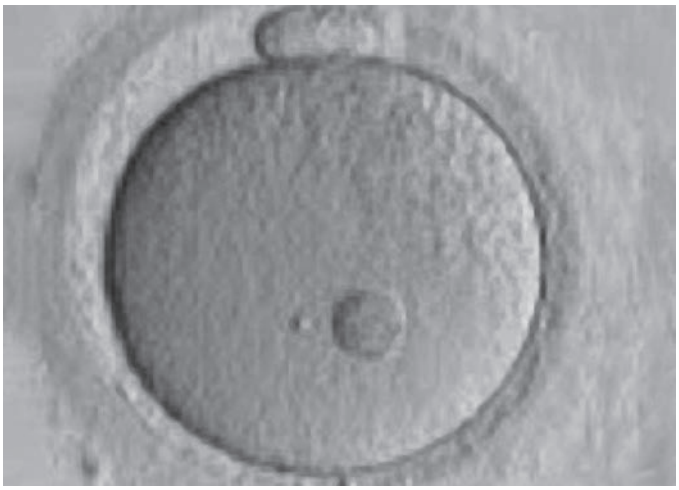

Fig. 16: Oocyte with refractile body.

and poor embryo cleavage rates, presumably because of their impaired meiotic competence.

A healthy oocyte has spherical or oval polar body. Occasionally, larger polar bodies are observed posing risk of aneuploidy, if inseminated **(Fig. 13)**. A fragmented polar body at OPU indicates postmature nature of the oocyte **(Fig. 14)**.

- *Vacuoles:* Some oocytes may display circular cytoplasmic inclusions either single or in clusters. Though their cellular basis is presumably of endocytotic origin, they are postulated to be associated with atresia with decreased fertilization rate and adversely affected cleavage pattern.[10] A few small, transparent, fluid-filled vacuoles (<5 μm diameter) are unlikely to be of consequence, whereas large vacuoles (>6 μm diameter) are associated with fertilization failure, and if fertilized, results in poor embryo development **(Fig. 15)**.
- *Refractile bodies:* These are dense, insoluble protein bodies that are produced within the cells presumably as a result of accumulated lipofuscin. They are called refractile bodies because their greater density (than the rest of the cell's body mass) causes light to be refracted (bent) when it is passed through them causing appearance of very bright and dark areas around them visible under a microscope. It is observed that refractile bodies are the single largest cause of failed fertilization even after ICSI[11] **(Fig. 16)**.
- *Smooth endoplasmic reticulum (sER):* It is an interconnected network of membranes without ribosomes. Normally, when evenly distributed, they are not prominently visible. When aggregated, they are visible either in small bunches, or seen as a large structure distinctly noticeable. Formation of sER is seen only in MII oocytes and is generally associated with high E2 levels. sER aggregation may be associated with early fetal demise and, in newborns, with certain imprinting disorders (e.g., Beckwith–Wiedemann syndrome)[12,13] **(Fig. 17)**.
- *Meiotic spindle:* Meiosis consists of two reduction steps. Meiosis I (MI), where homologous chromosomes

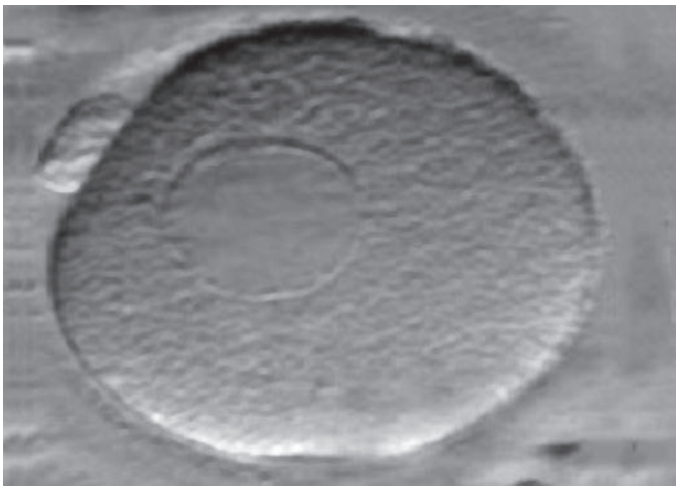

Fig. 17: Oocyte showing single cluster of aggregated smooth endoplasmic reticulum.

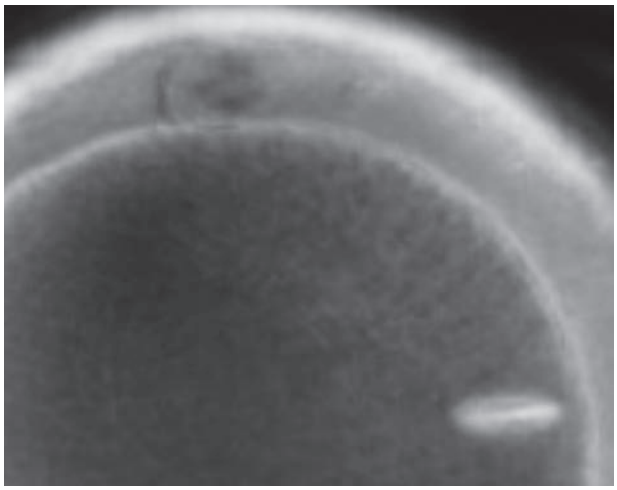

Fig. 19: Spindle away from polar body.

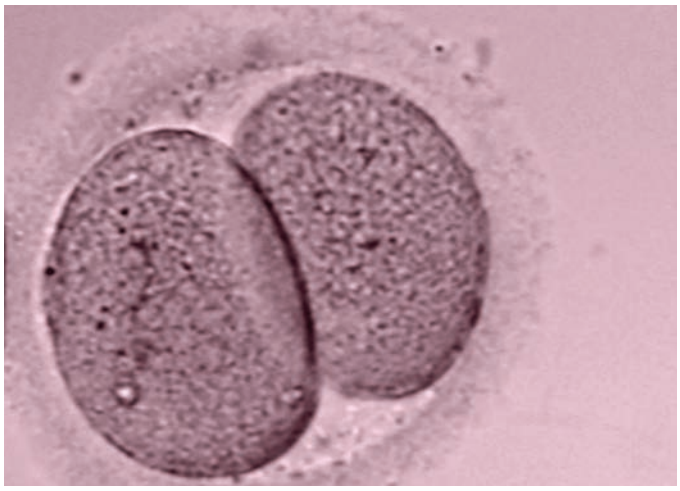

Fig. 20: Parthenogenetically activated oocyte.

separate, and metaphase II (MII), where chromatids separate. Mature oocytes are arrested in MII, with the MII spindle tethering chromatids, and a single extruded polar body. It is not possible to view meiotic spindle with commonly used contrasting systems like Hoffman modulation or differential interference contrast (DIC). However, they can be visualized using polarized microscopy because of a special property possessed by macromolecular tubules of spindle, called anisotropy.

Polscope helps to locate spindle in the oocyte. Though generally spindle is located near the first polar body **(Fig. 18)**, on some occasions, it is observed to be farther away from it **(Fig. 19)**. Under such circumstances, it is possible to disrupt it during ICSI.[14]

- *Parthenogenetically activated oocyte:* Occasionally, either immediately post-OPU or at the time of denudation, one can see oocyte with two to three blastomeres like structures. This can be a parthenogenetic activity caused due to excessive handling or sudden influx of Ca^{++} during removal of cumulus corona investments around the oocyte. Insemination at this stage is not recommended due to increased probability of chromosomal imbalance in resulting embryo **(Fig. 20)**.

ZYGOTE

A zygote is formed as a result of fertilization through sexual reproduction between two haploid cells—an ovum and a sperm. For a successful fertilization to occur, several events must follow in a disciplined manner, as under:

- Sperm penetration through cumulus oophorus
- Binding of sperm to the zona
- Sperm-oocyte fusion
- Oocyte activation
- Sperm nucleus decondensation nucleus
- Development and migration of male and female pronuclei
- Association of the parental chromosomes on spindle of first cleavage division.

Morphologically, optimal fertilized oocyte displays two spherical polar bodies and two centrally-located and

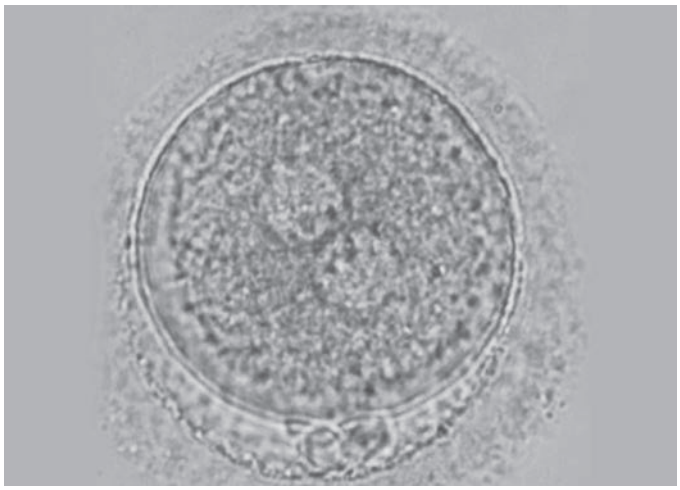

Fig. 21: Polarized zygote.

Fig. 23: Halo around pronuclei.

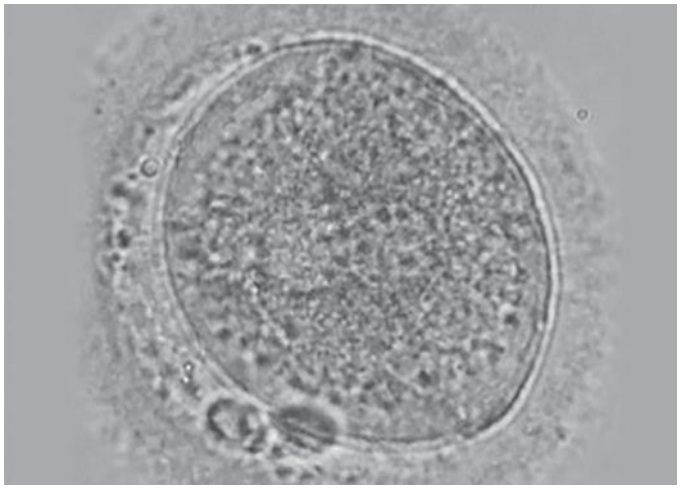

Fig. 22: Nonpolarized zygote.

Fig. 24: Oocyte with single pronucleus (17 hours postinsemination).

juxta-posed pronuclei that are even-sized with distinct membranes. The pronuclei containing nucleolar precursor bodies equivalent in number and size, equatorially aligned at the region of membrane juxtaposition are called as polarized pronuclei **(Fig. 21)**. When pronuclei contain uneven number or uneven distribution of precursor bodies, they are known as nonpolarized pronuclei **(Fig. 22)**. The positive predictive value of pronuclear scoring has been the subject of some debate, with some papers showing a prognostic effect,[15-18] while others identified a correlation with aneuploidy,[19,20] and still others found no positive predictive value.[21,22]

Some zygotes display a characteristic halo appearance in the ooplasm. This phenomenon is thought to be the manifestation of a microtubule-organized translocation of mitochondria and other cytoplasmic components to the center of the oocyte due to their increased activities. This is a promising sign of getting good and implantable embryo **(Fig. 23)**.

Occasionally, oocyte displays single pronucleus post ICSI. This is because of suppressed oocyte activation. Terada et al. reported acceptable fertilization rate using Ca ionophore and ionomycin to induce cytoplasmic activation[23] **(Fig. 24)**.

EARLY CLEAVAGE

Sign of syngamy **(Fig. 25)** and early cleavage **(Fig. 26)** (26 hours ± 1 post ICSI, 28 ± 1 post IVF) is predictive of further even cleavage pattern, and reported to have lower incidence of chromosomal errors.[24]

However, embryos with cleavage earlier than 20 hours postinsemination or those directly entering three or more cell stage have been shown to be associated with chromosomal abnormalities[24] **(Fig. 27)**.

CLEAVAGE STAGE EMBRYOS

From day 2 onward, the number of blastomeres keeps on dividing at regular intervals. It is necessary that this division is stage specific. Mitosis in blastomeres should produce two equally sized daughter cells. When the division is

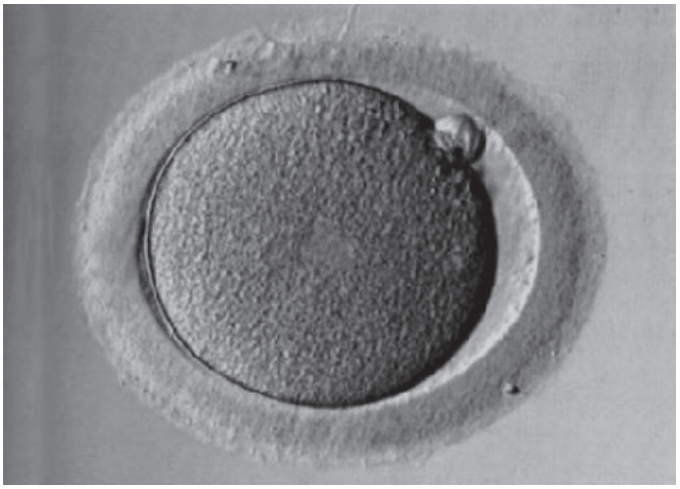

Fig. 25: Syngamy—21 hours postinsemination.

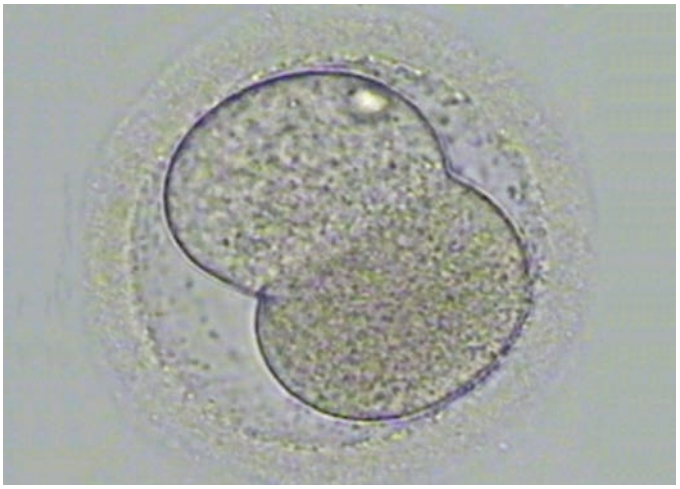

Fig. 26: Early cleavage (23 hours postinsemination).

Fig. 27: 3-cell embryo.

asymmetric, one of the blastomeres of the next generation will inherit less than half the amount of cytoplasm from the parent blastomere, leading to a defective lineage in the embryo. 4- and 8-cell embryos with equal cell sizes have been shown to have lower multinucleation and aneuploidy rates and increased implantation rates.[25,26]

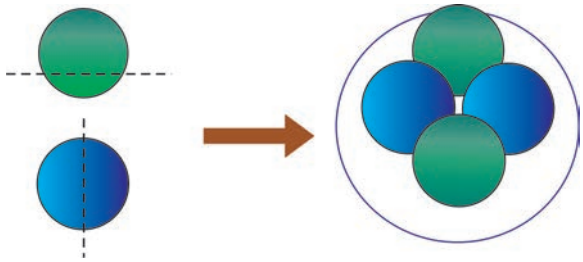

Fig. 28: Dividing planes of second mitotic cleavage. One cell cleaves equatorially and other cleaves meridionally resulting in four daughter cells with different polarity.

Fig. 29: Day 2: 4-cell grade I embryo.

Human oocytes are polarized from their earliest stages of formation and consist of an animal and vegetal pole.[27-29] This animal and vegetal gradient is distributed differently to specific 4-cell blastomeres via the combination of meridional and equatorial cleavage divisions.[30]

The first cleavage occurs meridionally and results in two nearly identical daughter blastomeres each inheriting similar polarities of animal and vegetal cytoplasm. In the second cleavage, one cell divides meridionally while the other cell divides equatorially which results in four cells with different polarity **(Fig. 28)**. The two daughter cells resulting from the meridional cleavage have inherited full polarity, while the two daughter cells from the equatorial cleavage differ in polarity with one cell containing mostly animal cytoplasm and the other cell containing mostly vegetal cytoplasm.[31,32]

Day 2

At 44 ± 1 hours postinsemination, a healthy embryo display four equally sized mononucleated blastomeres in a 3-dimensional tetrahedral arrangement, with preferably nil or <10% fragmentation **(Fig. 29)**.

Day 3

At 68 ± 1 hours postinsemination, a healthy embryo displays six to eight equally sized mononucleated blastomeres with

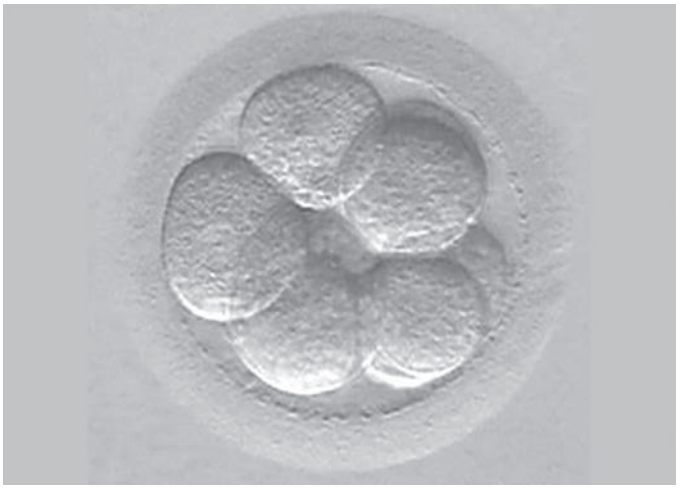

Fig. 30: Day 3: 8-cell grade I embryo.

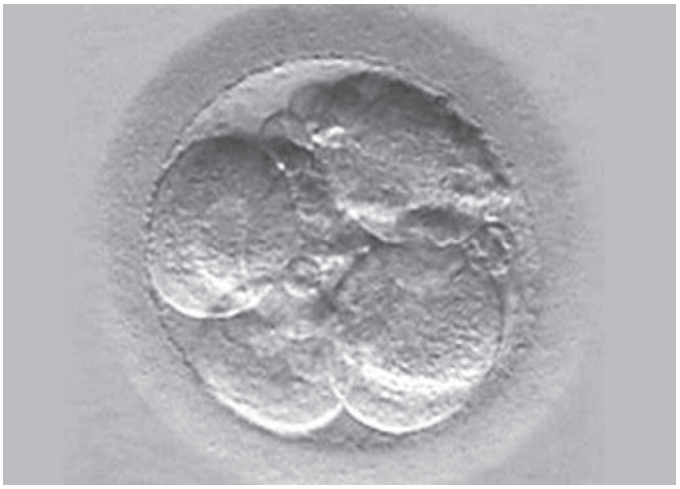

Fig. 32: Day 3: 6-cell grade II embryo with 15% fragmentation.

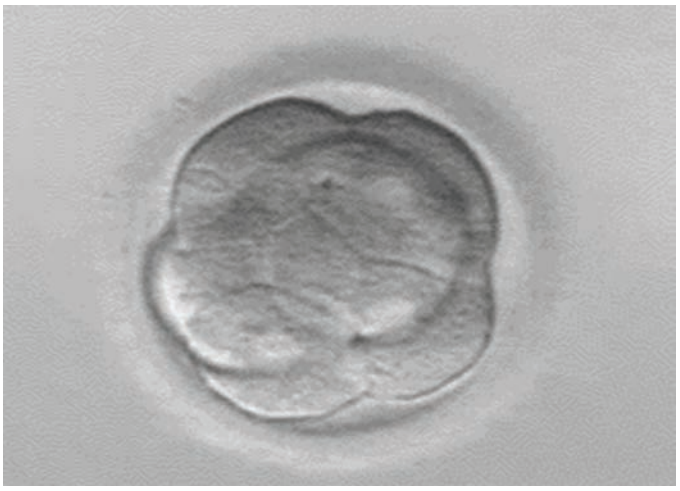

Fig. 31: Day 3: Beginning of compaction in 8-cell embryo.

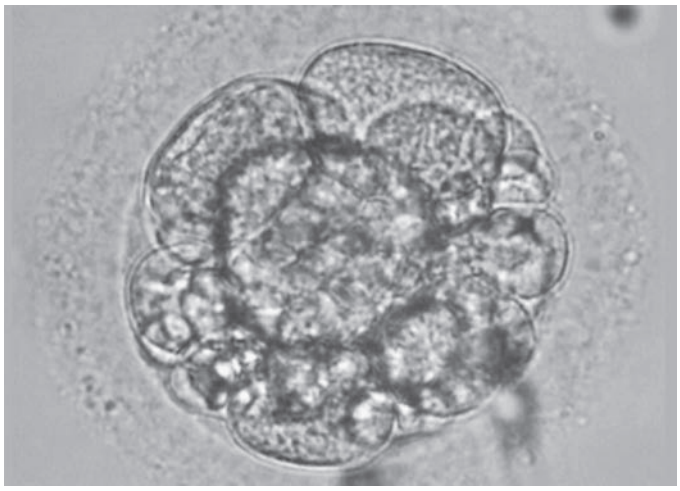

Fig. 33: Day 3: A 6-cell grade III embryo with >50% fragments, uneven blastomeres.

nil or <10% fragmentation **(Fig. 30)** and a sign of beginning of compaction **(Fig. 31)**. This is an important stage from embryogenesis point of view, as paternal genome is activated at this point that decides effect of genetic filiation on embryo development. Embryos with >15% fragmentation are categorized as grade II **(Fig. 32)**. Those with >50% fragments are termed as grade III and are not selected for transfer **(Fig. 33)**.

Day 4

At 92 ± 2 hours postinsemination, one can observe a structure called "morula", where it is not possible to count number of blastomeres that range from 8 to 32 **(Fig. 34)**.

At this point, it is also not possible to assess presence of multinucleation, if any. Immediately after morula within 2–4 hours, a healthy embryo displays stage of compaction where intercellular junctions of blastomeres fuse to form an uneven, irregular ball-like structure. Such embryo almost always results in a blastocyst **(Fig. 35)**.

Fig. 34: Day 4: Grade I morula

Day 5

At 106–108 hours postinsemination, a healthy embryo turns into a blastocyst **(Fig. 36)**. However, not all blastocysts are

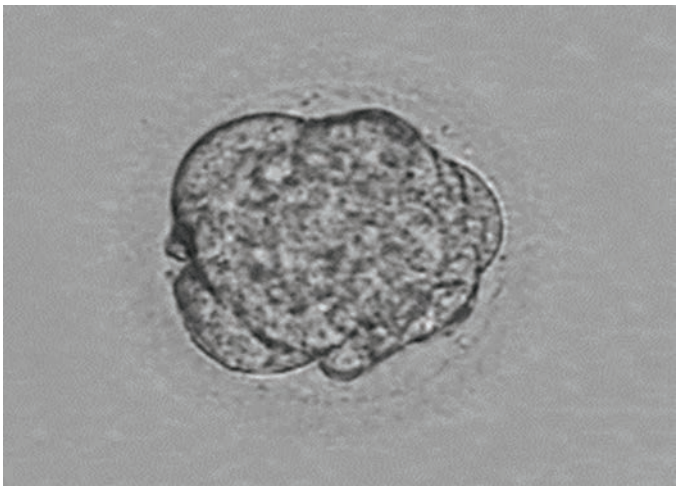

Fig. 35: Day 4: Compacting stage.

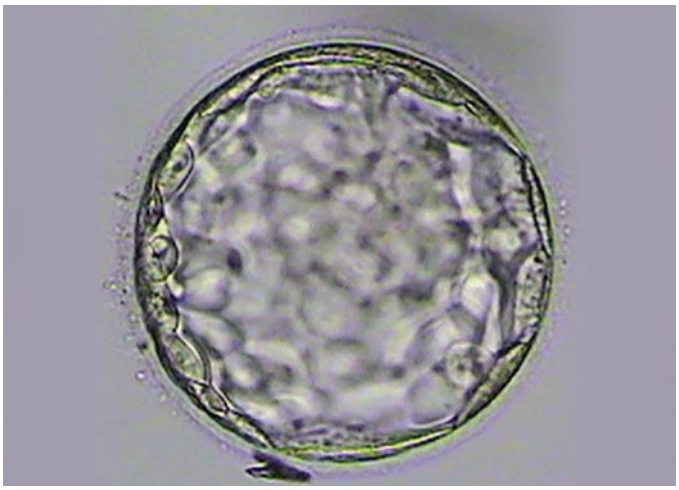

Fig. 37: An expanded blastocyst without inner cell mass.

Fig. 36: Day 5: Grade I blastocyst.

Fig. 38: Hatching blastocysts.

capable of implantation. Timing of blastocyst formation and its morphology is crucial for its viable status. An expanded blastocyst with thin zona, blastocoel filling almost entire area, clear sickle-shaped trophectoderm, and tightly packed inner cell mass (ICM) comprising about 25% of blastocoel are obvious markers to certify a blastocyst as grade I. Whereas, an expanded blastocyst with poorly developed or absent ICM is nonviable **(Fig. 37)** and, if transferred and gets implanted, may result in blighted ovum.

One can even observe a hatching blastocyst on day 5 or day 6 **(Fig. 38)**. It indicates healthy morphological status of the growing embryo.

MORPHOLOGICAL ASSESSMENT USING MORPHOKINETICS

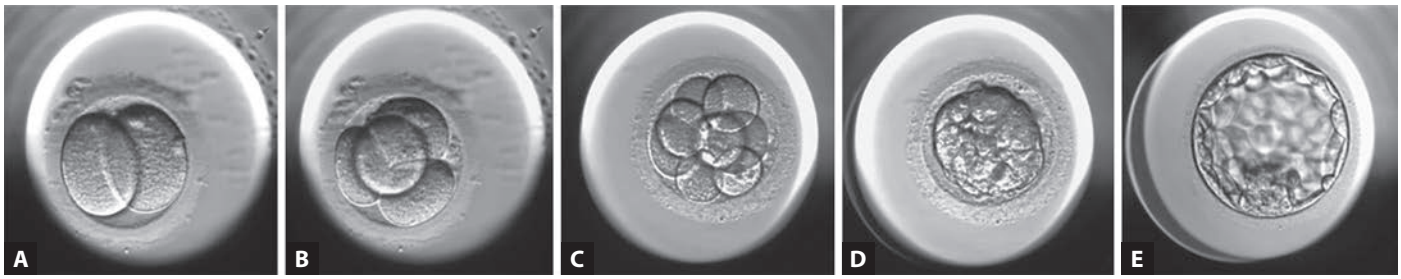
With the advanced scientific developments, dynamic growth of growing embryo can be monitored using techniques like time-lapse monitoring where embryo's images are taken at intermittent intervals throughout development without disturbing microenvironment **(Figs. 39A to E)**.

Using "time-lapse" imaging system, morphological competency can be checked in more predictive manner, where embryo can be assessed as:

- Those remained healthy throughout development stages
- Those which were healthy during early stages, but became unhealthy at later stages
- Those which were unhealthy initially, became healthy later
- Those showing unhealthy pattern throughout development.

These systems tell us which embryos display ideal growth pattern. However, they cannot tell with certainty that other embryos can never initiate a pregnancy. Question is—should we discard them or cryopreserve them and ultimately transfer in subsequent cycles, because there are pregnancies reported from grade II or even grade III embryos.

Though these devices do not have confidence in declaring noncompetency of poorly developed embryos, they help us in selecting "most probable" embryo that can result in live birth if transferred in a competent and receptive endometrium.[33] This presumably shortens number of efforts



Figs. 39A to E: Time lapse images of growing embryo.

in terms of embryo transfers and hence duration for patient to become pregnant.

SUMMARY

Selecting optimum embryo for transfer through morphological assessment under inverted microscope is most widely used criteria in IVF centers. Though, it is possible to predict probability of pregnancy to some extent, research is on to correlate genomics and proteomics involved during embryogenesis along with morphology of individual embryo to further enhance selection criteria. While using morphological assessment, it is important to note that embryo should not be selected only at the end point, but throughout its development. For example, an embryo showing grade I blastocyst after 20% fragments in embryo on day 2 or day 3 can be less optimum than one retaining its grade I status from day 2 through day 5. This imposes certain limitations on embryo culture like "group culture" of embryos, which is known to be beneficial. Secondly, detail evaluation of each embryo at each stage requires extended exposure during observation unless time-lapse imaging systems are used. This demands quick assessment with minimum fluctuations in culture system.

A combination of evaluation protocol involving morphology and biochemistry with practical and economical feasibility to select a single viable embryo for transfer is need of the time to improve take-home baby rates while reducing multiple gestations.

CHAPTER 108

Blastocyst Culture and Transfer

Rajvi H Mehta, Mohammed Ashraf C, Mir Jaffar

INTRODUCTION

The birth of a single, healthy baby is the desired outcome of any assisted reproductive technology (ART). But not all couples who undergo treatment for their infertile condition with ART manage to achieve this goal. Most embryos fail to implant when transferred into the uterus at the four- to eight-cell stage.

It has become a common practice to transfer multiple embryos into the uterus to improve the chances of a pregnancy. When more than one embryo was transferred, it was not possible to predict with certainty which of the embryos would implant and which would not. Transfer of multiple embryos did improve the chances of pregnancy, but along with it, there was an increase in the incidence of multiple pregnancies as well as the obstetric complications that go along with multiple gestations. It has been reported that the incidence of twinning has doubled, while that of triplets has increased sevenfold in the last few decades in the United States[1] and this has been attributed to some form of fertility treatment. Thus, an ideal situation would be to transfer only one embryo that has the highest potential of implantation, wherein the risk of multiple pregnancies is reduced without compromising on the chance of pregnancy itself. The crucial question that arises is what is the optimal stage at which the embryo should be transferred into the uterus.

WHY CULTURE EMBRYOS TO THE BLASTOCYST STAGE IN VITRO?

In an in vivo situation, early embryonic development occurs in the fallopian tube, and it enters the uterus at the stage of a blastocyst. However, following conventional in vitro fertilization (IVF), embryos are only at the four- to eight-cell stage when they are transferred to the uterus either on day 2 or day 3. Are the embryos being transferred into the uterus too early?

Second, embryos from many mammalian species are known to undergo a "metabolic block" when cultured in vitro, i.e., a stage where the metabolism in the embryos switches from the control of the maternal genome to the embryonic genome. This embryonic gene expression occurs in humans at the four- to eight-cell stage.[2] Therefore, when embryos are transferred into the uterus at this stage, one is unsure whether the embryo is capable of further development after the activation of the embryonic genome. In fact, it is not even possible to determine whether the embryo is viable at the time of transfer.

The best option to overcome both of these limitations seems to be to culture the embryos in vitro till the blastocyst stage. Transfer of blastocysts into the uterus would be closer to the in vivo situation. Secondly, culturing embryos for an extended period will select the developing embryos from those that have undergone developmental arrest. Buster et al. reported high pregnancy rates following transfer of blastocysts obtained after uterine flushing from donors.[3] Thus, it only seemed logical to transfer blastocysts into the uterus after extended culture of embryos obtained after IVF.

Culturing Blastocysts In Vitro

Attempts to extend the culture of embryos in vitro till they reached the blastocyst stage using conventional media remained unsuccessful. About 40% of oocytes fertilized in vitro, developed to blastocysts, but only 10% led to pregnancy after transfer on day 5 post insemination.[4] This was primarily because the metabolic requirements of early human embryonic development were unknown.

Coculturing Embryos with Somatic Cell Lines

Coculture of human embryos with autologous or heterologous somatic cell lines offered a means of successfully culturing human blastocysts in vitro. In the early 1990s, Menezo's group in France and Bongso in Singapore cocultured human embryos with Vero cells and tubal ampullary cells, respectively.[5,6] Vero cells were selected over the others since the kidney cells have the same origin as the reproductive tract. Ampullary cells were the closest to the in

vivo environment. Nearly 60% of the embryos did develop to the blastocyst stage in these studies.

What led to the improvement in the blastocyst formation rate following coculture remained unknown. It could be specific factors produced by the cocultured cells that promoted embryonic development or it could be the detoxification effect brought about by the cell line and the improved buffering systems. But neither of these could be characterized. The process of coculturing embryos with cell lines was cumbersome, and there was also the potential risk of using cell lines from animal species. Thus, this methodology did not become popular or attain routine application.

Blastocyst Culture using Sequential Media

Another approach to culture blastocyst that has gained popularity is the culture of embryos in defined, serum-free, sequential culture media.[7,8] The principle behind the formulation of such media is to reflect the changing environment in the maternal reproductive tract. The requirements of early human embryos are minimal and do not require glucose as an energy source. Development of cleavage-stage embryos to morula and then blastocyst requires more nutrients. Hence, two or more media are used sequentially for the culture of blastocyst in vitro, which takes into consideration the changes in the metabolic requirements and the different stages of development. On an average, nearly 50% of the embryos developed to a blastocyst stage when cultured in sequential media, of which about 50% were viable. Many commercial brands of media are currently available for blastocyst culture, and several studies have compared the quality of the different commercial media for culturing cleavage-stage embryos and blastocysts.[9-11]

Extended Culture in a Single Defined Medium

Biggers and Racowsky have reported a one-step protocol for culturing human embryos in the same medium till the blastocyst stage.[12] They report that a single-step protocol using potassium simplex optimized media (KSOM) is as efficacious as sequential culture for developing blastocysts. Five babies were born from transfer of nine blastocysts.

MORPHOLOGICAL EVALUATION OF BLASTOCYSTS

Extended culture of human embryos till the blastocyst stage helps in improving the implantation rate by improving the selection of embryos. A further improved selection of blastocysts can help in further improving the implantation rates. The evaluation of blastocysts is primarily based on the morphological assessment of the embryos. Morphological assessment is limited by its subjectivity, but the development of grading and scoring makes the data on blastocyst quality comparable.

Normal blastocyst development required blastulation, a visible inner-cell mass, trophectoderm cells covering 60% of the inner zona surface and thinning of the zona.[13]

Gardner et al. developed a system to score the developmental potential of blastocysts based on their ability to implant following transfer of single or two blastocysts.[14] They observed that in 21% of the patients, one top-quality blastocyst was available for transfer, and the implantation and pregnancy rates in this group were as high as 50 and 70%, respectively. However, when a low-scoring blastocyst was available for transfer, the implantation and pregnancy rates were 28 and 44%, respectively.

Kovacic et al. classified 1,396 blastocysts and morula into eight morphological categories.[15] The optimal blastocysts were called B1. The other categories were characterized by different deviations from optimal blastocysts: Cytoplasmic fragments and necrosis in trophectoderm (B2), unexpanded blastocoele (B3), noncompact or small inner cell mass (ICM) (B4), fragments in trophectoderm and ICM (B5), up to 20% excluded blastomeres (B6), necrotic trophectoderm and ICM (B7), and >20% excluded cells from blastocysts (B8). The live birth rate was calculated from blastocysts with known outcomes after transfer. The birth rate declined from B1 to B8 in the same order and was 45.2, 32.8, 26.9, 23, 17.7, 16.7, 7.7, and 1.2%, respectively. Normal ICM was recognized as the most important parameter for implantation. They concluded that such a grading system is helpful in selecting the best of all available day 5 embryos for transfer.

Morphological Characteristics of Blastocyst with Impact on Implantation

Embryoblast is considered to be optimal if the ICM shows a tight package of numerous cells. In contrast with a well-expanded cavity and a cohesive trophectoderm, ICM size was significantly related to implantation. Blastocysts showing an ICM of <3,800 μm^2 showed lower implantation rates (18%) compared to blastocysts with a larger ICM of 4,500 μm^2 (45%). An optimal human blastocyst at day 5 of development should exceed 60 cells and at least double its cell number on day 6.[16]

Blastocyst Evaluation by Inner Cell Mass Morphometry

Roundness Index

The roundness index (RI) is an important scoring parameter with regard to clinical outcome. It can be defined as the length-to-width proportion of the ICM.

It is categorized into three shapes:

1. Round
2. Oval
3. Slightly oval

When the RI is <1.04 (almost round) and >1.20 (oval), it showed lower implantation rates of 7 and 33%, respectively, in comparison with an implantation rate of 58% for RI between 1.04 and 1.20 (slightly oval). However, high implantation rates of 71% were observed with optimal ICM size and shape.[16]

A mislead in the apoptotic process and a disproportionately oversized ICM increase the distance for diffusion of nutrients and oxygen. This leads to unhealthy central cells increasing the risks of large offspring syndrome.[17]

Trophectoderm

The presence of numerous sickle-shaped cells forming a cohesive epithelium (grade A) in the outer layer of the trophectoderm is considered to be optimal **(Fig. 1)**.[18]

Lower implantation rates were prevalent in blastocysts with an impaired trophoblast (e.g., extremely flattened cells, no sickle-shaped cells, no junctions between trophectoderm cells, cells with granulation, pigmentation, and/or vacuolization).

MORPHOLOGY OF POOR-QUALITY BLASTOCYSTS

These groups of blastocysts exhibit low cell numbers and higher degree of chromosomal aberrations.[19]

Poor-quality blastocysts consist of various morphological subtypes, namely blastocysts with excessive fragmentation, vacuoles, necrotic cells, and trophoblast vesicles.

Trophoblast Vesicle

Trophoblast vesicles are characterized by the absence of the ICM[20,21] and a rather rudimentary trophectoderm. Thus, it is more or less a trophoblastic vesicle with a dominant blastocyst cavity. The cavity can also be a large vacuole **(Fig. 2)**.

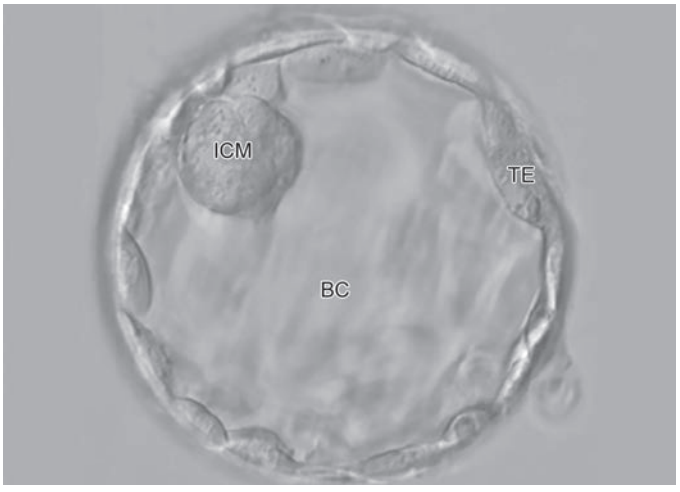

Fig. 1: Hatching blastocyst of optimal quality with the hatching site being at the 4 o'clock position.
(BC: blastocyst cavity; ICM: inner cell mass; TE: trophectoderm)

Necrotic Foci

Necrosis is the irreversible damage to cells, where the cells get distended and rupture their membrane, ultimately leading to cell death.

The assessment of the degenerative areas revealed that implantation rates were lower when ICM was affected (23% live births) and slightly higher when only the trophectoderm was affected (32.8% live births). Therefore, the compactness and the multicellularity of the ICM were more essential for implantation than the cohesiveness of the trophectoderm **(Fig. 3)**.[15]

Vacuoles

Vacuoles found within the blastocyst **(Figs. 4A and B)** tend to appear more in the trophectoderm than in the ICM. Vacuoles present in close proximity to ICM tend to have a more detrimental effect on the outcome. However, the restriction of these vacuoles to the trophectoderm yields better results.

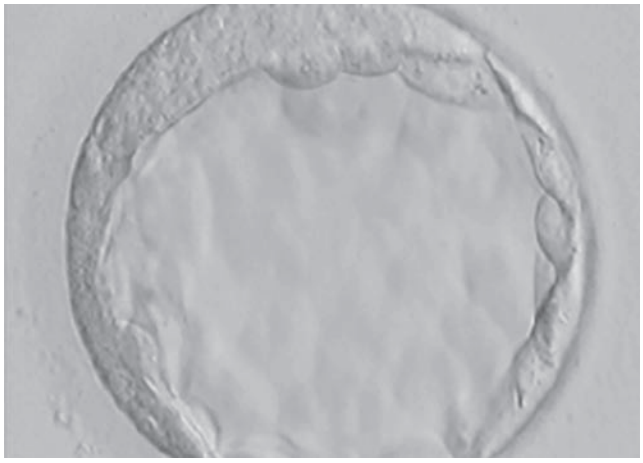

Fig. 2: Blastocyst with no visible inner cell mass (comparable to trophoblast vesicle).

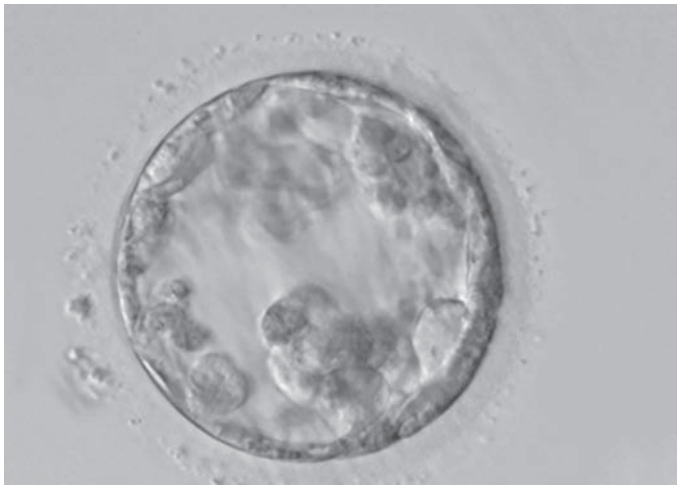

Fig. 3: Early blastocyst showing dark, degenerative changes.

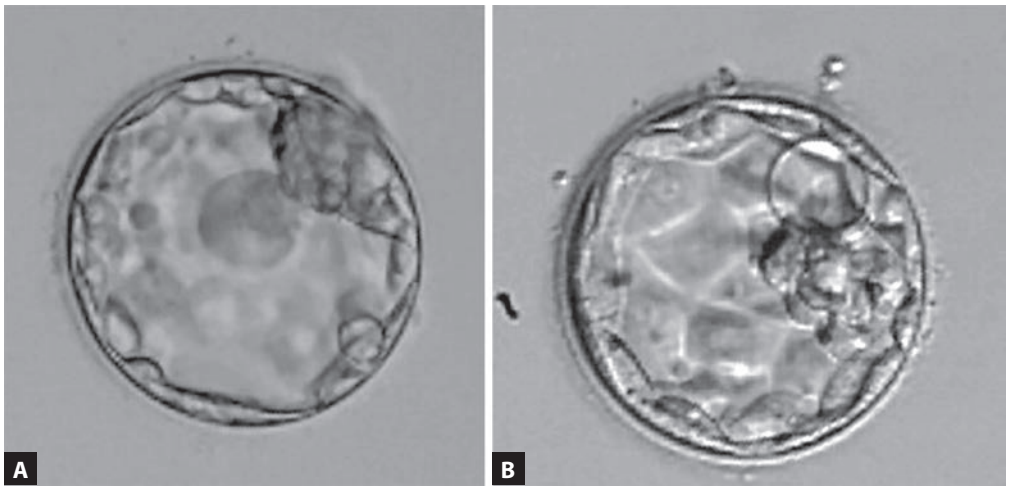
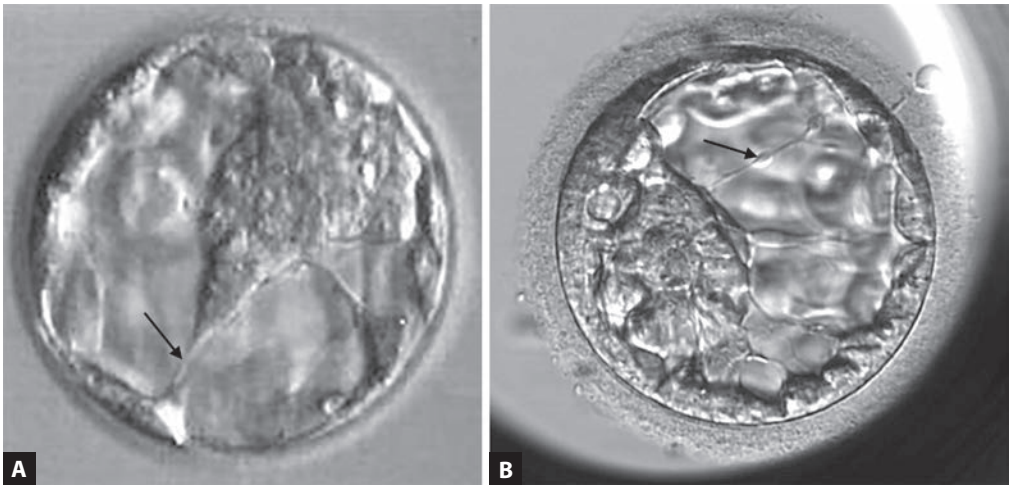


Figs. 4A and B: Blastocysts showing vacuole.



Figs. 5A and B: Blastocysts showing cytoplasmic strings (arrows).

Cytoplasmic Strings

Cytoplasmic strings are specialized projections that connect the cells of ICM and trophectoderm. The implantation behavior is affected by the presence of these cytoplasmic extensions that bridge the blastocyst cavity at the expansion stage or the later stages **(Figs. 5A and B)**.

They are commonly observed in nearly half of the junctional trophectoderm cells across the boundary between the polar and mural regions of trophectoderm and are directed at the blastocoelic surface of the ICM.[22] As these cytoplasmic extensions are linked to the polarized flow of cells from the polar to the mural trophectoderm, they tend to withdraw as the cells reach their destination. Strings vary in both shape (from broad triangles to string-like projections) and length (some fail to reach the ICM surface). Since early blastocysts are characterized by cytoplasmic extensions that cover the surface of the ICM, majority of the surface remains unaffected in the later stages of the blastocyst. Cytoplasmic strings were more likely to be found in fair and good quality blastocysts, and blastocysts with more cytoplasmic strings (>4) were associated with increased clinical pregnancies and live birth rates. However, when the cytoplasmic strings persist even in the expanded phase, they mark the developmental lability of the blastocysts, which possibly indicate polarization breakdown leading to diminished embryo quality and lower implantation rates.

EVALUATION OF ZYGOTES AND EMBRYOS AND THEIR POTENTIAL TO DEVELOP INTO BLASTOCYSTS

The improved implantation rate following blastocyst culture was not attributed to improvement in embryo quality by extended culture but to the selection process. Therefore, attempts were also made to develop grading systems whereby it may be possible to predict which of the zygotes and cleavage-stage embryos are capable of developing into blastocysts. Such systems would give the advantages of blastocyst culture without actually attempting it.

Zygotes were scored according to distribution and size of nucleoli within each nucleus. Zygotes displaying equality between the nuclei had 49.5% blastocyst formation, and those with unequal sizes, numbers, or distribution of nucleoli had 28% blastocyst formation.[23]

Fisch et al. attempted to culture 983 embryos up to the blastocyst stage.[24] When ranked by cell number and morphology alone, 34% of embryos with more than or equal to seven cells and <20% fragmentation formed good-quality blastocysts. This is corroborated by other investigators.[25] Stone et al. also analyzed the rate of blastocyst formation against the type of fragmentation 72 hours after insemination.[13] Embryos exhibiting no fragmentation or type I fragmentation had significantly higher blastocyst development rates (27.9 and 19.9%) than embryos with type 2 or 3 fragmentation. Vidaeff et al. reported that blastocysts developed when the embryos were at least eight cells on day 3.[1]

A reduction in the cytoplasmic volume of an embryo leads to a significant loss of cells in the blastocyst stage. This reduction in cytoplasmic volume is mainly caused due to cryoinjury or fragmentation. The embryos when subjected to cryopreservation drastically lowered the blastocyst cell numbers on day 6 in comparison to blastocysts obtained from fully intact cleavage-stage embryos post thawing. Fragmentation also had the same effect in lowering the cell number.[17] However, when the fragmentation was at minimal or moderate levels, ICM cell numbers remained the same, with reduced cell numbers limited to the trophectoderm.

FACTORS INFLUENCING BLASTOCYST DEVELOPMENT

The factors that influence the development of blastocyst in vitro are the age of the woman, number of oocytes retrieved, intrinsic factors, and culture conditions.[26] For example, Bedaiwy et al. analyzed the levels of reactive oxygen species (ROS) in the culture media and found that media associated with a low blastocyst rate had high levels of ROS in the media.[27]

- *Age of the woman:* The blastocyst developmental rate does get compromised in women over 40 years. It is just 22.2% in contrast to nearly 40% in younger women, and so pregnancy and implantation rates decrease in older women.[28]

  Shapiro et al. further analyzed the relationship between the age of the women and the blastocyst development and pregnancy rate.[29] The proportion of cycles with expandable blastocysts decreased with age although there was no difference with reference to fertilization rates. Pregnancy rates per stimulation cycle decreased, but the pregnancy rate per transfer was not related to age.
- *Embryonic development rate:* Jones et al. observed a significant positive correlation between the number of blastocysts formed and the number of oocytes, pronuclear zygotes, and eight-cell embryos formed on day 3.[30] There was a negative correlation with male factor infertility.
- *Culture conditions:* The culture conditions with reference to the volume of culture medium or the culturing of embryos in groups or individually did not influence the blastocyst formation rate.[31]

HATCHING PHENOMENON IN A BLASTOCYST

In vitro, the hatching process is supported by the increasing internal pressure due to the gradual accumulation of blastocoel fluid and cellular proliferation mainly originating from the trophectoderm. In vitro, the hatching process begins with the protrusion of small vesicles through the zona pellucida (ZP). However, this blebbing is not an indicator of the exact location of the subsequent hatching.[32] With the creation of this small opening, the herniation of the trophectoderm begins and creates a larger opening due to the mechanical forces governed by the trophectodermal projections.[33] Under the electron microscope, specialized cells known as "zona-breaker cells" lining both sides of the trophectoderm were observed at the hatching sites. Superficial microvilli and bundles of contractile tonofilaments allow these cells to interact with the ZP, somewhat acting like a sphincter.

The occurrence of blastocyst "breathing" provides an additional mechanical assistance by a series of rapid collapses and slow reexpansions to allow for its final extrusion from the ruptured ZP. The presence of secretory vesicles such as lysosomes indicates the involvement of biochemical processes, in addition to the mechanical forces. Hatching in close proximity to the ICM has the tendency to accelerate the contact among the trophectodermal cells that draw the blastocyst to the uterine wall and the endometrium. The presence of hernia opposite to the ICM may delay the interaction between the blastocyst and the uterus.

CRYOPRESERVATION OF BLASTOCYSTS

The improvement in implantation rates following blastocyst transfer results in supernumerary embryos requiring cryopreservation. Slow freezing as well as vitrification protocols have been successfully used to freeze blastocysts.

Stehlik et al. compared blastocyst freezing by slow freezing and vitrification.[34] 83% of the blastocysts survived thawing after slow freezing, while all the blastocysts survived thawing following vitrification. The pregnancy rate was only 16.7% following transfer of thawed embryos frozen slowly, in contrast to a pregnancy rate of 50%, i.e., 10 out of the 20 following transfer of thawed vitrified embryos.

The relatively poor pregnancy rates following frozen–thawed cleavage-stage embryos are due to two factors—the metabolic block of embryonic development in vitro due to maternal, paternal and the embryonic genomes as well as the culture conditions. The metabolic block is overcome in the blastocyst-stage embryos, so the number of embryos available for freezing may be lower, but the pregnancy rates following the transfer of thawed blastocysts are better.[35]

Optimal Time for Freezing Blastocysts

What is the right time to freeze blastocysts? Should they be frozen as soon as the cavity is formed or as advanced-stage blastocysts? Van den Abbeel froze blastocysts either at an early stage or at an advanced stage or hatching blastocysts.[36] Morphological survival post thawing was better for early blastocysts, while developmental potential of advanced-stage blastocysts was better.

Optimal Time for Transferring Thawed Blastocysts

Not all blastocysts that are frozen survive on thawing. Therefore, it becomes crucial to select the "right" thawed blastocyst for transfer. Most protocols incubate blastocysts for a few hours before transferring as that not only helps the selection process but also gives the blastocyst time to hydrate and adapt to environment. Guerif et al. compared the implantation rate after transferring blastocysts incubated for 4 or 20 hours after thawing and found that the implantation rates were better after a longer duration of incubation prior to transfer.[37]

ADVANTAGES AND APPLICATIONS OF BLASTOCYST CULTURE

Improved Pregnancy and Implantation Rates

Several studies suggest that embryo transfer at the blastocyst stage results in higher implantation rates compared to early cleavage-stage replacement on day 3.[38-40] In a retrospective analysis of 4,165 transfers, Pantos et al. also found improved pregnancy and implantation rates in blastocyst transfer as compared with day 2 transfer.[41] In a prospective, randomized trial of patients who responded well to ovulation induction, the implantation rate following blastocyst transfer was significantly higher (50.5%) than embryo replacement on day 3 (30.1%), although it should be noted that different culture systems were used for the two treatment groups.[38]

Barrenetexea et al. reported a 46% blastocyst formation rate and 23% implantation rate in patients in whom at least three previous cleavage-stage embryo transfers had failed to lead to a pregnancy, clearly suggesting that blastocyst transfer did have an advantage over cleavage-stage embryos in a certain group of patients.[42] Blastocyst transfer was found to be beneficial and led to pregnancies in patients in whom two previous cycles with day 2 or 3 transfer had failed.[43]

A recent Cochrane review of 12 randomized controlled trials that reported live birth following cleavage or blastocyst transfer was evidence of a significant difference in live birth rate per couple favoring blastocyst culture (days 2–3: 31%; days 5–6: 38.8%). This means that for clinics that use early cleavage-stage cycles, the rate of live births would increase from 32 to 42% if clinics used blastocyst transfer.[44]

Blastocyst Transfer—Decreased Risk of Multiple Gestations

As mentioned earlier, multiple pregnancies have become a serious concern following ART with reference to the obstetric complication and the health of the children born. The high implantation rates of blastocyst transfer, accompanied by the methods used for selecting the best embryo for transfer, make it possible to achieve a respectable ongoing pregnancy rate after the transfer of a single embryo with no dizygotic twinning.[45,46]

Preimplantation Genetic Diagnosis

The implantation rates and clinical pregnancy can be improved by the application of techniques like embryo biopsy and preimplantation genetic screening (PGS). These techniques can analyse the complete chromosomal status of the embryo. During a biopsy, a single cell at the cleavage stage or several trophectoderm cells are retrieved. However, PGS has limited applications due to technical issues and its effect on the long-term health of the off springs. Recently, the introduction of techniques like noninvasive methods of PGT (niPGT) can analyse the genomic DNA from embryo culture medium or blastocyst cavity fluid provides a less invasive alternative to embryo biopsy.[47]

Derivation of Human Embryonic Stem Cells

One of the most vital applications of blastocyst culture is the derivation of human embryonic stem (hES) cell lines from the ICM of the blastocyst. The potential benefits of hES cells are beyond the scope of this chapter as they may offer treatment of some chronic, untreatable diseases facing mankind.[48]

LIMITATIONS OF BLASTOCYST TRANSFER

Although blastocyst culture and transfer has many advantages, it has still not become a routine application in ART laboratories because of certain justifiable concerns. Blastocyst culture also imposes additional requirements in terms of personnel, equipment, and cost.

Poor Rate of Blastocyst Development In Vitro and Cancellation of Transfer

One of the major limitations of blastocyst transfer is that not all cleavage-stage embryos develop into blastocysts. Some

patients may not have any blastocysts available for transfer on day 5 despite having cleavage-stage embryos on day 3[38] leading to cancellation of transfer. The question that would then remain unanswered is whether that woman would have conceived with a day 3 transfer? A meta-analysis of 29 trials showed a significant number of cancellations of transfer when transfer was scheduled on day 5 because no blastocysts were formed.[49]

Monozygotic Twinning

Many studies have reported a higher incidence of monozygotic twinning following blastocyst transfer as compared to cleavage-stage transfer.[50,51] Peramo et al. were the first to report that the incidence of monozygotic twinning increased after blastocyst transfer.[52]

da Costa et al. reported that 3% of the pregnancies following blastocyst transfer were complicated by monozygotic twinning as compared with 0.7% after four- to eight-cell stage embryo transfer,[53] while 0.42% of natural pregnancies result in monozygotic twinning (Bulmer, 1970). The obstetric outcome of these pregnancies was poor.[54] It was thought that this incidence is higher in embryos developed after intracytoplasmic sperm injection (ICSI) or assisted hatching possibly because the drilling may have caused premature herniation of the blastocyst. But Sills et al. did not find a difference in monozygotic twinning rate between manipulated embryos such as those with ICSI or assisted hatching as compared with those obtained after conventional IVF.[55] The increased incidence of monozygotic twinning is clearly a result of blastocyst culture and transfer and has been corroborated by many more studies. Milki et al. showed that the incidence of monozygotic twinning was 5.6% with day 5 (blastocyst) transfer as compared with 2% with day 3 (cleavage-stage embryo) transfer.[56] The incidence was identical in ICSI and non-ICSI groups. A recent retrospective analysis of 14,956 clinical pregnancies from single blastocyst transfer indicated a 1% monozygotic twinning with an odds ratio (OR) of 2.0 irrespective of zona drilling, ICSI, or type of stimulation used.[57]

While monozygotic twinning need not be considered as a major disadvantage of blastocyst culture, it is important to take this phenomenon into account while deciding on the number of blastocysts to be transferred as well as appropriately counsel the patients. As of now, the mechanism by which the incidence of monozygotic twinning increases following blastocyst transfer is unclear.

Failure of Blastocyst Development and No Embryos Available for Transfer

There are several reasons that prevent an embryo from developing into a blastocyst like reduced metabolic activity. This results in the slow embryo development which eventually leads to its degeneration. Embryo development can be affected at any stage of its development. The failure in the process of embryo development is multifactorial which includes chromosomal errors, cell division errors and mitochondrial function.

Molecular failures can occur which can increase the chances of the onset of imprinting disorders in the offspring like large offspring syndrome.[58]

Large Offspring Syndrome

In vitro culture of embryos for 5–7 days in vitro has been associated with large offspring syndrome in certain animal species. This has been attributed to the suboptimal embryo culture conditions. This syndrome manifests as abnormal growth and development at fetal, neonatal, and later stages of life.[59] It has been shown that extended culture of embryos to the blastocyst stage can compromise many aspects of development including metabolism,[60] differentiation,[61] gene expression,[62] imprinting,[63] and subsequent fetal development after embryo transfer[64] in several mammalian species.

Menezo et al. did not find any difference in the birth weights of babies born after spontaneous conception and blastocyst transfer.[65] Although several healthy babies have been born following the transfer of blastocysts, there has been a concern that the birth of healthy babies does not preclude the possibility of long-term effects. Continued research and follow-up of the children conceived after transfer of blastocysts cultured in vitro is recommended.

Obstetric and Perinatal Outcomes

Fernando et al. studied the obstetric and perinatal outcomes in women who underwent day 2 or 3 and day 5 or 6 transfer. Multivariate analysis found no statistically significant difference between transfers on days 5 and 6 and days 2 and 4 for all maternal and perinatal outcomes.[66] However, Kalra et al. studied 69,039 live births following either cleavage-stage transfer or blastocyst transfer. Singleton IVF births conceived after blastocyst transfer, as compared with cleavage-stage transfer, were at an increased risk for preterm delivery (18.6% compared with 14.4%, respectively; adjusted OR 1.39, $p < 0.001$) and very preterm delivery (2.8% compared with 2.2%, respectively; adjusted OR 1.35, $p < 0.001$) but not low birth weight.[67]

KEY POINTS

- Blastocyst culture, although a little time consuming and has inherent limitations, is an important step ahead in the field of ARTs. However, before it can be routinely applied in an ART laboratory, it is essential that the laboratory first has the requisite infrastructure, maintenance, and skills.

- Although the pregnancy rate per blastocyst transfer is higher than pregnancy rates following cleavage-stage transfer, if one were to look at the cumulative pregnancy rate per cycle started or per patient, then the results are not that dramatic. The number of embryos that grow to blastocysts and are available for transfer or cryopreservation is much lesser. Till the concerns about the potential epigenetic changes that extended culture could lead to,[68] one should use extended culture to blastocyst only when there are multiple cleavage-stage embryos available for transfer so that those that do not develop to the blastocyst get deselected. As of now, its routine application for ART in all cases does not seem justified.
- Further studies are still required to have an optimal understanding of the metabolism of embryos and nutritional requirements. In the luminal secretions, the embryo is exposed to a variety of growth factors and cytokines[69] that are not routinely added to culture media. Growth factors are known to have pleiotropic effects on embryo development including blastocyst formation and hatching,[70] and it needs to be seen whether the addition of these would further improve the development of *blastocysts* in vitro.

CHAPTER 109

Cryopreservation of Oocytes

Goral Gandhi

INTRODUCTION

Cryopreservation of human cells is an integral part of assisted reproductive technology (ART). Unlike the human sperms and preimplantation embryos, it has been extremely difficult to cryopreserve the metaphase II (MII) oocyte. Even though the ability to store oocytes successfully at –196°C has numerous practical and financial advantages, together with ethical considerations, surprisingly, there was not much interest in cryopreserving oocytes. Chen reported the first human birth using cryopreserved oocytes as early as in 1986.[1] However, the failure to reproduce this early success became a major setback. The possibility of oocyte cryopreservation becoming a routine technique seemed unlikely for many years.

For a long time, oocyte cryopreservation was considered as an experimental procedure at best. A significant resurgence of interest in the human egg freezing came about in recent times owing to its perceived potential to preserve fertility. Vitrification was applied to oocyte cryopreservation techniques, which produced more consistent and reproducible results. Kuleshova et al. reported the first birth from vitrified human oocytes.[2] Various studies followed, which showed the superiority of vitrification over slow freezing in the postthaw survival of vitrified oocytes.[3,4] Vitrification was proposed as an alternative to conventional slow freezing methods. Recent advances in cryobiology have led to a newer option or protocols available for the oocyte cryopreservation in terms of technique used, media composition, and various storage devices used for vitrification. This has resulted in an improved survival of cryopreserved oocytes.

In fact, the results after oocyte vitrification have been extremely promising. As a result, a 2011 guideline from the Practice Committees of the American Society for Reproductive Medicine (ASRM) and the Society for Assisted Reproductive Technology (SART) indicated that mature oocyte vitrification and warming should no longer be considered as an experimental procedure[5] because this technology is recommended in cases of gonadotoxic therapies when there is a lack of alternative options for fertility preservation.

These guidelines have resulted in the vitrification of oocytes being offered as an option for women who wish to preserve their fertility to allow them to have a possibility of having their own genetic offspring in the future. Cancer patients as well as patients with other diseases who need to undergo potentially gonadotoxic treatments benefit from this. Another population to benefit from oocyte freezing is women who wish to postpone childbearing for a variety of "nonmedical" reasons. This form of egg freezing is popularly known as "social egg freezing."

INDICATIONS FOR OOCYTE FREEZING

- Loss of reproductive function due to chemotherapy, radiation, and/or surgery for cancer
- Premature menopause and ovarian failure
- Overcoming ethical and legal issues involved in embryo freezing
- Oocytes cryobanking for facilitation of egg donation program
- To prevent age-related infertility and options for delaying motherhood
- Prevention of ovarian hyperstimulation syndrome
- Male factor infertility or inadequate seminal samples
- Poor egg quality due to endometriosis
- Immunological disorders

HURDLES ASSOCIATED WITH OOCYTE CRYOPRESERVATION

In spite of so many reasons to freeze oocytes, it took scientists many years to successfully preserve oocytes. The reason was the extreme cryosensitive nature of the human oocyte. Oocyte cryopreservation is technically more challenging than embryo cryopreservation. Differences in membrane permeability and in physiology are two main reasons why successful oocyte cryopreservation had remained elusive

and also explain why it has taken so long to introduce oocyte cryopreservation even though the first embryo was cryopreserved as early as 1978.

FACTORS AFFECTING OOCYTE SURVIVAL

- *Spherical shape and surface area:* Oocytes are extremely difficult to cryopreserve because of their low surface area to volume ratio and high susceptibility to intracellular ice formation. Perfect sphere of the oocyte slows down permeation and equal distribution of cryoprotectant in the oocyte. This continuous concentration gradient results in a longer exposure of the oocyte to cryoprotectants, which may lead to toxic damage in one part of the oocyte offering less than optimal protection in other.[6]
- *Size:* Size is a very important parameter in cryobiology. Larger the cell, more difficult to cryopreserve it. Oocytes are the largest cell of the human body. Size of the oocyte widely affects crystal formation and the slow dilution or accumulation of toxic cryoprotectants, thus increasing the challenge of survival.
- *Monocellular nature:* Since oocyte is a single-cell structure, there is no backup to regenerate from serious injuries as compared to multicellular embryo, which can survive up to 50% loss of its cells.[6]
- *Physiology of the membrane:* It is very difficult to predict the membrane permeability characteristics of human oocytes along with other biophysical parameters.[7] Studies have also revealed the negative effects of cryopreservation on the stability of microtubules and microfilaments in mammalian oocytes, which are vital for normal chromosomal segregation.[8]
- *Cryoinjuries*: The oocyte is highly susceptible to the cryoinjuries to the cytoplasmic content and the nuclear spindle.[9] Chilling injury occurs at high temperature and induces irreversible damage to the cytosolic content, membrane, and zona pellucida. Hardening of the zona due to premature cortical granule release may result in the decreased fertilization rate. Therefore, a very careful approach has to be applied for oocyte freezing. There is an increase in the intracellular calcium concentration following cryopreservation. This can cause cortical granule release, zona pellucida hardening, and parthenogenic activation of the oocyte.[10-12]

Due to these varied difficulties associated with oocyte vitrification, for many years, oocyte vitrification was considered experimental, and therefore, embryo cryopreservation was the only established option for fertility preservation in female cancer patients.[13]

However, with the advent of vitrification, everything changed. The optimization and widespread use of vitrification methods for human oocytes in laboratories worldwide have been one of the major advancements in the field of ART. The traditional slow freezing methods of cryopreservation also underwent improvements in the last decade, but the real game-changer in the field of cryopreservation has been vitrification.

VITRIFICATION

Vitrification is a process of cryopreservation which involves exposure of oocyte to high concentration of cryoprotectants and ultra-rapid cooling to solidify the cell into glass-like state without the formation of ice crystals. There are five principal steps in vitrification:

1. Add cryoprotectants.
2. Cool the cells to –196°C.
3. Store at –196°C.
4. Warm the cells.
5. Remove cryoprotectants.

There are many factors that impact successful vitrification during these five steps.

Cryoprotectants

Vitrification dramatically increased the survival rates of the oocytes. However, one of the major concerns surrounding vitrification is the high concentration of cryoprotectants that are used in vitrification solutions.

There are mainly two types of cryoprotectants. The penetrating cryoprotectants, as the name suggests, penetrate the cell membrane. They protect the cells and tissues by replacing some of the water they contain, thus increasing the viscosity in the cells, preventing the formation of ice crystals, and making the vitrification process easier by inducing the transition to the glass state. The commonly used penetrating cryoprotectants are ethylene glycol (EG), dimethyl sulfoxide (DMSO), and propylene glycol [1,2-propanediol (PrOH)]. The nonpenetrating cryoprotectants protect the cells from the outside. They guard against osmotic damage, especially during the warming procedures. During the warming process, the transfer of the oocytes from a solution containing a high concentration of cryoprotectant to an isotonic solution can lead to a reverse osmotic shock and swelling of the oocyte. This may be dangerous for the oocyte. Use of a hypertonic solution containing nonpenetrating cryoprotectants can prevent this osmotic shock by slowing down the movement of water across the membrane.[14] The typically used nonpenetrating cryoprotectants are sucrose and trehalose. Protein in the vitrification solution helps due to its surfactant characteristics.

During the first phase of research and development of vitrification, efforts were focused on decreasing the toxic and osmotic effects of cryoprotectants. The double or triple amount of cryoprotectants required for vitrification compared to traditional freezing was a big concern.

To decrease the specific toxicity, mixtures of two or three cryoprotectants were applied. At least one of these

compounds was permeable. With two cryoprotectants, the concentration of each can be lower than that needed when either is used separately, thereby making the solution less toxic.

Freezing Rate

A high freezing rate is crucial to achieving proper vitrification and survival. This can be achieved via direct contact between the sample and liquid nitrogen or indirect contact if the sample is contained in a closed carrier.

Decreasing the temperature of the liquid nitrogen can also increase the freezing rate. This way, the freezing rate can increase in two ways. More rapid heat transfer is achieved by a wider temperature difference and it may also minimize the chances of the formation of gas bubbles that can insulate the heat transfer.

The liquid nitrogen temperature can be decreased in two ways: (1) By applying a vacuum over the liquid nitrogen, or (2) By the use of liquid nitrogen slush.[14-16]

In order to achieve the maximal freezing rates, current vitrification loading devices hold a minimal volume of solution, such as the EM grid, CryoLoop™, CryoTip™, CryoTec, CryoTeb, CryoTop, and Cryoleaf™ high security straws. Currently, the most acceptable target in designing vitrification loading devices for oocytes or embryos is to use a small volume (<1 μL) of high-concentration cryoprotectant (approximately 30%) and very rapid freezing rates of 15,000–30,000°C/min.[17]

Warming Rate

The cells are more sensitive to the warming rate compared to the cooling rate during vitrification. It has been suggested that slow warming is lethal for the cells since it allows the growth of tiny ice crystals by recrystallization.

To achieve high-warming rates, it is essential that minimum volumes are used during vitrification. Mixing the cells in pre-warmed media will aid in achieving high-warming rates.

In open system vitrification, very high-warming rates can be achieved by mixing the sample in the thawing solution that is warmed to 37°C **(Fig. 1)**.

Loading of the Carrier

Choose a carrier that facilitates rapid heat transfer. Choose a system that is easy for the embryologist. This will ensure reproducibility of consistently high survival rates **(Fig. 2)**.

Open versus Closed System Vitrification

There are two types of vitrification methods. In one method, the cells come into direct contact with liquid nitrogen. This is called "open system vitrification." There has been much concern about the risk of disease transmission through the use of this method. As a result, another method was developed, where the cells do not come in direct contact with liquid nitrogen. The carrier is closed before plunging into liquid nitrogen. This is known as "closed system vitrification." The cooling rate achieved with the closed system is, however, reported to be much lower than those achieved with open system.

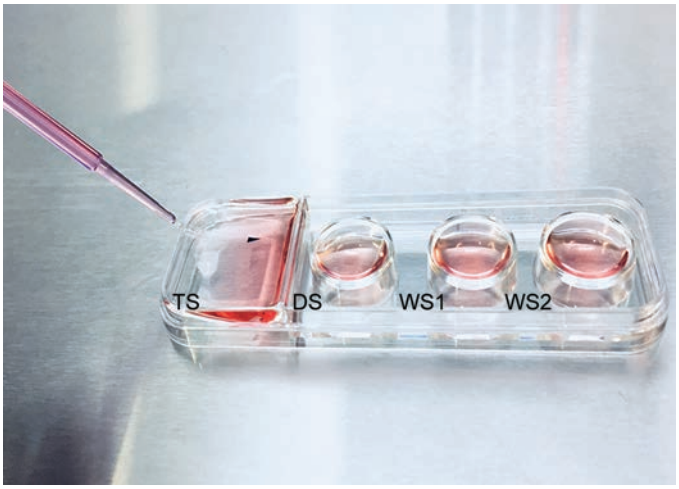

Fig. 1: Warming plate by Cryotech Japan which has a warm well included in the plate to facilitate rapid warming rates. (DS: diluent solution; TS: thawing solution; WS: washing solution)

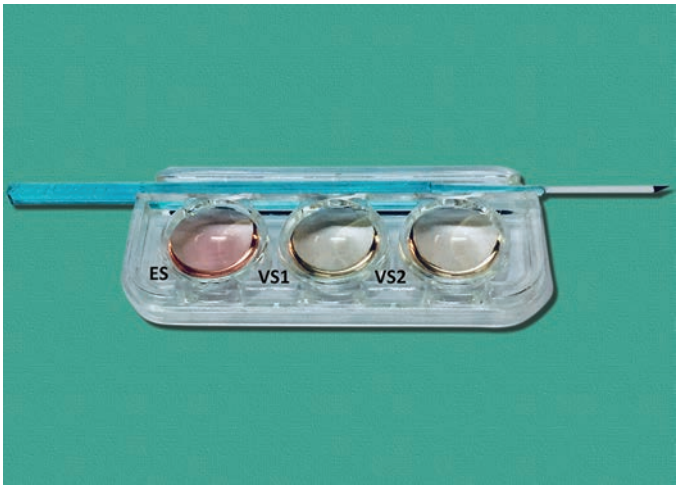

Fig. 2: Vitriplate by Cryotech Japan with a holder for the Cryotech. Loading becomes very efficient due to the special plates. (ES: equilibration solution; VS: vitrification solution)

Effectiveness of Open and Closed Systems

A review of the literature shows that the best survival rates reported for oocytes using closed system vitrification are between 70 and 85%[18] whereas a survival rate of 98–100% for oocytes is reported by many workers using the open system.[19] Hence, clearly for oocytes, open system vitrification seems to be working much more effectively than closed system vitrification.

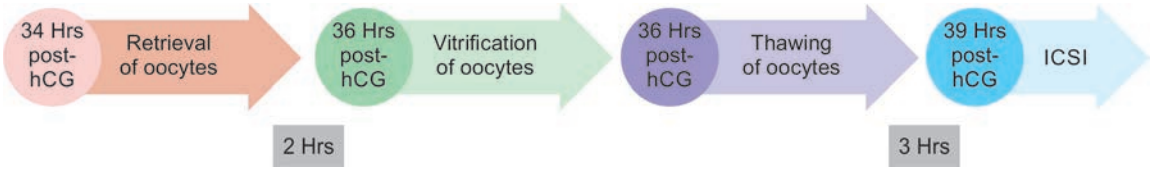

Fig. 3: Time schedule to be observed for oocyte vitrification and warming.
(hCG: human chorionic gonadotropin; ICSI: intracytoplasmic sperm injection)

Risk of Disease Transmission

The main concern against the use of open systems is the risk of disease transmission. However, no such disease transfer has yet been reported, although estimated 600,000–1,000,000 vitrified embryos or embryos derived from vitrified oocytes by using open systems have been transferred. So, is this risk applicable to real-life situations?[20]

Vajta et al. have compared the open and closed systems of vitrification and have noted that overwhelming evidence shows that open systems are efficient for both blastocyst and oocyte vitrification; relevant data on closed systems, however, are sporadic, especially in the case of human oocytes, and far from convincing. The authors recommended that a pragmatic approach in legislation and scientific evaluation should be used. They advised to consider the facts instead of theories and acknowledge the value of methods that are used in a huge number of cases.

There are ways of preventing contamination during storage that can be adopted:

- Proper sealing of carriers containing oocytes is an effective measure against contamination during storage.
- An alternative preventive step is filtration of liquid nitrogen and the application of accessory protective storage containers.
- Cross contamination may be prevented by storing oocytes/embryos from patients with known infections in separate liquid nitrogen tanks.

DYNAMICS OF MEIOTIC SPINDLES OF FROZEN-THAWED OOCYTES

The spindle is very sensitive to cryoprotectants and low temperature. Oocytes analyzed immediately after thawing displayed severe disorganization or disappearance of spindles. This disappearance of the meiotic spindle is one of the most significant changes caused by oocyte cryopreservation. The meiotic spindles are crucial for the events following fertilization at completion of meiosis, the second polar body (PB) formation, and migration of the pronuclei. Incubation for 1–3 hours resulted in recovery of spindles.[21-23] Even though spindle abnormalities in cryopreserved oocytes were originally of concern, the incidence of chromosomal abnormalities in human embryos derived from cryopreserved oocytes is not statistically different from that of control embryos.[8,24]

TIME SCHEDULE FOR VITRIFICATION OF OOCYTES AND FERTILIZATION

The optimum time for intracytoplasmic sperm injection (ICSI) for human oocytes is between 37 and 41 hours posthuman chorionic gonadotropin (hCG).

We know that inseminating oocytes soon after thawing, when there is serious spindle disorganization, adversely affects fertilization outcome.[1]

Choosing the optimum time interval between oocyte thawing and ICSI is crucial for normal fertilization and subsequent development.

Oocyte recovery can be performed at 34 hours post-hCG, vitrification of oocytes being performed at 2 hours after oocyte recovery, and ICSI being performed at 3 hours postthaw (post-hCG 39 hours) **(Fig. 3)**.

SAFETY OF VITRIFICATION

There have been many concerns regarding the safety of vitrification and the metabolomics, proteomics, and epigenetic risks involved with vitrification.

A study on the metabolomics profile of embryos developed from fresh and vitrified oocytes has suggested that the embryonic metabolomics profile is not disturbed by oocyte vitrification.[25] The influence of vitrification on the oocyte proteome of in vitro grown germinal vesicle (GV) as well as MII oocytes was assessed in a study on mouse oocytes. Transient changes in mitochondrial activity by vitrification occur at the preantral stage, but proteome of in vitro grown and matured oocyte is not affected.[26] Oocyte proteome and developmental potential may get affected[27] because of changes in cellular integrity and protein alterations with the use of high concentration of cryoprotectant in an animal model.[28,29]

In a study where messenger ribonucleic acid (mRNA) contents in MII oocytes after slow freezing/rapid thawing and vitrification/warming protocols were compared with the fresh MII oocytes, it was found that mRNA abundance may decrease in both types of cryopreservation methods which may result in molecular injury. However, the mRNA content level in vitrified oocyte remains sufficient to sustain biological function.[30]

Recovery of the meiotic spindle occurs after cryopreservation in both conventional and vitrification technology.[31-33] Thus, it is suggested that there are no

increased risks of disturbances in spindle formation or chromosome segregation with vitrification of oocytes.[34] Studies have shown that oocyte vitrification does not increase the rate of aneuploidy or diminish the implantation potential of viable blastocysts.[35]

In a study conducted to check the neonatal outcomes of babies born using vitrified oocytes, a total of 58 reports were reviewed from 1996 to 2008. Of the total 936 newborn, 1.3% had birth anomalies. No difference was noted in the birth defect rates when compared with naturally conceived babies.[36] A similar study has revealed no difference in birth weight or congenital anomalies among those born from vitrified oocytes as compared to children conceived after fresh in vitro fertilization (IVF).[35,37] A successful live birth has been reported from vitrified oocytes after 5 years of cryopreservation.[38] These findings suggest that there are no reported increase in miscarriages, chromosome abnormalities, and birth defect in the infants born from vitrified oocytes. With many recent studies now reporting similar findings, vitrification procedures have certainly become mainstream and led to an increase in our confidence in oocyte vitrification.

OUR RESULTS WITH OOCYTE VITRIFICATION

The oocytes were subjected to vitrification by using the Cryotech vitrification method (Repro-Support Medical Research Centre, Co. Ltd., 2-5-5-8F Shinjuku, Tokyo, Japan).

A retrospective analysis was done to study the outcome of oocyte vitrification using the Cryotech method. We compared the outcome of fresh versus frozen oocytes in the oocyte donation program. The data was evaluated over a period from January 2015 to December 2016. A total of 2,095 oocytes were obtained from 174 oocyte donors. The study included 1,676 mature oocytes. From this, 792 eggs were used in fresh cycles and 884 oocytes were vitrified using the Cryotech method. The oocytes were later warmed using the Cryotech warming solutions, fertilized by ICSI, and the embryos thus created were transferred into the recipients. A total of 171 embryo transfer cycles were performed on day 3 of embryo development. The parameters which were assessed and compared between the two groups included survival rate, fertilization rate, cleavage rate, embryo development, and the clinical pregnancy rates.

OUR EXPERIENCE WITH OOCYTE VITRIFICATION

A comparative study to evaluate the outcome of oocyte vitrification using the Cryotech method, observed in an egg donation program with fresh versus frozen oocyte, was done. The data was evaluated over a period from January 2011 to December 2011. A total of 1,210 oocytes were obtained from 112 oocyte donors. The analysis included a total of 1,029 mature oocytes, 485 oocytes were used in fresh cycle, and the remaining 544 oocytes were vitrified using the Cryotech method. The vitrified oocytes were subsequently warmed using the Cryotech warming method. The warmed oocytes were fertilized by ICSI and the embryos thus created were transferred into the recipients. A total of 209 embryo transfers were performed on day 3 of the embryo development. The laboratory and clinical parameters of both the groups were compared **(Tables 1 and 2)**.

TABLE 1: Comparative data showing survival, fertilization, and cleavage rates between fresh and frozen–thawed human oocytes.

	Fresh oocytes	*Frozen-thawed oocytes*	*p-value*
Number of oocytes	792	884	
Survival rate (%)	NA	98.8	
Fertilization rate (%)	85.0	83.8	NS
Cleavage rate (%)	98.2	98.6	NS

(NA: not applicable; NS: not significant)

TABLE 2: Clinical outcomes of fresh and frozen-thawed human oocytes.

	Fresh oocytes	*Frozen-thawed oocytes*	*p-value*
Number of cycles	99	110	NS
Pregnancy rate	76 (76.76%)	84 (76.36%)	NS
Biochemical pregnancy rate	5 (5.05%)	6 (5.45%)	NS
Missed abortion rate	6 (6.06%)	7 (6.36%)	NS
Live birth rate	64 (64.65%)	71 (64.55%)	NS

(NS: not significant)

Our results with oocyte vitrification are extremely encouraging. It has proved that the current vitrification protocols are extremely efficient and effective in cryopreserving oocytes. Excellent clinical outcome indicates that this technology can be applied successfully for cryopreserving oocytes for various indications including preserving fertility for cancer patients, building donor oocyte banks, and preserving female fertility for age-related reasons.

IMMATURE OOCYTES

Oocyte cryopreservation is associated with many factors, such as different human oocyte sources including in vivo mature, in vitro mature, and immature oocytes. There are reports about babies born using vitrified oocytes of the three types.

However, studies have shown that in vivo and in vitro mature human oocytes are more suitable to vitrification than immature human oocytes.[39]

POOR MORPHOLOGY OOCYTES

It is well known that the majority of the oocytes retrieved from stimulated cycles (60–70%) exhibit one or more abnormal morphological characteristics.[40]

The presence of large PB, large perivitelline space (PVS), refractile bodies, or vacuoles is associated with decreased oocyte fertilization. It is generally hypothesized that morphologically abnormal oocytes could be more affected by the vitrification procedure than normal oocytes. Embryologists tend to expect a negative influence of oocyte morphological abnormalities on survival rates postvitrification and ICSI outcomes. However, studies have shown that oocyte morphology, observed prior to vitrification, does not predict postwarming survival.[41,42] The noninvasive identification of predictive markers for oocyte survival potential remains a difficult task. Hence, it would not be wise to omit poor morphology oocytes from vitrification, especially for autologous cases of oocyte cryopreservation.

KEY POINTS

- Very efficient protocols for oocyte vitrification are now available. It is our duty as reproductive scientists to use these protocols efficiently and preserve precious human life till the patient's dream of becoming parents comes true.
- Vitrification is highly skill dependent, and close adherence to the prescribed protocol is absolutely essential for excellent results.
- As per the current technology available, open system vitrification is more efficient for oocyte vitrification than close system vitrification.
- It is advised to vitrify the oocytes within 2 hours of retrieval and to wait for 3 hours after warming before fertilizing them. This will take care of meiotic spindle recovery as well as avoid oocyte aging.
- Oocyte vitrification does not increase the rate of aneuploidy or decrease the implantation potential of the embryos. This makes oocyte vitrification a very valuable tool for young women wanting to preserve their fertility for either medical or age-related reasons.

CHAPTER 110

Embryo Cryopreservation

Nitin Laxmikant Lad, Mir Jaffar

INTRODUCTION

The history of cryopreservation dates back to as long as 2000 BCE where the Mesopotamians used ice houses to store food. The magical use of "cold" temperatures soon became a "hot" topic of interest for many. Reproductive biologists too, left no opportunity to explore the use of ultra-cool temperatures for storage of gametes and embryos. Since its inception in the 1980s, embryo cryopreservation has thereafter seen a profound expansion in its routine clinical use. A report from the US Center for Disease Control and Prevention has stated that the proportion of frozen embryo transfers has risen from 20% in 2005 to almost 50% in 2014.[1,2] Initially, embryo freezing was restricted to patients with medical indications, because back then in vitro fertilization (IVF) was carried out in natural menstrual cycles. So, only one oocyte used to be available, the embryo of which, would immediately be transferred in the same cycle. Advancements in ovarian stimulation, tailored treatments and efficient cryopreservation have expanded the demand for embryo freezing. Some nonelective and elective reasons for embryo freezing include: (1) *Fertility preservation:* embryo freezing allows cancer patients to freeze healthy embryos in order to negate the ill effects of radiation or chemotherapy; (2) *OHSS:* embryo freezing allows time for ovarian recovery in patients prone to OHSS and its related complications; (3) *Elevated progesterone:* high levels of progesterone have a detrimental effect on the implantation rates, thus, embryo freezing allows the privilege to transfer at a suitable time; (4) *Preimplantation genetic testing (PGT) screening:* embryo freezing allows time for patients to select a suitable euploid embryo to be identified for transfer; (5) *Patients or physicians choice:* freezing allows a chance to reduce the risk of multiple pregnancies and need for repeated stimulation cycles; (6) *Personal reasons:* embryo freezing allows couple to conceive at their time-of-choice without compromising on age-related side effects.[2-6] Although cryotechnology has come a long way and made substantial advancements there is still scope for improvement. Great scientific efforts are being made to discover more logical, ethical and economical procedures in order to ensure utmost success without compromising on the safety of these cryoprocedures.

Mammals, being homoeothermic, are not capable of surviving cold temperatures or tolerating freeze injuries unlike some poikilothermic animals that can easily tolerate freezing temperatures. Cryoinjury is the root cause of cell death at low temperatures. When temperatures go below 0°C, the aqueous fluids of the cell supercool to form ice crystals. Ice crystals pose a threat as they mechanically tear into the organelles or at times also rupture the entire cell. Secondly, low temperatures send the cell into an osmotic stress thereby creating a concentrated environment within the cell, eventually leading to cell death. To survive low temperatures, the cell first needs to be sufficiently dehydrated in order to minimize the formation of ice crystals. This can be easily achieved with the use of cryoprotective agents (CPAS).

CRYOPROTECTIVE AGENTS

Spermatozoa were the most popular cells used by cryobiologists to test the protective ability of different compounds. Since sperms are motile cells, their motility gave direct indications of their viability. All this could be observed simply using a light microscope without having to use any fancy apparatus. Such was the advantage of using sperm cells. This came as a natural advantage to reproductive biologists since most of the cryoresearchers used spermatozoa as their study model. In the 1940s, it became clear that certain sugar solutions give more cellular protection at low temperatures than others. Glycerol is one of the most commonly used cryoprotectants; but how it was discovered, is a story of serendipity. Cryobiologist, Sir Alan Parkes and his student Chris Polge were testing the efficiency of fructose solutions in protecting spermatozoa. They were testing different concentrations of fructose solutions, but to their nightmare after every warming cycle they saw non-motile, dead spermatozoa. One fine day, surprisingly, they saw almost all the thawed spermatozoa were happily

motile. This accidental success was because two of the stock bottles in the refrigerator had lost their labels and they had mistakenly used glycerol instead of fructose. From there on began the quest for finding a good CPA.

Cryoprotective agents cause lowering of freezing point of solution, displace water from the intracellular to extracellular environment and alter the solute concentration in the liquid phase. Extracellular CPA increases the extracellular osmolarity, thereby generating an osmotic gradient across the cell. This facilitates dehydration of the cell. During warming, CPA also prevents the rapid entry of water into the cell during the process of rehydration.[6-9] Thus a good CPA must be of a small size with low molecular weight, should easily penetrate cell membrane at high concentrations, should be highly water soluble and should "ideally" be non-toxic.[10] Based upon the nature of the CPA, they are divided into two groups—(1) permeating CPAs and (2) non-permeating CPAs.

Permeating Cryoprotective Agents

As the name suggests, permeating CPAs are small molecules that readily permeate into the cell membrane. They form hydrogen bonds with water molecules to prevent ice crystallization.[9] To create a higher osmotic gradient, highly concentrated solution of CPAs needs to be used. Since these CPAs enter the cell, higher the concentration of CPA, higher will be the risk of cytotoxicity. In order to minimize the risk of cytotoxicity, scientists came up with the idea of combining two CPAs. For example, ethylene glycol has a low molecular weight and high permeability, therefore it is widely used. But when used by itself, it needs to be used in a very high concentration of about ≥5.5 M. So, it is usually combined with dimethyl sulfoxide (DMSO) in 1:1 ratio, thereby reducing the concentration of either of them by half, without compromising on the effective CPA working concentration. Some commonly used permeating CPAs are:

- Glycerol
- Ethylene glycol (EG)
- Dimethyl sulfoxide (DMSO)
- 1,2-propanediol (PrOH).

Non-permeating Cryoprotective Agents

In contrast to permeating CPAs, non-permeating CPAs work extracellularly. They draw out intracellular water by creating an osmotic imbalance. They are usually used in combination with permeating CPAs, so that the dual action of extra- and intracellular CPAs dehydrates the cell more efficiently during freezing. Non-permeating CPAs also play a crucial role in the process of warming. During warming, the intracellular ice melts quickly thereby increasing the risk of osmotic swelling of the cell. It is very necessary that the intracellular cryoprotectants (used during freezing) are diffused out of the cell quickly to avoid swelling and rupture of the cell. Nonpermeating CPAs, during warming, prevent excessive influx of free water and draw out permeating CPAs quickly.

Some commonly used non-permeating CPAs are:

- Sugars such as sucrose, trehalose, galactose, mannose
- Polymers such as polyvinylpyrrolidone (PVP), polyethylene glycol (PEG), polyvinyl alcohol (PVA), ficoll and dextran
- Hydroxypropyl cellulose (HPC), human serum albumin (HSA), serum substitute supplement (SSS), dextran serum substitute (DSS).

Safety and Cytotoxicity of Cryoprotective Agents

Even though most of the permeating CPAs are natural metabolites, they are used in super-physiological concentrations. Thus, the fact that there certainly will be some cytotoxic effects is inevitable. However, the mechanism and the extent to which CPAs negatively affect embryo preservation remains a topic of interest. Studies have shown that temperature fluctuations and exposure to CPAs independently lead to disruption/disorientation of the cytoskeleton such as the microfilaments or the meiotic microtubule assembly, therefore potentially creating a risk of chromosomal abnormalities.[11-13] In fact, higher incidences of chromosomal abnormalities were reported after oocyte cryopreservation. CPA toxicity studies done in thawed oocytes revealed that there is an increased likelihood of oocytes to undergo parthenogenetic activation as a result of various physical and chemical stimuli used during the process.[14-16] Certain studies indicated CPA toxicity to be related to the hydrophobic interactions between CPAs and proteins and the extent of hydrogen binding between CPA molecules and water. It has also been shown that CPAs change the intracellular pH, cause intracellular Ca^{2+} release and formaldehyde formation in the cryopreservation medium.[17-19] Scientists are also trying to figure out whether the toxicity of CPA arises from the wide changes in osmolarity induced due to CPAs or the actual exposure of cells to chemical CPAs. Nonetheless, valuable efforts are being made to mitigate the cytotoxic effects of CPAs.

Tips for Minimizing the Toxicity of Cryoprotective Agents

While it is impossible to entirely eliminate the toxicity and osmotic injuries posed by CPAs on the embryos, the following can minimize its negative effects.

- Use highly permeable CPAs at lowest required concentrations.
- Keep exposure time of CPAs to bare minimum
- Permeation of CPAs is a temperature dependent process. High temperature accelerates the rate of permeation

and thereby increases the risk of cytotoxicity. Thus it is essential to maintain optimum temperatures of the solutions.
- Combine a balanced concentration of a strong glass former such as DMSO and a weak glass former such as EG or acetamide.
- Increasing the viscosity of vitrification solution (VS) is used as one of the strategies to assist dehydration and reduce cytotoxicity.

FREEZING OR SLOW FREEZING

Slow freezing or equilibrium freezing is a technique where cryopreservation of cell occurs at a sufficiently slow rate to allow adequate cellular dehydration while minimizing intracellular ice formation. The first successful pregnancy of frozen embryo used a cooling rate of about 1°C/min to –70°C. The principle behind this process is that when cells are loaded with CPAs, they transiently shrink by osmosis since their membranes are more permeable to water than to the solute. When ice nucleates in the extracellular space, the overall concentration of the solutes rises, causing a secondary and lasting dehydration of the cell.[10]

The process involves two main steps: (1) *Equilibration* and (2) *Freezing*. An overview of the process is discussed here. In the first step, embryos are transferred from an isotonic culture medium to a hyperosmotic medium containing one or more permeating CPAs. The embryo is allowed a brief period to take up the CPA. During this period due to difference in the intracellular and extracellular osmotic pressure, the embryos undergo a transient shrinkage. Water and CPAs gradually reenter the cells to maintain the intracellular osmotic equilibrium. Once equilibrium is achieved between the efflux of water and influx of CPA, the shrinkage stops. This is the equilibration state. Equilibration is complete when no further osmotic and chemical gradients between CPA and water exist. At this point, embryos are loaded onto plastic straws and cooled at the rate of 0.5–2°C/min from room temperature to a temperature slightly below the melting point of the solution, which is approximately –5°C to –7°C. Manual seeding is performed at this temperature by manually touching the cryo-container with prechilled forceps, to initiate extracellular ice formation and avoid supercooling. The embryos are further allowed to equilibrate for another 5–10 minutes. After this step, the temperatures are lowered at the rate of 0.3–0.5°C/min until below –30°C. During this period, increasing extracellular ice crystal formation drives intra cellular water out of the cells, leading to a gradual increase in the intracellular ice crystals. The cooling process continues until the intracellular CPA concentration is high enough to allow the solidification of intracellular water without ice crystal formation. At this point in time, the embryos are plunged into liquid nitrogen. The process of warming involves retrieval from liquid nitrogen, warming to 37°C and gradual rehydration to remove CPAs from the embryo.

Slow freezing has its own advantages and drawbacks. The most crucial advantage is the use of less-concentrated CPAs. This serves the critical purpose of achieving dehydration without exerting cytotoxic effects on the embryo. The major limitation of slow freezing is that it is a very lengthy and time-consuming process. Secondly, there are chances of mechanically damaging the embryo in the process. Over time, vitrification has proved to be more efficient than slow freezing. Nonetheless, the journey of embryo freezing began with the concept of slow freezing, after which vitrification took its shape and became renowned.

VITRIFICATION

Vitrification is a term applied to refer the physical phenomenon where the solidification of water or water-based solutions into a glass-like amorphous liquid state (called vitreous state), due to extreme elevation in viscosity during cooling, without the formation of ice crystals.[20,21] Successful vitrification depends on two factors are following:

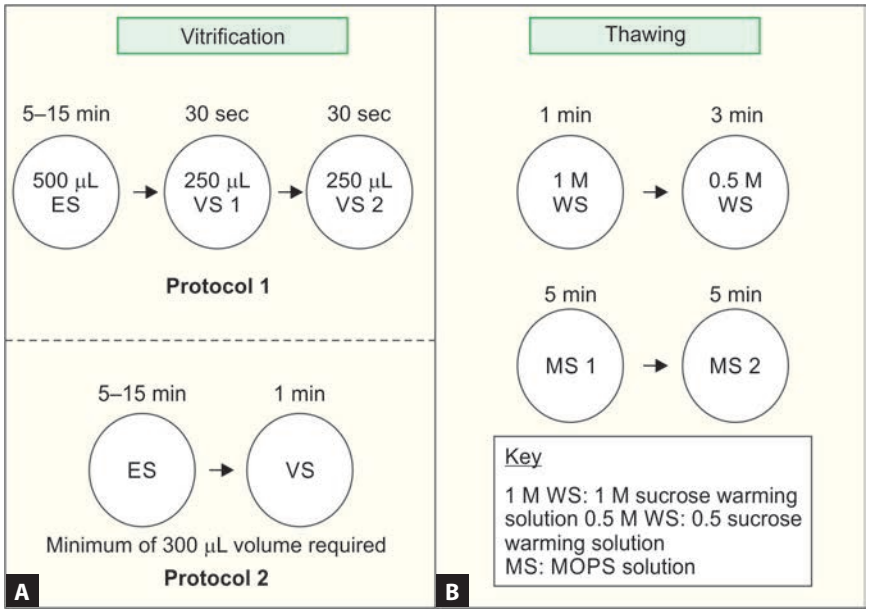
1. A very high concentration of CPA to inhibit the crystallization water into ice.
2. Extremely high cooling and warming rates (up to 20,000°C/min) to rapidly pass through the dangerous temperature zone between +15°C and –5°C to avoid cryoinjuries.

Since most CPAs are toxic under high concentrations, it is imperative to reduce its exposure time to embryo. If the exposure is too brief, its permeation to the embryo may be inadequate and intracellular ice will form even in the absence of extracellular ice. Vitrification procedure circumvents' two major limiting factors for exceeding optimal cryopreservation: (1) cryoinjury; (2) ice formation. The common protocol for vitrification of embryo is to first equilibrate them in a solution (called equilibration solution or ES) containing a lower concentration of one or more permeable CPA and then transferring it into a final solution, called vitrification solution (VS) containing a full-strength permeable CPA and a nonpermeable CPA.

Vitrification of embryos are generally carried out with carrier systems such as electron microscopy (EM) grid, open pulled straw (OPS), Cryotop, Cryoleaf, and Cryotip, successfully. However, in human assisted reproductive techniques, Cryotop and its derivatives such as Hemi-Straw System (HSS), Cryolock, Cryoleaf, Cryoloop, EM grid and OPS are more widely used.

Laboratory Procedure for Vitrification

Commercial kits are quite similar in their composition with certain modifications in their protocol. While performing the procedures kindly follow the protocol as per the manufacturers' instructions.



Figs. 1A and B: (A) Two commonly used protocols of vitrification; (B) Protocol commonly followed for thawing.

Vitrification is a two-step procedure which involves moving embryos first to the equilibration solution (ES) and then to the vitrification media. In general, two protocols are most commonly used for embryo vitrification **(Figs. 1 A and B)**. The main differences between the commercial protocols includes the number of vitrification drops (varies between one drop to four drops) and the recommended volume of use (varies between 0.1 and 1 mL). To enhance uniformity in procedures, scientists are now developing universal protocols for vitrification and warming. Parmegiani and team have tested the efficacy of a universal warming protocol for embryos frozen using different commercial kits. The experiments have shown promising results with a single universal protocol that is based on sequential use of 1 M and 0.5 M concentration of extracellular cryoprotectant (ECCP).[22]

Vitrification Protocol

- Prepare all the materials prior to starting the process of vitrification. Keep all things handy, since time is very crucial during the process of vitrification. Prewarming of media, dishes, pipettes and tips, labeling of cryo-devices, keeping marker, stop watch etc., are some things to be prepared beforehand.
- Carry out all procedures at room temperature (22–27°C).
- Gently shake all vials before use (do not homogenize the solution by pipetting). Dispense 0.1–1 mL of equilibration solution (ES) into well/dish (SAGE, Origio, Denmark).
- Dispense 0.1–1 mL of vitrification solution (VS) into the second well/dish (SAGE, Origio, Denmark).
- Transfer the embryo(s) to the first well (ES) and let it equilibrate for 5–15 min. The equilibration time depends on the stage of embryo. Broadly, cleavage stage need 5–7 min, collapsed blastocysts need 5 min and expanded blastocysts need 12–15 min.
- While the embryos are equilibrating, prepare the cryo-devices under sterile conditions. Label under appropriate witnessing.
- At the end of equilibration time, transfer the embryos to the second well containing VS. Incubate it for 1 min.
- At the end of incubation, load the embryos onto the cryo-device in minimum volumes. Remove excess medium.
- Place the device in liquid nitrogen and stir gently.
- Cap the device, whilst under liquid nitrogen and store until further use.
- Perform all procedures under a microscope. Adjust the focus well, since embryos tend to float in the medium.

Warming Protocol

- Prepare all the materials prior to starting the process of warming. Keep all things handy, since time is very crucial during the process of warming. Media, dishes, pipettes and tips should be pre-warmed at 37°C.
- Note that all the warming procedures should be carried out 37°C.
- First start by preparing the dishes. Gently shake and dispense 500 µL of 1 M warming solution (WS) (SAGE, Origio, Denmark) into a dish. The frozen embryos will be removed into this dish first.
- In a well dispense 500 µL of 0.5 M WS.
- In well number two and three, dispense 250 µL of MOPS solution (MS).
- Now it is time to remove the cryo-device. Remove the correctly labeled cryo-device from liquid nitrogen under appropriate witnessing.

- Quickly open the cryo-device and place the tip in dish containing 500 µL of 1 M WS. Incubate for 1 min.
- Transfer the embryo(s) to 500 µL of 0.5 M W for 3 min.
- Now transfer the embryo(s) to the first drop of MS for 5 min.
- Transfer the embryo(s) to the second drop of MS for 5 min.
- Transfer the embryo(s) to your preferred culture medium and place them in the incubator.

Tips for Optimizing Vitrification Success

- Maintain and follow Standard Operating Procedures (SOPs) in the clinic and take all small considerations into account. All operators, regardless of their experience should follow this SOP. This maximizes success rate by reducing interperson variability. Back tracing of problems is also easier if a SOP is maintained in the clinic.
- Try to use good quality embryo(s). Embryos of questionable quality can be vitrified, but they limit the success of survival. Hence try to vitrify top quality embryos.
- Be particular with the control of timing, temperature, osmolarity and pipetting.
- Do not exceed the maximum number of embryos recommended for the cryo-device.
- Load the embryos in minimal volumes to support an appropriate cooling rate.
- Carry all procedures under a microscope. Ensure that the lens is properly focused since embryos tend to float in the medium.

"FREEZE-ALL" STRATEGY

The last decade or so has seen a substantial rise in the concept of "freeze-all' strategy wherein all the embryos following IVF are first frozen, thawed and then transferred in subsequent cycles. The rationale behind this strategy is that the transfer of embryos in a non-IVF cycle would provide a more "physiologically natural" environment which would result not only in higher pregnancy rates but also reduce the risks of maternal and perinatal morbidity as compared to fresh cycle transfer.[23] Some occasional reports have shown increased reproductive outcomes using this strategy whereas some groups suggest that this strategy is more beneficial for certain subgroups of patients and detrimental to others. An interesting SWOT (strengths, weakness, opportunities, and threats) analysis of "freeze-all" strategy was done by Blockeel and group.[24] They suggest the following SWOT's of the "freeze-all" strategy—

Strengths:

- Increased maternal safety, OHSS-free clinic
- Improved pregnancy rates
- Lower ectopic pregnancies
- Better obstetric and perinatal outcomes

Weakness:

- Evidences of three RCTs only
- Less evidences providing promising results in all groups

Opportunities:

- Stimulation can be started at any time of the cycle
- Scheduling possibilities
- Patient friendliness

Threats:

- Cost increment.

Thus, all in all it seems to be on the physicians acumen to decide whether to use "freeze-all" strategy for "all" patients or a certain subgroup of them. Subgroup of patients being poor ovarian responders or those prone to OHSS. Promising results have been shown in these subgroups.[24]

SAFETY OF REPRODUCTIVE CRYOPRESERVATION

Higher birth-weight associated with FET has been observed in large epidemiological populations in the UK. However, it is a matter of debate whether the actual process of FET contributes to higher birth-weight or are there any other factors. An increased risk of placental problems (placenta accreta), pregnancy-induced hypertension and preeclampsia have been observed following FET.[25] One of the reasons for preeclampsia has been attributed to the use of estrogens in endometrial priming protocols during FET cycles.[26-28] Also, the epigenetic effect of cryopreservation remains a question of study in FET babies. According to the Developmental Origins of Health and Diseases, it is hypothesized that cryopreservation of gametes and embryos may alter the epigenetic make-up of the DNA, which could result in altered developments of the fetus.[29-32]

Although scientists have seen the abovementioned outcomes in FET groups, these outcomes still remain a question of debate. In all of the mentioned outcomes there are contradicting evidences that show no differences between frozen and fresh embryo transfer cycles.[2,28,29]

CONCLUSION

Cryopreservation has seen a pragmatic boom in the field of ART since its advent in the 1980s. Scientific advancements have led to higher success rates of survival post cryopreservation, making cryopreservation accessible to clinicians and patients alike. It is undoubtedly a boon for many. However, it is necessary to explore the fine physiological effects of cryopreservation. It is imperative that there is a need for larger studies, long-term evaluation of FET born babies and thorough evaluation of toxicity-related studies to determine the safety of reproductive cryopreservation.

CHAPTER 111

Viral Contamination Risk to Gametes and Embryos in Cryostorage during COVID-19

Prathima Tholeti, Satish Kumar Adiga

INTRODUCTION

Cryopreservation is an essential component of a successful assisted reproduction technology (ART) program that involves freezing of gametes and embryos of infertile couples at ultralow temperatures, thereby providing flexibility of time for effective management.[1] This technique also forms the crux in fertility preservation programs recommended by the American Society of Clinical Oncology to young and adult cancer patients,[2,3] as well as in non-oncological medical conditions,[4] thereby helping them preserve their reproductive cells such as spermatozoa, oocytes, testicular, or ovarian tissues for a fertile future.

The success of cryopreservation has led to an increased number of in vitro fertilization (IVF) clinics across the globe routinely freezing their patients' samples for future use, highlighting the need to ensure safe and reliable storage, both short- and long term.[5] One of the major concerns with cryostorage is the contamination of liquid nitrogen (LN2), a commonly used cryogenic medium, by viral pathogens, especially leading to transmission of infectious diseases between samples[6,7] or transmission to the patient itself during fertility restoration. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which is responsible for the recent coronavirus disease 2019 (COVID-19) pandemic, is one such viral pathogen that has shown to infect reproductive cells and can therefore pose a relevant risk in cryostorage and potential disease transmission.[7]

SARS-COV-2 AND ITS IMPACT ON REPRODUCTIVE CELLS

SARS-CoV-2 virus is a single-strand ribonucleic acid (RNA) virus belonging to the coronavirus family and shares 82% genome similarity with SARS-CoV. SARS-CoV-2 facilitates its entry by binding to angiotensin-converting enzyme 2 (ACE2) receptor of the host cell, after which the viral spike glycoprotein priming occurs through transmembrane serine protease 2 (TMPRSS2).[8] This allows for the fusion of viral and host cell membranes enabling successful entry and invasion of the host cell. Most of the tissues of the human reproductive system, gametes, or embryos express ACE2 receptors and are therefore highly susceptible to a SARS-CoV-2 infection. However, the effect of COVID-19 infection on these cells and its impact on reproductive outcomes are not completely known.[9] Alternate binding receptors such as BSG (basigin/CD147) have also been reported; however, their direct role in enabling viral invasion is yet to be established.[10]

Effect of SARS-CoV-2 in Male Reproductive Cells

SARS-CoV-2 infection appears to affect male fertility in various ways such as a direct impact on the sperm parameters or testicular function, on male steroidogenesis, or indirectly through an immune response mounted by the virus causing damage to the male reproductive cells.[11] The testis is a potential target for SARS-CoV-2 infection as ACE2 receptors have been shown to be expressed in spermatogonia and Leydig and Sertoli cells.[12] Some of the patients infected with COVID-19 have shown symptoms similar to those of Sertoli cell-only syndrome suggesting that SARS-CoV-2 infection could cause viral orchitis resulting in impaired spermatogenesis.[13] A few other reports have suggested autoimmune orchitis due to COVID-19 infection leading to disruption of the blood–testis barrier.[14,15]

The presence of SARS-CoV-2 in human semen remains controversial due to insufficient literature. While some studies have reported the presence of SARS-CoV-2 in the semen of patients during the acute phase of infection,[14] others have failed to detect the virus through reverse transcription polymerase chain reaction (RT-PCR) in the semen of COVID-19 patients or in a postmortem testicular sample of a patient diagnosed with COVID-19.[16-18] However, impaired sperm parameters have been reported in patients with moderate COVID-19 infection though the presence of virus was not detected in the semen; hence, it is unclear whether the infection or treatment itself is causing the impairment.[19] Overall, there is no conclusive evidence to

draw a firm conclusion on the effect of SARS-CoV-2 on spermatozoa, the severity of infection at the time of semen sampling, and the possibility of SARS-CoV-2 presence in the semen of the asymptomatic COVID-19 patients which cannot be completely ruled out.[20]

Effect of SARS-CoV-2 in Female Reproductive Cells

The female reproductive tract appears to be less impacted by SARS-CoV-2 than the males,[21] although ACE2 is widely expressed in the ovary,[22] uterus, and vagina.[23] While the presence of ACE2 is indicative of the female reproductive organs being potential targets for SARS-CoV-2 infection, no evidence so far has been convincing of infection or sexual transmission.[24] However, it has been observed that the hormonal profile and ovarian reserve in SARS-CoV-2 infected patients reveal lower anti-Müllerian hormone (AMH), increased follicle-stimulating hormone (FSH), and higher testosterone and prolactin levels compared to the age-matched control group, thereby suggesting an impact of COVID-19 infection on the ovarian function.[25] The presence of SARS-CoV-2 in follicular fluid of infected patients has also been reported, but it appears to have no significant effect on oocyte yield and fertilization rate;[26,27] however, top-quality embryos on days 3 and 5 were significantly lower.[28,29]

The American Society for Reproductive Medicine (ASRM) recommends following standard universal precautions while handling gametes from patients with other viral illnesses, such as human immunodeficiency virus (HIV) and hepatitis, to reduce vertical transmission to noninfected partner and cross-contamination of reproductive tissue within the ART laboratory.[30] However, whether these special precautions are to be recommended even for SARS-CoV-2, given the lack of insufficient evidence for transmission through blood or sexual contact, is still not clear.[24,31]

FERTILITY PRESERVATION

Oncofertility is an upcoming area of science,[2] and with the American Society of Clinical Oncology recommending guidelines to offer fertility preservation services to oncological patients,[3] many young and adult cancer patients preserve their spermatozoa, testicular tissues, ovarian tissues, oocytes, or embryos for a fertile future. Various cryopreservation protocols have been developed for each of the reproductive material to ensure efficient long-term storage and recovery while also sustaining the fertility potential.[1] These samples are usually cryopreserved in either open or closed cryodevices, which are then plunged in LN2 that maintains an ultralow temperature of –196°C,[32] facilitating prolonged cryostorage of reproductive material. However, one of the main concerns of fertility preservation in patients with a virus infection, including SARS-CoV-2, is the risk of cross-contamination through the storage devices or LN2 and reintroduction of the virus when patients need fertility restoration, which could even be decades later in the case of prepubertal patients.[7]

CROSS-CONTAMINATION OF VIRUSES IN LIQUID NITROGEN CRYOTANKS

Several concerns exist pertaining to contamination of LN2, which could result in transmission of infectious diseases either between the stored samples[6,7] or transmission of infection to the patient itself years later during fertility restoration.

While there have been no reports of transmission of viral pathogens in cryotanks of fertility centers,[33] other reports of cross-contamination of hepatitis virus from cryopreserved bone marrow transplant to other frozen samples in the same LN2 tank[34] have been reported. Viruses such as HIV, hepatitis, influenza, and papillomavirus seem to retain their infectivity even after cryopreservation, thereby highlighting the biohazard that LN2 can pose when exposed to the virus, hence leading to cross-contamination.[34-38] The use of cryoprotectants in protecting reproductive cells during freeze–thawing also seems to confer protection to the enveloped viruses, thereby making them cryoresistant and thus leading to transmission of the pathogen between stored biomaterials.[5,39-41] An experimental contamination of LN2 with bovine viral diarrhea virus (BVDV) and bovine herpesvirus-1 (BHV-1) has shown that while there was no transmission from infected semen samples to noninfected samples stored in the same LN2 tanks, cross-contamination of the same viruses to frozen embryos was seen during this experiment.[41]

It is reassuring that upon screening LN2 used for gamete or embryo cryopreservation in chronic HIV, hepatitis C virus (HCV), hepatitis B virus (HBV) seropositive patients undergoing ART treatment, RNA or deoxyribonucleic acid (DNA) sequences could not be detected.[42] Also, since no studies have demonstrated the SARS-CoV-2 virus binding to the zona pellucida (ZP) of human oocytes, other studies reporting the penetration of ZP by other viruses such as BHV-1 and bovine herpesvirus 5 should be taken into consideration.[43,44] However, breaching of ZP during manipulation such as intracytoplasmic sperm injection (ICSI), laser-assisted hatching, or embryo biopsy could facilitate SARS-CoV-2 entry.[45] Nevertheless, ASRM has recommended repeated washings of gametes or embryos to effectively eliminate the viral pathogens.[46]

As a precautionary measure for safe cryostorage and to assure patients that their gametes or embryos would not be infected by SARS-CoV-2 or other viral pathogens, viral testing can be made mandatory for all patients cryopreserving their reproductive samples.[47]

Additionally, there is a risk of iatrogenic transmission of pathogens from either laboratory personnel or LN2 operators to the frozen samples. As stated earlier, the particles of SARS-CoV-2 or other viruses are cryotolerant, and therefore, could survive the freeze–thaw process.[46] Hence, there is a need for standard guidelines for safe handling and cryopreservation of reproductive samples during fertility preservation.

RISK MITIGATION STRATEGIES AND SAFETY DURING CRYOSTORAGE

Due to the various concerns associated with SARS-CoV-2, international reproductive societies and clinical groups have provided guidelines for the smooth conducting of ART cycles in lieu of the global pandemic. The same guidelines can also be applied to infertile patients with other viral infections. The risk prevention strategies that can be incorporated at IVF clinics are as follows:

- Viral testing including SARS-CoV-2 for infertile patients before starting the ART cycle and also in oncofertility patients recruited for fertility preservation.[46-49]
- Ensuring implementation of disinfection protocols in semen collection rooms and procedure rooms.[50]
- Handling or culture of gametes/embryos/reproductive tissue of suspected or infected patients in class II biological safety laminar hoods and incubators, thereby reducing the risk of contamination, keeping in mind aerosol generation.[51]
- Oocyte retrieval of patients who are suspected or infected can be performed only in IVF clinics with expertise in managing infectious specimens and should also be equipped to offer better protection to healthcare providers.[52]

Strategies for risk mitigation in cryostorage include proper selection of carrier devices, sterilization of LN2 tanks, and appropriate washing steps during gamete/embryo handling[7] as detailed below.

CRYOSYSTEMS AND CARRIER DEVICES

Depending on whether open or closed cryopreservation systems are used, the carrier devices can vary. Closed devices, such as sealed straws, help ensure that the reproductive samples are not directly exposed to LN2, therefore reducing the hazard of cross-contamination.[53] Other closed carrier systems for cryopreservation include microvolume air cooling (MVAC) device,[54] high-security vitrification straw (HSV), or Cryotip, which have been used for human embryo vitrification in order to hermetically isolate the reproductive samples.[55-57] Hence, for patients with COVID-19 or other viral infections, the use of high-security straws and vapor-phase storage for cryopreservation of reproductive samples can be recommended.[48] However, most laboratories use screw-capped plastic vials that can lead to contact with surrounding LN2 by generation of vacuum in the vial through atmospheric condensation at such low temperatures, thereby drawing in LN2.[58] In such cases, it may be safe to use a secondary enclosure for such cryodevices or to store samples of patients who are suspected/infected in separate LN2 cryotanks, thereby avoiding the risk of disease transmission through contaminated LN2.[39] While using the open carrier system during vitrification, in order to avoid contamination, other alternatives to LN2 can be used such as a bench-top device that produces cooled clean liquid air (CLAir) with similar temperature to that of LN2.[59] It is also advisable not to share LN2 between patient samples during cryopreservation.[60] Vapor phase nitrogen can also be used as a safer alternative,[56] although the risk cannot be completely negated.[61] This can be a more practical option, especially in cases of storing unwashed semen samples or for those awaiting viral test results.[62]

LIQUID NITROGEN STERILIZATION

Liquid nitrogen is an efficient cryogenic medium but considering the risk of cross-contamination, it would be advisable to ensure the sterility of LN2,[39,46,63] either by using certain devices (http://www.freepatentsonline.com/5737926.html) or by filtering LN2 using 0.2 µm pore size disposable filters[64,65] and also by exposure to ultraviolet (UV) radiation in a temperature-controlled manner in a short interval for effective sterilization.[66] However, the efficacy of such methods on eliminating the different viruses including SARS-CoV-2 remains to be seen. Other methods to sterilize LN2 include periodic disinfection of the cryotanks as well as the tools used during cryopreservation, by UV exposure or chemical disinfectants.[39,63] Irradiation with ultraviolet C (UVC) rays of 254 nm for >15 minutes has shown to be effective in deactivating the SARS-CoV-virus, but whether the same exposure would be sufficient for use in LN2 remains to be seen.[67] It is worth noting that care should be taken to avoid putting the stored reproductive samples at risk during removal from cryotanks while cleaning.[68]

WASHING PROCEDURES TO ELIMINATE PATHOGENS

To minimize the risk of contamination, a safe three-step washing procedure of carrier devices with sterile LN2 has been reported to eliminate bacterial and fungal pathogens from human cryopreserved specimens.[69] It may be advisable to implement a similar strategy for viral pathogens as gentle repeated washes of gametes and embryos before cryopreservation and after thawing can minimize the infectivity by high dilution of viral particles.[39,46] It has been shown that such washing–dilution procedures can dilute the infective agents to a probability of <0.0002% even with open vitrification systems, far below the threshold level required

for causing clinical infection.[70] Established sperm-washing procedures such as double density gradient followed by swim-up have been known to effectively separate motile sperm free of viral particles in males infected with HIV or HCV; therefore, such sperm-wash procedures could also be used for other viral infections[30] such as SARS-CoV-2.

SAFETY ISSUES

While the above precautionary strategies offer protection to the cryosamples, it is equally important to implement standard precautions for the safety of the laboratory personnel while handling LN2,[71] to prevent any health hazards. One of the risks during cryohandling, especially with contaminated LN2, is the generation of aerosol mist particles of 1–5 μm sizes which are generated near the LN2 surface, even up to a distance of 10–20 cm, resulting from evaporation and floating of particles.[72] This, in turn, could pose a risk to the personnel while handling contaminated LN2 containers. Hence, it is advisable for the laboratory personnel to use safety cryoaccessories such as goggles or face visors and protective clothing while working with LN2, thereby ensuring safety and efficiency.[7,71]

CONCLUSION

It is essential for healthcare providers to be aware not only of the effect of viral infections, such as SARS-CoV-2, on male and female reproductive cells but also of the risk of cross-contamination and transmission through cryobanking services. Recent literature is controversial on the presence of SARS-CoV-2 and its impact on sperm parameters as well as on the ovarian reserve. However, as the human gonadal tissues are abundant in ACE2 receptors, they are potential targets for SARS-CoV-2 infection which can, in turn, lead to the transmission of infections to other samples in cryostorage due to cross-contamination. Hence new strategies must be adopted when offering fertility services, especially pertaining to cryopreservation, to combat viral infections including COVID-19.

Cryostorage commonly uses LN2 for long-term cryopreservation, however, it carries the risk of cross-contamination by viral pathogens that can lead to disease transmission among cryosamples or to the patient itself later when they come for fertility restoration. Hence, it is important to identify and mitigate such risks involved in cryostorage through safety and precautionary measures. Some of the strategies include viral testing, including COVID-19 testing of both partners before initiating ART cycle, utility of closed-carrier cryodevices, and sanitary cryostorage protocols followed by efficient washing of gametes or embryos during cryopreservation, all of which would minimize the risk of disease transmission. However, each IVF laboratory, especially in developing countries, will have to decide on the feasibility of adopting these strategies depending on their setting and available resources without compromising on patient and laboratory personnel safety.

KEY POINTS

- SARS-Cov-2 virus can pose as a relevant risk during cryostorage of fertility preservation biomaterials.
- Important to identify and employ risk mitigation measures in cryo-facilities to ensure safety of patient as well as laboratory personnel
- Depending on the available resources, each IVF laboratory can adopt feasible strategies to minimize risk of disease transmission during cryostorage.

Advances in Assisted Reproductive Technologies

CHAPTER 112

Assisted Hatching in Assisted Reproductive Technology

Gaurav Majumdar

INTRODUCTION

Over the last decade, many attempts have been made to improve embryo implantation in in vitro fertilization (IVF). A high incidence of chromosomal anomalies has been observed in embryos generated from IVF. However, genetic factors alone cannot explain the low implantation rate of morphologically normal embryos, indicating that a number of other factors could be involved. One of these factors is possibly the inability of the embryo to hatch out successfully from within its outer covering, i.e., the zona pellucida (ZP). It has been reported that 25–30% of embryos fail to hatch in optimal culture conditions in vitro.[1-3] If the rate of hatching is similar in vivo, it may explain in part the low implantation rates after IVF. An embryo must hatch out completely before it can implant into the uterine endometrium.

The impaired hatching may be due to the extended time in culture, in an artificial environment, causing hardening of the ZP. Hence, the strategy of assisted hatching, which involves artificial thinning or breaching of the ZP to facilitate embryo hatching, has been proposed to improve implantation rates in selected patients.[4,5] Several approaches have been adopted since then for assisted hatching, such as mechanical incision of the zona, chemical zona drilling with acidic medium, and laser-assisted drilling or thinning of the zona. Assisted hatching can be performed on both cleavage-stage embryos and blastocysts. Assisted hatching may be associated with certain adverse effects, such as damage to individual blastomeres resulting in reduced embryo viability; therefore, the procedure did not gain access as a routinely used adjunct treatment to all cases undergoing assisted reproductive technology (ART). In addition, there have been very few reports to support the efficacy of assisted hatching after the initial randomized controlled trials (RCTs) published by Cohen et al.[6] in 1992. This chapter shall, therefore, focus on identifying the patient groups that would benefit most from assisted hatching to maximize pregnancy rates.

CAUSES FOR IMPAIRED HATCHING

Embryo hatching involves a spontaneous breach in the zona, thus allowing the expanding blastocyst to "hatch out" of the ZP and gain access to the endometrium for further implantation to occur. During the normal course of embryonic development in vitro, as a blastocyst undergoes expansion, it results in thinning of the zona to a point where finally the zona spontaneously ruptures. Subsequently, either the expanding blastocyst herniates out of the breached ZP or the embryo undergoes repeated cycles of contraction and expansion, which ultimately enables the blastocyst to break out of the zona. In addition to mechanical factors, lysins of embryonic and uterine origin are also involved in ZP thinning and hatching. The normal process of hatching may be impaired due to one of the following conditions:

- *Zona hardening:* This can occur either spontaneously or following gonadotropin therapy, cryopreservation, or after extended culture in vitro.
- *Increased zona thickness:* A thick zona is defined as having a mean ZP >18 μm. This measurement is dependent on the duration of follicular stimulation and maternal age.[7]
- *Reduction in zona lysins*: Lysins are compounds that are produced by the embryo and/or the endometrium that dissolve the ZP, thereby reducing its thickness. The blastocyst expands and contracts repeatedly before hatching, leading to further thinning and eventual rupture of the zona. Therefore, a reduction in these lysins may impair the normal process of hatching.
- *Embryos with extensive fragmentation or cell death:* After freezing and thawing, these embryos may also encounter hatching difficulties.

ASSISTED HATCHING: PLAUSIBLE MECHANISMS

Primarily, a breach in the zona may help the embryo to hatch by overcoming the mechanical barrier of a hard or thick zona. Cellular energy requirement for hatching might be insufficient in patients with poor prognosis. Therefore,

assisted hatching may also decrease this energy requirement of the embryo to commence hatching. Artificially rupturing the zona promotes early hatching[8] and may therefore increase chances of implantation by optimizing the implantation window. Normally, hatching occurs 5 days postfertilization in a nonstimulated cycle, after which an embryo has 48 hours more to implant as judged by the presence of endometrial pinopods (120–168 hours post insemination). However, in a gonadotropin-stimulated cycle, the phenomenon of endometrial advancement may lead to a premature shift of the implantation window to between 72 and 120 hours postfertilization. Thus, if hatching occurs at 120 hours, then endometrial advancement may result in limiting the opportunity for implantation to occur. Assisted hatching seems to allow earlier hatching and therefore offers higher chances of implantation, obviating the closing of the implantation window in stimulated patients.

Fig. 1: A day 5 blastocyst seen hatching from its outer covering zona pellucida. Part of the embryo has herniated out of a breach in zona pellucida at 4'o clock position with the remainder of the embryo still inside the zona.

Overview of Techniques

It has been observed that although human blastocysts expand readily in vitro, about 20% of such blastocysts have hatching problems. Therefore, it was proposed that such embryos could be rescued by disrupting the zona physically on day 2 or day 3, thereby promoting the natural process of hatching. The reason for delaying the procedure until the third day is that intercellular connections start to form at this stage, thereby preventing loss of blastomeres following opening of the ZP **(Fig. 1)**. Thereafter, various approaches have been adopted, some of which have been shown to be useful. The different techniques that have been tried are given in the following text.

Mechanical: Partial Zona Dissection on Day 2

Originally, the technique of partial zona dissection (PZD) had been used to assist or enhance fertilization in vitro, mainly in cases of male factor infertility, where patients could not be helped by conventional IVF. This technique was subsequently given up because of poor fertilization rates. However, in 1993, Cohen et al. demonstrated that the same technique could be used on day 2 embryos to assist hatching and improve implantation rates of these embryos, which otherwise may have failed to implant.

In this technique **(Fig. 2)**, (1) the embryo is held firmly in place by a holding micropipette; (2) a sharp dissection micropipette is inserted through the ZP, at the other end, in the perivitelline space between two adjacent blastomeres; and (3) a slit in the ZP is created by gently rubbing the holding pipette over the small part of the zona trapped against the micropipette until the embryo is released. This technique is preferably performed on day 2 embryos since the embryo does not have more than four blastomeres, and therefore, there is enough perivitelline space between adjacent blastomeres to assist the procedure of PZD.

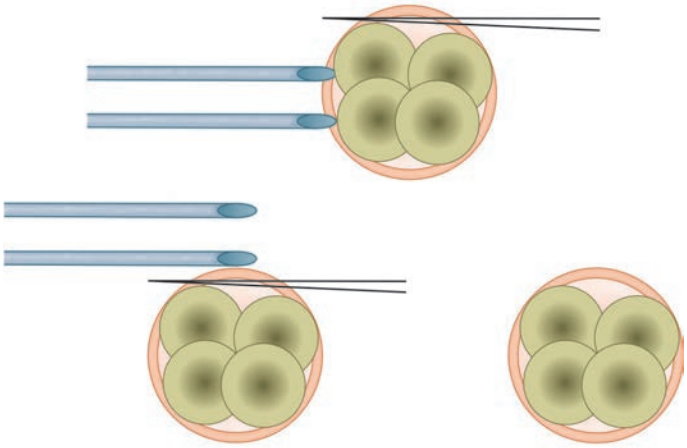

Fig. 2: Partial zona dissection.

Chemically Assisted Hatching: Zona Drilling with Acid Tyrode's Solution (pH 2.5)

Zona drilling involves creating an opening in the zona measuring 15–20 μm on the inside and 30–50 μm on the outside, by spraying acid Tyrode's solution on the zona **(Fig. 3)**. This is generally done on day 3 embryos. Initially, it was shown that zona drilling significantly improved the implantation rates in patients whose embryos had thick zona. The best results were achieved for patients with elevated basal follicle-stimulating hormone (FSH) levels or for those older than 38 years. Nonetheless, both these techniques of mechanical and chemical manipulation did not turn out to be very popular since there were a lot of practical problems associated with the procedures, some of which were simply the result of technical drawbacks and/or lack of standardized protocols. For instance, it was observed that embryos with a thin zona (<13 μm) appeared to get damaged following the

Fig. 3: Opening in the zona by drilling with the help of acid Tyrode's solution.

zona drilling procedure.[9] Some of the common problems with respect to PZD and zona drilling are as follows:

- Formation of holes <10 μm, which may lead to trapping of embryos during hatching or cell separation
- Formation of holes >25 μm, which may lead to cell loss during a traumatic embryo transfer
- Excessive exposure to acid Tyrode's solution, which could damage the adjacent cells in the embryo.

Several recent studies evaluating the impact of chemically assisted hatching with zona thinning have been inconclusive with respect to any improvement in outcomes. Interestingly, majority of these studies were focused on fresh embryos. However, data emerging from retrospective analysis as well as from prospective randomized studies evaluating the effect of assisted hatching on frozen/thawed cycles have shown an improvement in implantation rates but no improvement in pregnancy rates.[9]

Enzymatic: Zona Softening or Complete Removal with Pronase

Enzymatic treatment of the ZP to either soften or remove the zona totally before blastocyst transfer has resulted in high implantation rates.[10] The zona is usually completely dissolved after 1.5 minutes of exposure to 10 IU pronase at 37°C. The increase in implantation rates may be due to better cell-to-cell anchorage between the trophectoderm (TE) and endometrium as a result of complete zona removal.[11] In the method described by Fong et al., day 5 blastocysts were transferred to 10 IU/mL pronase for 1 minute.[11] Embryos were quickly checked (on a heated stage) for zona stretching, zona becoming faint, and subsequent increase in perivitelline space. Thereafter, the embryos were washed in culture medium and incubated until transfer. All the embryos that were transferred either had a faint zona or were zona free. Complete zona removal should not be done before compaction due to lack of junctional complexes between adjacent blastomeres.

Laser-assisted Drilling

Laser technology has found widespread use in medicine. It is especially appreciated for its precise and atraumatic mode of action. This fact encouraged the application of lasers for micromanipulation, especially to perform assisted hatching. This easy and precise procedure offers a gentle way to create an opening in the zona using only a few laser pulses within seconds. However, keeping in mind the delicate nature of micromanipulation techniques, it is recommended that the following four criteria be taken into account before selecting a suitable laser system for your embryology laboratory:

1. Absolute avoidance of thermal effects causing coagulation or vaporization, thereby causing irreversible denaturation of proteins
2. Prevention of genetic damage by a wavelength well above the absorption maximum of deoxyribonucleic acid (DNA) (268 nm)
3. Low ablation threshold to ensure precision and to minimize mechanical vibration
4. Easy handling using existing micromanipulation equipment.

There are two types of laser systems:

1. Contact laser in which the laser beam is guided through a glass/optical fiber. The fiber is fitted to the micromanipulator by a pipette holder and is brought in direct contact with the zona, but the tip is not forced further into it before application of the laser beam. This prevents any contact of the fiber with the surface of the ooplasm or blastomere once it penetrates the zona. The laser fiber should be either disposable or sterilizable before being used on other patients' embryos.
2. Noncontact laser systems[12] are more popular since they are very easy to use. In this system, the laser beam is guided through an optical lens and focused on the specimen. None of the equipment comes in contact with the embryo or culture media; therefore, this system ensures complete sterility, high precision, and selectivity avoiding all problems of cross-contamination. The simplicity of the procedure does not require skilled laboratory technicians or a great deal of training.

Lasers can be used in thinning[13] of the ZP, creating a complete breach,[12] through the zona. Thinning of the zona has been preferred because a complete breach may impair the natural process of blastocyst expansion and zona thinning. The opening results in releasing any pressure exerted by the expanding embryo on the zona and consequently the zona remain relatively thick. Furthermore, a larger than normal opening may lead to loss of blastomeres or loss of the whole embryo during contractions of the reproductive tract.[14] Nevertheless, in either case, the use of laser for assisted hatching has proven to be much more advantageous than that with PZD or acid Tyrode's since laser allows making holes of standardized sizes, avoiding both the

escape of blastomeres or embryo trapping. Also, compared to mechanical or chemical methods, the use of lasers greatly reduces the risk of damaging the embryo because of its high precision and ease of handling.

A number of laser systems have now been reported, and there is continuing evaluation to determine the most effective and the least hazardous of these systems. In the "contact mode," different lasers have been used to drill holes: Argon fluoride at 193 nm[15] and the neodymium-doped yttrium aluminum garnet (Nd:YAG) at 1,064 nm.[16] Strohmer and Feichtinger made use of an erbium YAG (infrared) laser at a wavelength of 2.94 μm along with a glass fiber with a 20 μm tip diameter.[17] In 1994, Obruca et al. reported the use of the same laser system obtaining an improvement in implantation and pregnancy rates.[18] Antinori et al. again used the same erbium YAG system for zona thinning.[13]

A PALM UV laser at 337 nm operating in a "noncontact mode" was used to assist hatching in embryos by making complete holes in the zona.[12] The other laser systems that have been used in the noncontact mode are the xenon chloride excite laser at 248 nm,[19] the krypton fluoride laser at 248 nm,[20] and the diode laser at 1.48 μm.[21]

The use of laser technology for ZP thinning has been shown to be of benefit in some studies. The results were obtained in favor of the partial zona thinning as compared to the complete breaching of the ZP in studies comparing different laser-based techniques.[9]

Piezo-assisted Drilling

In 1999, Nakayama et al.[22] demonstrated that assisted hatching, using a piezo-micromanipulator, improved the pregnancy and implantation rates in infertile patients with a poor prognosis with good-quality embryos for transfer. Piezo-assisted drilling of holes in the ZP has been achieved in animal models. The technique entails the use of electromagnetic pulses wherein the zona is corked off without any bending.[23] Piezo-assisted drilling is very fast and extremely easy with no potential detrimental effects on the embryo. The procedure has been used to perform nuclear transfers (in all animal species except the cow) and might, in future, be considered as the method of choice for clinical application in humans.

PITFALLS OF ASSISTED HATCHING

In some instances, the creation of a hole or thinning of ZP may not be enough to improve the chances of the embryo to adequately hatch. Current research shows that the benefits of assisted hatching are limited to selected cases and there is no evidence of benefit for the overall patient population. Some of the common problems identified with assisted hatching are as follows:

- It deprives the embryo of its protective coat, which otherwise shields it from detrimental factors such as bacteria and viruses in the female reproductive tract.[24]

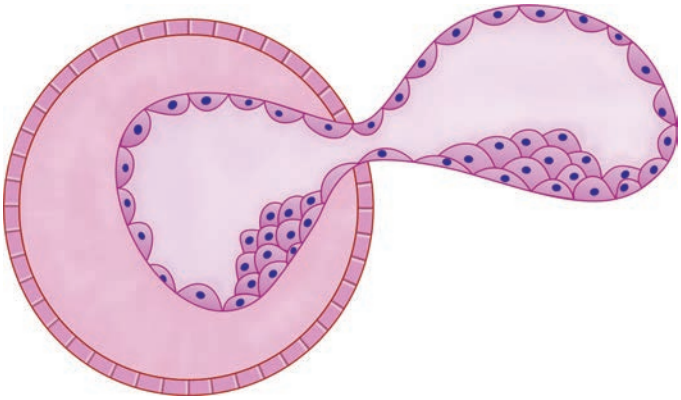

Fig. 4: Figure-of-eight configuration of the embryo.

- The absence of an intact ZP may lead the embryo to be immunocompromised. This may fail to support the implantation of ZP-dissected human embryos.[24]
- There is possibility of an increased loss of blastomeres or whole embryos during contractions of the female reproductive tract.[14]
- The natural expansion of blastocysts with breached ZP may fail to occur.
- A higher incidence of monozygotic twinning as a result of smaller hole size in ZP has been reported.[25]

Monozygotic Twinning

The size of the hole in the ZP has a major impact on the hatching embryo. A blastocyst with narrow artificial holes may lose trophoblastic vesicles as they expand and attempt to hatch through the narrow gap. Most importantly, a very small hole may lead to a figure-of-eight configuration of the embryo **(Fig. 4)** at the time of hatching, while multiple gaps of the same dimension promote multiple herniations. Any of these situations may also lead to splitting of the inner cell mass (ICM), forming dichorionic or diamniotic twins. If this takes place after the differentiation of the trophoblast, then a monochorionic or diamniotic twin pregnancy may result.[26]

It is important to note that monozygotic twin formation may be viewed as an adverse effect of assisted hatching, as it creates a complex obstetric situation by potentially increasing morbidity and mortality rates of the fetus before and after birth. Monoamniotic twin pregnancies may lead to an increased risk of intrauterine fetal death, due to fetal entanglement, umbilical cord accidents, or formation of conjoint twins.

Currently, the available evidence is insufficient to conclude that assisted hatching increases the rate of monozygotic twinning since the outcome is rare and conflicting results have been obtained from different studies.[27] A meta-analysis, evaluating the risk factors for monozygotic twinning after IVF, which included 16 studies that compared IVF with and without assisted hatching, demonstrated a statistically significant association between

monozygotic twinning and assisted hatching [odds ratio (OR) 1.17; 95% confidence interval (CI) 1.09–1.27; $p < 0.0001$]. However, this association could not be confirmed when the analysis was limited to only high-quality cohort and case–control studies.[28] A study analyzing the results from the Society for Assisted Reproductive Technology (SART) database between 2004 and 2010 demonstrated that although monozygotic twinning was more likely with day 5 or day 6 embryos, addition of assisted hatching had no significant effect, whereas assisted hatching had a substantial effect on day 2 or day 3 embryos (OR 2.05–2.48).[29]

There are a similar number of studies showing no increase in monozygotic twinning rates with assisted hatching; however, majority of studies are underpowered or inconsistent in the number of embryos transferred or the method of assisted hatching used.[30]

PATIENT SELECTION FOR ASSISTED HATCHING

The criterion for selecting individual embryos for assisted hatching is dependent on many variables. It is believed that a thick or hard zona may act as a mechanical barrier for a hatching embryo. Zona hardening may occur as a natural consequence of in vitro embryo culture and cryopreservation. Similarly, zona thickness, which correlates negatively with implantation rates, may be influenced by factors such as maternal age and elevated basal FSH. Therefore, assisted hatching may be considered in the following cases.

Indications

- Women aged >38 years
- Elevated basal FSH levels
- Zona thickness >18 μm
- Repeatedly failed IVF or intracytoplasmic sperm injection (ICSI) cycles after transfer of multiple good-quality embryos
- Embryos generated from in vitro matured oocytes
- Embryos generated from cryopreserved oocytes
- Frozen–thawed embryos in cryopreservation cycles.

Contraindications of Assisted Hatching

- If a traumatic embryo transfer is anticipated, assisted hatching should not be attempted.
- Assisted hatching may not be performed if the blastomeres do not appear to be in interphase; for example, a dividing four-cell embryo might be more sensitive to external influences as compared to an embryo with cells at the interphase stage.

A Cochrane review assessing the impact of assisted hatching, including 39 RCTs with 2,486 clinical pregnancies, reported a slight increase in clinical pregnancy rate (OR 1.20; 95% CI 1.09–1.33) as well as multiple pregnancy rate (OR 1.38; 95% CI 1.13–1.68); however, the quality of evidence was poor. They reported no beneficial impact of assisted hatching on the live birth rate (OR 1.09; 95% CI 0.92–1.29). Miscarriage rates were also similar in both the groups. On accounting for the heterogeneity in the studies included, there may also be little to no difference in clinical pregnancy rates.[31]

MEDICAL MANAGEMENT

The ZP is the protective covering for the embryo and its blastomeres during its passage through the female reproductive tract. Breach in the zona, while the embryo is still lying in the uterine cavity, waiting to hatch and to be implanted, exposes it to microorganism and immune factors, including antigens. Therefore, use of antibiotics and immunosuppressive drugs has been proposed for patients, whose embryos undergo assisted hatching, as prophylactic therapy, to possibly protect the embryo from local insults. The most preferred therapy is methylprednisolone (16 mg four times a day) and tetracycline (250 mg four times a day) started from the day of oocyte retrieval. However, the utility of these drugs is still not established and should be regarded as empirical for the time being.

CONCLUSION

The latest guidelines published by the American Society for Reproductive Medicine (ASRM) and SART (2022) (investigating the role of assisted hatching in IVF) state that there is moderate evidence that assisted hatching does not significantly improve live birth rates in fresh IVF cycles. In patients with poor prognosis (such as those of advanced maternal age or with recurrent implantation failure) or undergoing frozen embryo transfer cycles,[30] the available data are insufficient to demonstrate any benefit of laser-assisted hatching. Hence, ASRM in its recommendations states that currently, laser-assisted hatching should not be incorporated in to routine clinical practice for all patients undergoing IVF.[27]

KEY POINTS

- Assisted hatching has been applied during IVF treatment in an attempt to improve pregnancy rates. However, the application of assisted hatching as a technique has still not gained widespread acceptance, even though some publications report improved implantation rates with its use.
- The laser system has been better appreciated for its precise and atraumatic mode of action when compared to PZD or zona drilling with acid solution, and therefore might be very important in future as an adjunct to IVF treatment.
- Use of prophylactic steroid and antibiotic treatment is controversial and may not be recommended for routine use after embryo transfer.
- Further research is needed, utilizing more recent and standardized techniques, with properly conducted prospective RCTs in a well-defined subgroup of patients to allow better appraisal of results.

CHAPTER 113

Preimplantation Genetic Screening and Diagnosis: Laboratory Aspects

Krishna Chaitanya M, Durga G Rao, Sushma Baxi, Abhishek Shah

INTRODUCTION

Assisted reproductive technologies (ARTs) are currently focused on introducing advanced technologies to improve live birth rate (LBR), which includes extending embryo culture till the blastocyst stage, along with algorithms and annotations including the time-lapse technology to select the single embryo for transfer that has the best implantation potential. Above criteria help in the ultimate goal of safe mother and a healthy child. Preimplantation genetic testing (PGT) is one of the advanced ART methods which has been introduced to enhance the reproductive outcomes further. Since its first report in 1990,[1,2] till date, there has been a lot of developments with PGT, in both clinical application and laboratory aspects for embryo biopsy and genetic screening; currently, the updated version in practice is 3.0 as suggested by the European Society of Human Reproduction and Embryology (ESHRE) special interest group. This chapter, in particular, will deal with the laboratory aspects of PGT. A prerequisite for successful implantation of PGT program is the laboratory setup, which will be dealt with in detail in this chapter. Ideal embryo stages for biopsy, ideal platform for chromosomal screening, and ways to handle the limitations of PGT have been extensively researched in the past few years. Despite advancing technology and successful implementation of PGT, controversy still exists about the application of PGT routinely to all infertile couples seeking ART.

TERMINOLOGY

In the past few years, the terminologies of preimplantation genetic screening (PGS) and preimplantation genetic diagnosis (PGD) have changed and are currently referred to as preimplantation genetic testing.

Preimplantation genetic testing is divided into three subtypes as mentioned below:

1. *PGT-A (aneuploidy):* PGT-A determines whether the correct numbers of chromosomes are present in the embryo. It was previously known as PGS (pregenetic screening). It is indicated in cases such as advanced maternal age (AMA), recurrent implantation failures (RIF), recurrent pregnancy loss (RPL), and severe male factor (SMF) couples. PGT-A deals with aneuploidy in embryos alone.
2. *PGT-SR (structural rearrangement):* PGT-SR screens for chromosomal translocations, inversions, and deletions. This also identifies the embryos with the correct amount of genetic material (balanced/normal) and embryos that have extra or missing genetic material. PGT-SR deals with screens for structural rearrangements such as translocations, inversions, and deletions in an embryo.
3. *PGT-M (monogenic):* PGT-M screens for deoxyribonucleic acid (DNA) pathogenic variant(s) causing single-gene disorders, also called monogenic disorders.[3] It was previously known as PGD (pregenetic diagnosis). It is indicated in cystic fibrosis, cancer (autosomal dominant disorders), Huntington's disease, thalassemia, sickle cell anemia, hemophilia, fragile X syndrome, etc.

Human leukocyte antigens (HLA) typing: HLA-matched embryo selection via PGT is the best option in couples who already have an affected child with malignancy, genetic disorder, or an acquired disorder where the affected child can be treated with stem cell therapy from an HLA-matched sibling.[3]

This change in terminology to PGT along with the usage of comprehensive chromosomal screening (CCS) methods such as next-generation sequencing (NGS) has been termed PGT 3.0 version by the Preimplantation Genetic Diagnosis International Society (PGDIS).

SETTING UP A STATE OF ASSISTED REPRODUCTIVE TECHNOLOGY LABORATORY AND AN EFFICIENT PROGRAM FOR PREIMPLANTATION GENETIC SCREENING/ PREIMPLANTATION GENETIC DIAGNOSIS

A PGT program involves several units. Ensuring optimal communication between these units has to be clear and informative with the implementation of strict quality control.[4]

Informed consent from all patients entering the PGT program regarding the expected results, details of the PGT cycle from start to end, and the limitations of the technique should be undertaken. Treatment consent forms should be discussed with the patients in detail, in the language they understand, and a written consent to be obtained prior to starting the procedures.

Every couple seeking PGT needs detailed evaluation of reproductive history and adequate genetic counseling as a part of the preliminary workup, particularly for couples at high genetic risk due to chromosome structural abnormalities or monogenic diseases.

It is advisable to set up the embryology laboratory as per the guidelines for good practice in an in vitro fertilization (IVF) laboratory prepared by the ESHRE Embryology Special Interest Group.[4] Standard operating procedures (SOPs) should be collected in a manual that is kept updated by the laboratory director; the current version should be accessible to every member of the staff. This ensures strict uniformity of treatment. The procedures for single-embryo culture, cell biopsy, tubing of the tissue, transportation of the tissue post biopsy, details of the genetic laboratory, and later transfer of the selected embryos on the basis of the genetic results are additional aspects expressly related to the PGT program, which should be clearly explained in the SOPs.

Considering the risk of contamination and the risk of embryo toxicity with the extensive use of cleaning solutions, it is recommended to have a separate designated area exclusively for embryo biopsy and cell tubing.

Standard operating procedures should also have a detailed checklist for carrying out the embryo biopsy in the IVF laboratory.

Following are few of the aspects the checklist should have:

- Details of validation and calibration of various laboratory equipment
- Adequate stock of consumables, disposables, and culture media required for the biopsy
- Proper planning of IVF cycles and other procedures in the IVF laboratory to ensure balance between ongoing cycles, manpower, and the load acceptability of the laboratory
- Availability of the adequate laboratory staff is mandatory.
- Ensuring optimal cleaning of IVF laboratory pre- and post-biopsy.
- Intimation to the genetic laboratory through a test requisition form about the indication for PGT, expected oocyte retrieval date, number of embryos, stage of biopsy, tentative plan for embryo transfer fresh or frozen cycle, and organizing the transportation of samples post biopsy.

Equipment and Disposables for Embryo Biopsy

- Class 100 vertical laminar air flow (LAF) with a stereo zoom microscope
- Micromanipulator with an inverted microscope, heated stage, and a diode laser
- Benchtop incubator to temporarily store embryos during the biopsy process
- –20°C freezer to store the biopsied tissue till it is transported to the genetic laboratory.
- Inverted microscope equipped with:
  - Micropipettes:
    - Holding pipettes
    - Biopsy aspiration pipettes.

Reagents

- 2.1 media for biopsy
- Ca^{2+} and Mg^{2+} free buffer
- Human serum albumin (HSA)
- Mineral oil.

All of these above-mentioned reagents have to be new, unopened bottles.

PATIENT MANAGEMENT

An important prerequisite for PGT is patient counseling and informed consent.

The need for PGT is to be discussed in detail. Especially in couples undergoing PGT, feasibility of the genetic laboratory to handle the underlying gene defect and the process has to be elaborated. For PGT cycles, pre-PGT workup for designing the probes for the particular single gene has to be planned beforehand. This might involve transportation of blood samples of the couple, parents of the couple, and sometimes the affected child. The genetics laboratory will design the necessary probe and use this at the time of PGT and arrive at a final report of normal embryos, carrier embryos, and affected embryos. Pre-PGT workup might take 2–6 weeks; therefore, keeping the patient informed about the timelines is very important. However, karyomapping is a new technique that is evolving which is a universal probe and the pre-PGT step can be skipped, which ensures a quicker process time

for PGT couples. Further data for routine usage is yet to be established.

Reproductive counseling would involve an in-depth evaluation of reports and formulation of a plan. Counseling should also address the success rates, financial logistics, and limitations of PGT.

HISTORY, COUNSELING, CONSENTING, AND DOCUMENTATION

Before starting a clinical cycle, extensive genetic and reproductive counseling is provided to the prospective parent(s). Psychological support may be offered as well.

Detailed couple history and family history are of upmost importance before offering genetic analysis options and starting clinical treatment.

- Complete medical history of the couple and child/children if applicable.
- Complete medical and genetic history of the family of the couple with direct blood relation.
- Possible karyotype of the couple and child/children if applicable.
- Complete counseling of the stimulation cycle, oocyte retrieval and risk of medical complications, embryo formation rate and biopsy stage, risks associated, and survival of embryo biopsy and cryopreservation.
- Counseling of embryo transfer policy of the organization and local regulations.
- Minimal risk of no conclusive results, misdiagnosis rate, limitations of the testing methods, and possibility of epigenetic disorders can arise with the continuation of pregnancy, etc., which are to be explained in detail.
- Percentage of conception with PGT embryos and miscarriage rates to be counseled.
- Cost factor for the entire process and timeline required for it should be estimated to the couple.
- In embryos having genetic abnormalities and not selected for transfer, the option of donation for research or training should be selected as per the country's regulations and guidelines.
- Entire counseling, all risk factors, and possibilities to be counseled by the treating physician and genetic counselor, and written consents are to be taken, framed by local regulations and organization.
- Entire counseling and consenting (preferably) is to be done in the couple's local or known language.

IN VITRO FERTILIZATION STIMULATION PROTOCOLS

Preimplantation genetic diagnosis/preimplantation genetic testing is an expensive and laborious process. There is no probability as to how many embryos will have a normal genetic status after screening. Hence, it is always desired to have a good ovarian response to hormonal stimulation.

Poor responders should be counseled regarding their reduced success rates, and also a balance needs to be maintained between feasibility for PGT, cost, success, and alternative approaches to optimize reproductive outcomes in this group of patients.

Stimulation protocols should be devised to increase the optimal number of retrieved oocytes but a calculated approach to avoid ovarian hyperstimulation syndrome (OHSS).

CHOICE OF ASSISTED REPRODUCTIVE TECHNOLOGY FOR PREIMPLANTATION GENETIC SCREENING/PREIMPLANTATION GENETIC DIAGNOSIS

In cases where fluorescence in situ hybridization (FISH) is used for screening, there are no restrictions on the technique of insemination. However, for carriers of single-gene disorders where polymerase chain reaction (PCR) will be applied or for molecular [comparative genomic hybridization (CGH) and DNA microarrays] assessment of chromosome status, intracytoplasmic sperm injection (ICSI) is recommended in order to avoid sperm contamination.[5] For the same reason, the removal of corona cells should be especially meticulously performed. Additionally, to ensure an optimal tracking of embryo post biopsy, keeping them in individual culture drops prior to cryopreservation is mandatory. Therefore, necessary culture plates with provision for single droplet culture depending on the number of embryos for biopsy are to be planned. A recent guideline by the American Society for Reproductive Medicine (ASRM) recommends the usage of ICSI for PGT in the absence of male factor infertility, which should be restricted to situations where contamination of extraneous sperm could affect the accuracy of test results.

IDEAL STAGE FOR EMBRYO BIOPSY

Scientists have attempted embryo biopsy for genetic screening at various stages. This segment will address the pros and cons of each stage and discuss the ideal stage for biopsy in the current scenario. Considering that the traditional biopsy techniques are invasive, the current focus has been to introduce noninvasive techniques to perform genetic screening, but further validation and efficiency of traditional biopsy techniques are yet to be proven.

POLAR BODY BIOPSY

Polar body (PB) is extruded after completion of the first meiotic division in a mature metaphase II (MII) oocyte and after completion of the second meiotic division in a zygote. PBs are a haploid set of chromosomes in an MII oocyte, and in zygote, it is the extra set of chromosomes.

PB biopsy is considered to mirror the genetic status of the oocyte or zygote. PB biopsy is relatively less invasive when compared to the blastomere or trophectoderm (TE) biopsy. In countries where regulations do not permit blastomere or TE biopsy, PB biopsy is the preferred stage. As per ESHRE, PGT consortium use of PB biopsy for genetic screening is still debatable. Several studies have highlighted technical, economical, biological, and clinical deficiencies underlying this approach. Capalbo et al.[6] inferred that PB biopsy gives high false-positive and -negative error rates when compared against other stages. There is an operative concern and lack of consensus on whether to biopsy the first PB of mature metaphase oocyte in one sitting and the second PB in a separate sitting or should it be biopsied simultaneously at the zygote stage. There is no consensus on the timing of PB biopsy, although 8–14 hours post fertilization seems to be optimal. There is a risk of enucleation due to spindle remnants if biopsy is performed too early or a risk of degeneration if biopsy is delayed.[7]

In the current scenario, the application of PB biopsy is gradually reducing in favor of TE biopsy due to lack of supporting data in terms of its efficacy and diagnostic accuracy.[8]

CLEAVAGE STAGE BIOPSY—BLASTOMERE BIOPSY

Cleavage stage biopsy is normally performed on day 3 embryos post insemination with at least six blastomeres.

Cleavage stage embryos are briefly exposed to calcium/magnesium (Ca/Mg) free medium to loosen up the gap junction and compaction between the blastomeres making the process of biopsy easier. Scientists have posed a concern with the inappropriate use of Ca/Mg free medium, which would adversely affect the blastulation process.[9] Mice models have shown this exposure to be detrimental.[10,11] A final conclusion is still elusive. As per ESHRE, PGT consortium cleavage stage biopsy still remains to be the most commonly followed method for PGT than TE biopsy.[12]

After exposure to Ca/Mg-free medium, the next step is assisted hatching. Assisted hatching of zona pellucida to facilitate biopsy can be done by laser-assisted hatching (LAH)[13] or Tyrode drilling[14] or mechanically by use of pipettes.[15] Randomized controlled trials (RCTs) on sibling embryos have shown all three methods to be safe and show no detrimental effects on clinical outcomes.[16,17]

PROTOCOL FOR EMBRYO BIOPSY AND TUBING

General Rules to Prevent Contamination

Always use gloves for the manipulation of all the material and samples. All disposables, consumables, and gloved hands have to be wiped with 70% ethanol to avoid contamination.

PROTOCOL—BLASTOMERE BIOPSY

- Warm buffer supplemented with 5% HSA at 37°C for 20 minutes before starting (to make this buffer, take 1.8 mL of Ca/Mg free buffer and add 200 µL of HSA in a 5 mL tube and leave in the gassed incubator with a tightly closed cap).
- Place the culture plates in the laminar flow hood over the heated area.
- Check day 3 embryo morphology. Use the following criteria to choose embryos to biopsy:
  - *Cell number:* More than six cells
    - *Fragmentation:* <20%
    - *Multinucleate:* <50%
    - *Nucleus:* Present
- Place the aspiration (right hand) and holding (left hand) pipettes at the microinjectors and focus them.
- Prepare a biopsy plate with drops of biopsy media covered by mineral oil. For each embryo: Prepare one drop to wash the embryo (50 µL), one drop to wash the pipette (35 µL), and one drop to place the embryo (35 µL). There should not be more than two embryos per plate. See **Figure 1** for an example of two embryos.
- Turn on the laser.
- Label the plate with the patient's name at the top and the embryo number in the base, close to the corresponding drop.
- Place the embryos into the biopsy plate (one per drop).
- Wash the aspiration pipette in the washing buffer drop.
- Focus the embryo and hold it with the holding pipette. Rotate the embryo to select a blastomere for removal (choose one with only one nucleus).
- Make a hole of approximately 30 µm diameter in the zona pellucida using as few laser pulses as possible.
- Gently insert a biopsy pipette through the hole while holding the embryo with the holding pipette.
- Wash the aspiration pipette after the first embryo is biopsied. Use a new pipette if there is remaining cytoplasm from the previous cell.

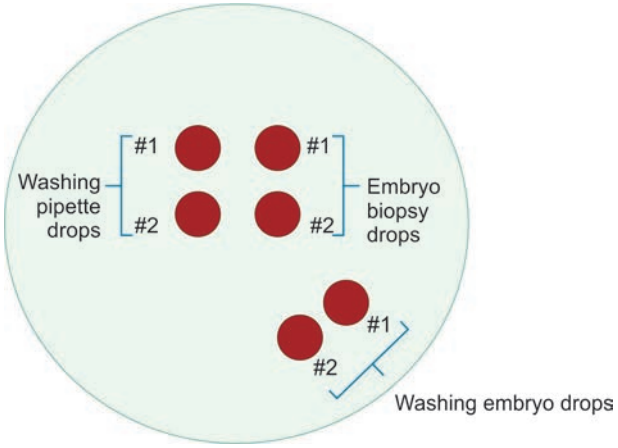

Fig. 1: Preparation of biopsy plate with drops of biopsy media covered by mineral oil: No more than two embryos per plate.

- Apply a gentle suction to grasp one blastomere and gently pull out the biopsy pipette while maintaining the suction. *Caution:* If the blastomere is still attached, extreme care should be taken at this point to avoid breaking the plasma membrane. Any sudden aspiration or movement should be avoided.
- Remove the blastomere with the pipette completely out of the embryo and gently expel the blastomere in the medium.
- Remove the embryos from the biopsy plate and wash them in drops of cell culture medium (CCM) to remove traces of buffer. Place embryos in their prolonged culture drops/wells.
- The blastomeres should remain on the biopsy plate until further processing based on the subsequent analysis type [FISH, array comparative genomic hybridization (aCGH), and PCR].

ADVANTAGES OF CLEAVAGE STAGE BIOPSY

- Biopsy at this stage is less operator dependent.
- More reproducible.
- Embryos in the cleavage stage are more synchronous and are similar in terms of morphology, and biopsy can be attempted in one sitting.
- It is easier and convenient to biopsy a second blastomere immediately at the cleavage stage for any reason. Contrary to this, when a TE biopsy is done, a second biopsy immediately might be difficult due to the collapse of the blastocoel cavity.
- Embryo biopsy at the cleavage stage and fresh embryo transfer at the blastocyst stage are possible in the same cycle. On the other hand, a fresh transfer after TE biopsy is difficult unless there is an in-house genetic laboratory.

LIMITATIONS OF CLEAVAGE STAGE BIOPSY

- Breaching of zona for biopsy at cleavage stage would impact blastocyst formation rates.[18]
- Removal of a few blastomeres would adversely affect clinical outcomes.[19]
- Kirkegaard et al.[20] did a comparative study of cleavage stage biopsied embryos and nonbiopsied embryos using time-lapse technology. Their findings showed that there was delayed compaction and blastocoel expansion in biopsied embryos at cleavage stage.
- Blastomere biopsy is associated with a high rate of amplification failure.[21]
- Chromosomal mosaicism is highest at the cleavage stage, and this might lead to errors in clinical management. In order to avoid this, two blastomere biopsies were suggested, but this would negatively impact the embryonic cell mass and the clinical outcomes further.[22]
- In 2013, Scott et al. did an RCT of transferring one biopsied (cleavage stage biopsied embryo) and one nonbiopsied good-quality embryo from the same cohort. A dramatic 39% relative reduction in implantation rate was reported when cleavage stage biopsy was conducted with respect to control.[23]
- Considering the fact that embryos at cleavage stage are relatively fragile since embryonic genome activation and cell differentiation processes are not completed, removal of a cell at this stage would compromise further developmental events and clinical outcomes.[24-26]

Though at this point TE biopsy seems to be a preferable option over cleavage stage biopsy, owing to the ease of cleavage biopsy, there are a lot of RCTs ongoing to further evaluate its efficacy with newer CCS methods as most of the studies have been done with FISH in the past.

MORULA STAGE BIOPSY

Morula stage biopsy is not a common practice; however, some groups have shown morula biopsy to be beneficial owing to the more number of blastomeres available for biopsy.[27] Technically, the biopsy process is similar to cleavage stage biopsy, and similar limitations are applicable. The risk of mosaicism still remains a concern at the morula stage in comparison with TE biopsy. Hence, morula stage biopsy is not widely practiced.

BLASTOCYST STAGE BIOPSY

In the year 2004, de Boer et al. reported successful biopsy and PGT of TE tissue,[28] and later in 2005, live births were reported by McArthur et al. and Kokkali et al.[29,30] TE biopsy of blastocysts was a major breakthrough in the field of PGT.

PROTOCOL FOR TROPHECTODERM BIOPSY

- On day 3 of embryo development or day 5, make a small hole (approximately 20 μm) in the zona pellucida using the laser or acid Tyrode's in each embryo.
- On day 5 of embryo development, pretemper and precalibrate the biopsy medium for at least 4 hours.
- Place the culture plates in the laminar flow hood over the heated area.
- Check day 5 embryo morphology. Hatching TE is the ideal situation. In case the embryo is not hatching, locate the hole created on day 3 and attempt to reach the TE through the hole. Try to avoid the use of laser near the inner cell mass (ICM).
- In the case of vitrified embryos without assisted hatching, you can force the hatching of a cavitated blastocyst by making a small hole at the zona pellucida with a laser. The blastocyst will likely collapse, and then you have to wait for re-expansion before performing the biopsy.
- Prepare a biopsy plate with drops of biopsy media covered by mineral oil. For each embryo, prepare one drop to wash the embryo (50 μL), one drop to wash the pipette (35 μL), and one drop to place the embryo (35 μL). Only one embryo per plate should be used. See **Figure 2**.

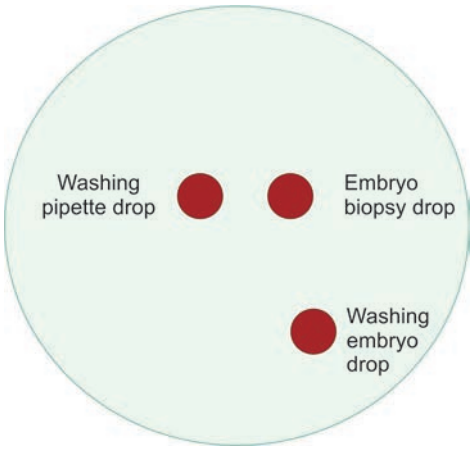

Fig. 2: Preparation of biopsy plate with drops of biopsy media covered by mineral oil: Only one embryo per plate.

- Label the plate with the patient's name at the top and the embryo number in the base, close to the corresponding drop.
- Place the plates in the dry incubator at 37°C.
- Place the aspiration (right hand) and holding (left hand) pipettes on the microinjectors and focus them.
- Place the blastocyst into the biopsy plate (one per drop).
- Turn on the laser.
- Hold the blastocyst so that hole created on day 3 is at 3 o'clock. If possible, the ICM should be at 6 or 12 o'clock. If this placement is not possible, try to avoid aspirating near the ICM.
- Change to the laser objective.
- Place the aspiration area on the target.
- Slowly bring the biopsy pipette close to the blastocyst.
- Apply gentle suction to grasp several cells and use four to six laser pulses to cut the TE. Caution: If the TE is still attached, release the blastocyst and squeeze the aspiration pipette to the holding pipette and make a quick movement down to separate the group of cells. Gently expel the TE in the medium.
- Remove the blastocyst from the biopsy plate and wash it in drops of CCM. Place blastocyst in its prolonged culture drops/wells.
- The TE remains on the biopsy plate until further processing according to the subsequent analysis type (FISH, aCGH, and PCR).
- Wash the aspiration pipette before the biopsy of each embryo. If there is any remaining debris from the previous embryo, use a new pipette to avoid cross contamination.

TUBING PROTOCOL: ARRAY AND SINGLE-GENE DISORDERS (BLASTOMERE OR TROPHECTODERM)

Materials Required

Equipment

- Stereomicroscope for cell manipulation from plate to PCR tube
- Automatic pipette 2–20 µL. Use exclusively for this purpose and always with gloves
- Sterile tips, with filter and DNA/ribonucleic acid (RNA) free
- Microcapillaries of a diameter between 100 and 130 µm
- Petri dishes (6 cm dishes from BD Falcon 3002)
- Sterile 0.2 mL PCR tubes with 2 µL of phosphate-buffered saline (PBS) solution—provided by genetic laboratory (stored at –20°C)
- Sterile safelock 1.5 mL tubes with 1 mL of cell washing media [1% PBS–polyvinylpyrrolidone (PVP)]—(stored at 4°C)
- Laminar flow hood with ultraviolet (UV) lamp
- PCR cooler rack
- Minicentrifuge for 0.2 mL PCR tubes.

Methodology

General Rules to Prevent Contamination

- Always use gloves cleaned with alcohol for manipulation of all the material and samples of this procedure.
- Switch off the heated stage of LAF. Tubing to be performed at room temperature (RT).
- The embryologist should wear a disposable operating room gown and cap.
- Before starting the procedure, turn on the UV lamp and the laminar flow for at least 15 minutes. Clean with alcohol the surface of the cabinet and the external surface of all the material that will be used for tubing (tip boxes, automatic pipettes, capillaries boxes, etc.). The placement of the cell within the PCR tube must be performed inside the laminar flow hood and under the stereo microscope.
- Things to be kept in the LAF for tubing:
  - 3 mL transfer pipettes (BD Falcon 7575)—two of them
  - Oil in 14 mL tubes at RT for making the dishes for washing the biopsied material
  - 2–20 µL micropipette tip from Gilson2
  - Micropipette—2–20 µL volume
  - 6 cm dishes from BD Falcon 3002—two dishes for every four embryos
  - Glass denuding pipettes—one per embryo
  - Two sterile semen collection containers
  - PBS + PVP tube—stored at 4°C
  - PCR tubes with the rack—this is stored at –20°C
  - Mouth pipette/stripper handle with glass stripper
  - Marker pens
- An isolated room is recommended for single-cell manipulation, if possible a room separate from the IVF laboratory. Avoid manipulating DNA in this room and in the freezer and fridge where the solutions are stored.

Protocol

- Every step should be performed using gloves, and all the material (not the embryos) should be exposed to UV light before starting the procedure.

- Use one new capillary for each individual cell (day 3 biopsy) or TE biopsy
- Place the mini spin inside the hood and spin the PCR tubes with 2 µL of PBS before starting. Check that there are no bubbles inside the PCR tubes and confirm that liquid is at the bottom of the tube. Manually, we can just shake the tubes to bring the PBS solution to the bottom of the tube.
- Prepare a Petri dish with one row with three droplets of 5 µL of cell washing media (1% PBS–PVP) for each embryo (include six rows maximum in one plate) and cover with mineral oil. Each blastomere/TE sample should be rinsed in these droplets.
- Place the blastomere/TE sample inside the PCR tube under the stereoscope. The embryologist should observe the release of the cell(s) inside the tube. This step is a key point of the procedure, and the cell(s) should be released inside the tube with a minimal volume of washing media (maximum 0.5 µL).
- For genetic disease testing only, submit one blank for each embryo sample. A blank is not needed for array testing.
- *Creating a blank*: After releasing each cell into the collection tube, release the remaining fluid in the capillary into a new collection tube to create a blank. If there is not enough solution left in the capillary, aspirate a small amount of the last washing drop used for this embryo with the same capillary and release into a new collection tube.
- For arrays and genetic disease testing also, include two PCR tubes with the solution but without cells which will be used as positive and negative control during the analysis.
- Close the PCR tubes and place them inside the cooler rack.
- Once every cell has been processed, cover the cool rack with parafilm. Place the cool rack inside the shipping box with at least two freezer packs/negative accumulators securely so the cooler does not move inside the box during shipping.

ADVANTAGES OF TROPHECTODERM BIOPSY

Following are the advantages of TE biopsy:

- TE biopsy has an advantage of higher technical and biological robustness.
- There is a lesser incidence of procedural errors and a lower impact of mosaicism on molecular analysis.[8]
- In general, as per the last Cochrane review, blastocyst stage embryos have higher LBR per embryo transfer than cleavage stage. Additionally, cleavage stage embryos have shown to impact embryo implantation and developmental kinematics compared to a blastocysts stage TE biopsy, inferring TE biopsy beneficial over other stages.[31]
- Considering the current trend of freeze-all policy and an elective single-embryo transfer (eSET) in a frozen embryo replacement cycle has helped to control the incidence of OHSS and multiple pregnancies. Doing a TE biopsy and picking a genetically normal embryo for eSET would give the best results.[23-25]
- At blastocyst biopsy, more TE cells can be obtained and this prevents the risk of nonamplification due to inadequate tissue, which can be a common occurrence in cleavage stage biopsy.
- Not all cleavage stage embryos make it to the blastocyst stage; hence on day 5 we will have a lesser number but competent embryos, which will be subjected to biopsy.

LIMITATIONS OF TROPHECTODERM BIOPSY

- The major limitation is the extended embryo culture system, which requires higher laboratory standards and technical expertise.
- TE biopsy is found to be beneficial only for good prognosis patients. In poor responders and couples with poor embryo quality, the proportion of blastocysts formed and the possibility of TE biopsy are limited.
- Considering the heterogeneous nature of herniation of TE tissue post-LAH for embryo biopsy, there might be a need for multiple sittings for biopsy. On the other hand, in cleavage stage biopsy with six to eight cells, we can do the biopsy in one sitting.
- Possibility for a re-biopsy for technical reasons can be done immediately in a cleavage stage biopsy but might be challenging in a blastocyst due to collapse of the blastocoel cavity.
- Blastocyst formation after extended embryo culture is again heterogeneous and might happen on day 5 or day 6, and in some instances, day 7 also. This calls for multiple sittings of biopsy, which increases not only the operational challenges but also the cost, which could be a major limitation.
- TE tissue is very sticky compared to a blastomere of a cleavage stage embryo. Hence, handling of TE tissue needs a lot of skill and care.
- Care needs to be extended to avoid manipulations with the ICM, which eventually forms the fetus properly.
- TE biopsy does not totally eliminate the risk of mosaicism,[32] but the incidence is lesser than cleavage stage biopsy.

NONINVASIVE METHODS FOR EMBRYO BIOPSY

The earlier embryo biopsy methods, though have been the most common practice, are still considered invasive.

There has been a constant effort to come up with methods which are noninvasive and have similar reproducibility to the traditional methods. A few of the noninvasive methods for genetic screening are as follows.

Blastocoel Fluid Sampling

Palini et al. showed for the first time that blastocoel fluid (BF) has presence of genomic DNA and can be used to screen for single-gene disorders.[33] Magli et al. used array CGH screening technique to evaluate the efficacy of BF biopsies for ploidy prediction in comparison with the conventional biopsy methods, i.e., blastocyst, blastomere, and PB biopsy, and inferred that BF biopsy was comparable to conventional biopsy materials for chromosomal analysis.[34] Nevertheless, embryo quality did show discordance of ploidy prediction between BF and blastocyst biopsy, suggesting that more experiments and clinical trials should be performed before BF sampling is ready for PGT.[34]

Assay of Cell-free Nucleic Acid in Culture Medium

Using cell-free nucleic acids released from embryos in the culture medium, DNA is extracted and screened for chromosomal analysis. This showed higher diagnosis efficacy than blastomere biopsy. However, this method still needs to be further validated by eliminating potential contamination and providing more robust evidence in PGT.[35,36]

Time-lapse Technology for Assessment of Embryo Quality

Continuous time-bound assessment of cellular morphology and morphokinetics is another noninvasive recent technology that is researched extensively. Studies have tried to correlate the timing of morphokinetics with embryo aneuploidy. Meanwhile, different assessment assays and statistical models were applied to refine the morphokinetic variables and increase the chance of predicting a top-quality blastocyst.[37] However, considering the potential technical and statistical error in time-lapse imaging, one should be cautious in over-interpreting the results.[38,39]

Current consensus about the best stage for embryo biopsy for PGT is yet to arrive. PB biopsy has become obsolete. Cleavage and morula stage biopsies have shown to bring about adverse clinical outcomes. TE biopsy seems to be encouraging and optimizing clinical outcomes, but its efficacy in terms of the delivery rate per intention to treat is yet to be proven.

CRYOPRESERVATION OF EMBRYOS

An efficient embryo-freezing program with maximum survival rates is another essential element for PGT program. Improved extended embryo culture systems, TE biopsies of blastocysts, freeze-all embryo policy, and policy of an eSET of a genetically normal embryo in a frozen embryo replacement cycle are all dependent on an efficient embryo cryopreservation program. Over the years, vitrification and warming protocols of oocytes and embryos have dramatically improved and enabled improved reproductive outcomes worldwide. Embryos need to be vitrified single on each cryo device after embryo biopsy. Proper witnessing system to track the identity of embryos from biopsy till cryopreservation is essential. Vitrification at 1.5–3 hours post biopsy in blastocyst is recommended.[40]

Comparative studies on post-thaw survival of biopsied embryos have shown similar survival rates with nonbiopsied embryos, in both cleavage and blastocyst stages.[41,42] Intactness of blastomeres and blastulation process post thaw has shown to be good in cleavage stage embryos after freeze and thaw post biopsy.

IDEAL PLATFORM FOR GENETIC SCREENING

After embryo biopsy, the tissue is tubed in small PCR tubes or it is fixed if the plan is FISH and sent to the genetic laboratory for further evaluation and screening. PGT can be performed at either the chromosomal level or at DNA level. FISH, PCR-based methods, and single-cell genomic methods are few of the techniques applied for PGT. For identifying single-gene mutations, PCR was the first technique introduced for PGT. On the other hand, FISH was introduced to screen for aneuploidies and translocation.

FLUORESCENCE IN SITU HYBRIDIZATION

Fluorescence in situ hybridization is a traditional method practiced for a very long time, for both PGT and prenatal diagnostic tests. Owing to its limitations, FISH is now becoming obsolete. The incidence of false positive and negatives has been shown to be high due to incapability of detecting de novo genetic mutations, contamination, and sensitivity issues.[43] A review and meta-analysis of all RCTs was done in 2011 and compared aneuploidy testing with FISH versus standard IVF without PGT.[44] As per this meta-analysis, aneuploidy screening with FISH showed no beneficial effect on LBRs. On the other hand, AMA patients had even lesser chance to attain live birth. The author's explanation for such results was that it could be due to technical drawbacks and proposed the need for novel screening methods. Technically, FISH screens limited chromosomes and not the entire 24 chromosomes, which is one of the major limitations. FISH is considered to be a low-resolution technique in comparison to newer CCS methods. The combination of these two limitations led to high technical variability, overestimation of mosaicism, and false positives and negative rates as high as 10%.[41]

Application of Single-cell Genomics in Preimplantation Genetic Diagnosis/ Preimplantation Genetic Screening

Single-cell genomics with high resolution has led to a major makeshift in the field of PGT, which enables screening with limited sample size. Whole genome amplification (WGA) and high throughput are the two major basic steps in single-cell genomics. WGA amplifies DNA from a single cell and generates sufficient templates for either microarray or next-generation sequencing (NGS) assays.

New diagnosis methods, such as aCGH, single nucleotide polymorphism (SNP) microarray, multiplex quantitative polymerase chain reaction (qPCR), karyomapping, and NGS, are developed to improve clinical efficiency and outcomes.

Microarrays

Single nucleotide polymorphism and CGH arrays are the two commonly used genetic tests for PGT. The TE cells are lyzed and amplified for WGA for both the microarray platforms.

Single Nucleotide Polymorphism Microarrays

Single nucleotide polymorphisms are pairs of single nucleotides (A, T, C, or G) in genomic DNA. SNPs microarray for PGT evaluates nonexon coding segments of the genome, and approximately 300,000 SNPs are spaced throughout the genome.[45,46] Using this platform, we can identify whole chromosome aneuploidy and it can also detect approximately 250 common structural chromosome aberrations throughout the genome. If enough TE cells are provided, these arrays can identify mosaicism. SNP arrays can generate genotype; hence they can identify uniparental disomy, which other microarray methods cannot. Limitations of SNP arrays are failure to identify aneuploidies in couples with consanguinity, limited ability to identify triploidy, and abnormalities below the resolution of 300,000 that can be significantly missed.

Comparative Genomic Hybridization Microarrays

Comparative genomic hybridization microarrays are less dense than SNP microarrays. These aCGH chips approximately have 4,000 markers spaced throughout the genome. The principle of aCGH is ratio labeling, where the clinical sample is compared to normal 46,XY and 46,XX DNA samples.[47,48] The major advantage of CGH arrays is their time frame to complete the entire analysis in 12–15 hours, whereas it takes around 30–40 hours with SNP arrays. aCGH cannot identify uniparental disomy. It can only identify the whole chromosome aneuploidies but cannot identify structural chromosomal aberrations. Though aCGH can identify mosaicism, there are some studies which have shown that aCGH has an approximate error rate of 15–30%.[49] A comparative study of 400 TE samples with aCGH and NGS has shown similar results and 99% concordance,[50] which encourages its application in the ART industry for PGT.

Quantitative Polymerase Chain Reaction or Real-time Polymerase Chain Reaction

Quantitative polymerase chain reaction or real-time polymerase chain reaction (RT-PCR) is a PCR assay which identifies whole chromosome aneuploidy by detecting the copy number of each chromosome analyzed.[51,52] This assay identifies aneuploidies of all 23 chromosomes in a very shorter time frame but is very labor intensive.[51,52] Even this assay cannot identify structural chromosomal aberrations and uniparental disomy.[49]

Next-generation Sequencing

Next-generation sequencing is a newer CCS method based on ultra-high throughput parallel DNA sequencing that achieves genome-scale sequencing faster. It has an advantage of detecting genetic mutations at a single nucleotide level and can detect aneuploidies such as triploidy and uniparental disomy. NGS is an efficient and robust technology and can be applied for both PGT and PGT.[53] Studies have reported successful live births with its application.[54,55] It has been validated with all stages of biopsy PB, blastomere, and TE.[56-58] There are few studies trying to combine newer noninvasive methods of sampling and NGS, and this would be bringing new excitement and revolutionize the clinical application of PGT.

However, the technical obstacle of nonlinear amplification limits these WGA methods. Single-cell genomics has been applied to comprehensively study the genome and transcriptome of individual cells to select an optimal embryo in IVF.

ERRORS WITH PREIMPLANTATION GENETIC SCREENING TECHNIQUES

Errors could be biological and are termed mosaicism or technical errors.

Mosaic Embryos and the Current Consensus

Mosaicism is defined as the presence of two or more cell populations with different genotypes. In other words, it is the presence of more than one chromosomally distinct cell line in a single sample originating from one individual.[59]

Fluorescence in situ hybridization of sex chromosomes demonstrated mosaicism at cleavage stage in preimplantation human embryos.[60] Occurrence of mosaicism is due to mitotic errors after fertilization during cleavage of embryos.[61] Mosaic embryos can be classified into two categories based on the extent of blastomere involvement: (1) Aneuploid mosaic, where two different aneuploid genotypes exist and 100% of the cells within the embryo are abnormal, and

(2) diploid—aneuploid mosaic, where one population of the cell is euploid and the other is aneuploid.[61]

At fertilization, the human embryo is genomically inactive, and this makes the embryo prone to meiotic errors. After fertilization, the first three cell divisions are dependent on oocyte cytoplasmic transcriptome. Anaphase lag, mitotic nondisjunction, inadvertent chromosome demolition, and premature cell division before DNA duplication[62,63] are few of the reasons explained in the literature for the occurrence of mosaicism. All these reasons support the higher incidence of mosaicism in cleavage stage embryos. In 50% of cases, there is an autocorrection of mosaic cleavage stage embryos to euploid blastocysts. Few theories which explain the autocorrection of aneuploidy are increased apoptosis of aneuploid cells, decreased division of aneuploid cells in relation to euploid cells, or preferential development of euploid cells within the ICM.[64] Trisomic cell populations may self-correct by losing the extra chromosome via anaphase lag or nondisjunction.[65]

New CCS techniques for PGT, such as NGS, have led to increased reporting of mosaicism.[66] The interpretation of mosaicism is complicated, and there is a dilemma whether to transfer such an embryo or not. Literature reports live births from the transfer of mosaic embryos in the past and hence the controversy.[67,68] On the other hand, the transfer of mosaic embryos leads to decreased implantation and decreased pregnancy potential as well as increased risk of genetic abnormalities and adverse pregnancy outcomes.[69] It is preferable to transfer genetically normal embryos over mosaic embryos. However, if there is a need to transfer, this should be done with proper genetic counseling. There are certain mosaic trisomies such as 2, 7, 13, 14, 15, 16, 18, and 21, which have potential risks to the pregnancy outcome and should be avoided in all circumstances. One of the recent studies suggested encouraging the couples to undergo another cycle to obtain euploid embryos, when possible, rather than transferring a mosaic embryo.[69] There is no consensus about transferring a mosaic embryo after PGT currently. However, discussion about the uncertain reproductive outcomes has to be put forward to the couple to make a conscious decision.

Technical Source of Error

A newer technique or newer embryo selection parameter can only be introduced in clinical practice after a structured validation protocol. Any new technique needs assessment for accuracy of specificity and sensitivity. All the CCS methods adapted to or designed to perform PGT screening showed very high consistency in the detection of whole chromosome imbalances when compared to the blinded validation study performed by Capalbo et al. and published in 2015.[49] Till date, there is no consensus on which CCS method gives 100% accuracy; each method has its own benefits and drawbacks.

EMBRYO TRANSFER

After the genetic screening of embryos, the next step is embryo transfer. For cleavage stage embryos, it is possible to consider a fresh embryo transfer. For TE biopsy, a fresh transfer might be challenging. Considering that the frozen embryo transfer (FET) cycle has better uterine implantation rates than a stimulated cycle, FET is preferred to have the best reproductive outcome. At embryo transfer, communication between clinical and embryology laboratory teams is essential to decide on which embryo to transfer. Embryos recommended for transfer should be clearly indicated. Discussing the PGT report with the patient and the intended plan is recommended. Couples where no normal embryos are obtained after PGT need an in-depth discussion about the report and the possible alternatives as the next step.

It is advisable to counsel the couples toward eSET. Forman et al., in their study, showed that eSET after PGT equals double untested embryo transfer in the general population in terms of LBR. This study further emphasizes the need for eSET for PGT patients.

Especially in PGT cases, where a confirmatory prenatal amniocentesis or chorionic villi sampling is advisable to ensure that the fetus is normal, a singleton pregnancy is preferable. Considering the error rates after single cell analysis is not negligible, prenatal diagnostic tests are still recommended. Hence, eSET should be encouraged to couples post PGT.

Embryo transfer catheter, transfer technique, and culture media remain similar to the routine practice of your individual clinics.

Double witnessing of patient ID at embryo thawing and embryo transfer is mandatory.

FOLLOW-UP OF PREGNANCIES

Follow-up of pregnancies is important to evaluate the efficacy of screening methods. Follow-up should be till live birth to ensure and document any adverse outcomes.

Follow-up of infants for identification of major and minor malformations will help determine the effects related to the embryo biopsy procedures and error rates of the screening methods. An extended follow-up would be especially valuable for the evaluation of long-term effects possibly derived from the invasiveness of the technique.

QUALITY CONTROL AND QUALITY ASSURANCE: OUTCOME MEASURES

Considering PGT being multidisciplinary work, the results should be monitored on a systematic basis from each individual center.[4] Outcome measures include the following:

- Proportion of cells overtly damaged during embryo biopsy
- Proportion of cells for which a diagnosis was not obtained
- Misdiagnosis rate per embryo and per pregnancy calculated in vitro

- Misdiagnosis rate calculated in vivo. Implantation rate and clinical pregnancy loss rate
- Take-home baby rate. Multiple pregnancy rate (monozygotic versus dizygotic)
- Minimum number of preclinical assays to be performed in a given laboratory before clinical application
- Criteria to assess the competence of the staff involved in the different steps of PGT.

EFFECTIVENESS AND EFFICACY OF PREIMPLANTATION GENETIC SCREENING IN THE FIELD OF ASSISTED REPRODUCTIVE TECHNOLOGY

In a review published in 2015,[70] Lee et al. summarized all the RCTs, observational and prospective studies that approached CCS-based PGT in comparison to standard care. They were able to show that in both young and AMA patient populations, PGT results in a higher delivery rate per embryo transferred. An eSET after PGT screening is shown to have better clinical outcomes compared to a double embryo transfer in unscreened population. Dahdouh et al. and Chen et al. in 2015 published meta-analyses,[19,20,71,72] which showed that embryo transfer with PGT-screened embryos results in a higher sustained implantation rate per transfer as well as a lower miscarriage rate with respect to the control. These studies also prove the efficacy of advanced embryology techniques introduced to optimize the reproductive outcomes such as extended culture to blastocyst stage, TE biopsy, and CCS, and by adopting a freeze-all and eSET strategy. Ubaldi et al. in 2015 conducted a retrospective study in AMA patient population across the years through all of the above-mentioned advanced embryology techniques and demonstrated similar cumulative LBR per cycle, while the miscarriage, and especially the multiple pregnancy rates, significantly decreased in comparison with non-PGT cycles.[73] Application of PGT in the field of ART is encouraging but needs further data on identifying groups of patients in whom it is beneficial. Multicenter RCTs comparing PGT cycles to standard care, where primary outcome should be the delivery rate per intention to treat, are still eagerly needed. Finally, there is an urgent need for cost-effectiveness analysis for PGT cycles. Majority of the studies published in the literature are on the good prognosis of patient and role of PGT in poor responders and RPL in women is debated, and financial logistics is one of the reasons for concern in poor responders and additionally time to pregnancy in RPL women.[74] Hence, there is a need for cost analysis with a specification to each subgroup.

KEY POINTS

- For successful implementation of PGT program, laboratory setup has to be state of ART and as per the guidelines of ESHRE special interest group.
- Both laboratory and laboratory teams should be geared up to handle extended embryo culture till blastocyst stage.
- ICSI is the preferred ART technique for PGT cases.
- Blastocyst stage seems to be a beneficial stage for embryo biopsy and PGT.
- FISH for genetic screening is obsolete.
- Single genomic techniques such as aCGH and NGS seem to address the technical issues of the traditional screening methods.
- eSET of genetically normal embryos after PGT seems to offer better reproductive outcomes than double-embryo transfers.
- Follow-up of pregnancies till live birth is an essential aspect of the quality management system of the PGT program.

CHAPTER 114

In Vitro Maturation of Oocytes: A Practical Approach

Varsha Samson Roy

INTRODUCTION

In vitro fertilization (IVF) is now a well-accepted and standard technique. Since the first report on the successful live birth in human IVF, this technique has been used to treat millions of infertile couples worldwide. Replacing natural cycle IVF with controlled ovarian hyperstimulation (COH) gave the added advantage of increasing the oocyte yield and the number of embryos for transfer. However, COH does carry a higher risk of ovarian hyperstimulation syndrome (OHSS), which can be potentially a life-threatening iatrogenic complication. In vitro maturation (IVM) was first used successfully in humans in 1991.[1] This technique has been practiced for 25 years with the intention to reduce the risk of OHSS, especially in patients with polycystic ovary syndrome (PCOS). Moreover, the procedure costs were less due to reduced requirement or at times there was no requirement of exogenous gonadotropins. However, the recent developments in COH, such as the use of gonadotropin-releasing hormone (GnRH) antagonist to prevent premature luteinization or the use of GnRH agonist for trigger, and the improved embryo survival rates by vitrification seem to have changed the primary indication of IVM. The fact that IVM oocytes show a lower developmental potential as compared to the in vivo matured IVF oocytes has contributed in its limited use. Recently, IVM has found a new indication in patients undergoing cancer treatment as a means of fertility preservation.[2] A paper published by Pincus and Enzmann[3] in 1935 raised a possibility that mammalian eggs can undergo normal development in vitro; this of course was based on their experience on rabbit oocytes. Later in 1969, Edwards[4] mentioned that human immature oocytes left in culture can undergo maturation in vitro. The first birth after IVM of immature oocytes was reported by Cha[5] in 1991. These oocytes were collected during gynecological surgeries for oocyte donation. It was Trounson et al.[6] who in 1994 reported the first birth through IVM with a patient's own oocytes. The categories of patients selected were the polycystic ovary (PCO) or PCOS group. They also advocated IVM by transvaginal aspiration under ultrasound guidance, thus making IVM seem more "possible and realistic" and paved way in making it more popular and acceptable. Introduction of IVM in regularly cycling women with normal gonadotropin sensitivity was reported by Mikkelsen[7] in 2004. Today, approximately 400 babies have been born through the procedure of IVM.[8]

OOCYTE MATURATION IN VIVO

At birth, there are about a million primordial follicles (female germ cells) in the ovaries. Each primordial follicle is enclosed by a basement membrane which is covered by a single layer of flattened pregranulosa cells. From this pool, a large number of them will grow but only a few are destined to be selected, mature, and will ovulate. At puberty, these follicles will respond to the growing levels of gonadotropins. During each menstrual cycle, a few will respond to the rising follicle-stimulating hormone (FSH) levels to grow, mature, and ovulate. Majority of them will undergo apoptosis and atresia at the early antral stage. During a woman's reproductive life span, she ovulates approximately 400 oocytes with the potential to fertilize and develop further.

During the process of haploidization, the oocytes get arrested at prophase I of meiosis during fetal development (first meiotic arrest). Following puberty, these oocytes undergo extensive growth and completion of the first meiotic division. This is an asymmetric cytokinesis resulting in a secondary oocyte and first polar body formation. These oocytes now undergo the second meiotic arrest at metaphase of meiosis II. The penetration of the sperm during the process of fertilization initiates the resumption of meiosis producing the haploid chromosomal complement within the oocyte. The oocyte is now ready to combine with the haploid chromosomal complement brought in by the sperm resulting in fertilization.

Oocyte maturation is defined as the process by which the oocyte attains the competence to undergo fertilization and embryogenesis. It involves both the nuclear and the

cytoplasmic maturation. Nuclear maturation is identified by the resumption of meiosis, and the extrusion of the first polar body. The events required in preparing the cytoplasm for fertilization and embryogenesis constitute cytoplasmic maturation. This, however, has no visual parameter unlike the nuclear counterpart and involves complex pathways required for protein synthesis and phosphorylation, reorganization of the cytoplasmic organelles (e.g., exocytosis of the cytoplasmic granules, formation and localization of the microfilaments), and activation of particular metabolic pathways to assist in the process. The human oocyte has a size-dependent ability to resume meiosis and complete the maturation in vitro, and this increases significantly as the size of the oocyte increases to 90–120 μm in diameter.[9,10]

For optimum outcome, both the nuclear and the cytoplasmic maturation should be well programmed and synchronous. As both can proceed independent of each other, oocytes can acquire competence to undergo cytoplasmic maturation independent of competence to complete nuclear maturation.[11] This asynchrony between the nuclear and cytoplasmic maturation seems to be one of the major hurdles in the process of successful IVM culture.

Granulosa cells seem to play a vital role in the process of oocyte development and maturation. By retaining the granulosa cell viability and function and the primary elements of follicular culture, Staigmiller and Moor[12] were able to maintain maturation and developmental competence of oocyte–cumulus complexes (OCCs) in the mouse when removed from their follicular environment. Oocyte growth is proportional to the granulosa cells. They increase the surface area of the oocyte and hence increase the maturation regulatory and nutritional molecules entering the egg. They are essential for the metabolic needs of the oocyte and also improve the competence of the oocyte to undergo nuclear maturation.

ADVANTAGES AND INDICATIONS FOR IN VITRO MATURATION

Historically, patients with PCOS were the selected group for IVM. Of recent, patients with different causes of infertility—tubal, endometriosis, and male factor—and those with a history of poor response to gonadotropin stimulation seem to be considered for IVM.[13]

The advantages provided by IVM include reducing or curtailing the risk of OHSS by reducing the requirement of gonadotropins and hence making the procedure cost-effective. Reduction in the monitoring aspect by scan and blood tests makes it more patient friendly. IVM seems a safer option in terms of the long-term theoretical risks of exogenous gonadotropins, which is yet to be determined.[14] In patients undergoing chemotherapy or radiotherapy which is gonadotoxic, fertility preservation becomes an important aspect because of the better survival rates of these patients post treatment. Cryopreservation of their immature oocytes followed by IVM years later has become a very important practical advantage of IVM.

About 15–20% of the oocytes retrieved during the standard IVF cycles are immature; IVM of these oocytes can put them to good use. These could be a compromised group of follicles.[15] However, immature oocytes obtained from conventional stimulation cannot be compared to those obtained from small antral follicles during IVM, as they exhibit poor developmental potential. One of the reasons for this could be poor perfusion of these follicles and poor response to gonadotropin stimulation.

The field of oncology has seen marked changes in the diagnosis and treatment options which reflect in the increased cancer survival rates. However, the impact of these treatment options on lowering the fertility remains to be a concern. The options for fertility preservation in women are embryo, oocyte, and ovarian tissue cryopreservation. Though embryo cryopreservation is the most effective among them all, it is not suitable for women without a male partner. Ovarian tissue cryopreservation requires repeated operations and lack of standard reliable protocols for ovarian tissue freezing. Oocyte cryopreservation overcomes these shortcomings and is currently regarded the most promising option for female fertility preservation. IVM can be performed urgently irrespective of the phase of menstrual cycle and even without ovarian stimulation.

The potential indications for IVM include:

- PCOS- and PCO-like ovaries
- Hyper-responders and patients with a history of OHSS
- History of oocyte maturation abnormalities
- Emergency oocyte aspiration due to malignancy (estrogen-sensitive tumors)

- Resistant ovary syndrome.

CLINICAL ASPECTS OF IN VITRO MATURATION

The technique of IVM is far from standardized. The patient selection, stimulation protocols, culture conditions, and stage of embryo transfer (ET) vary considerably between clinics. These reflect in the extremely variable pregnancy rates that are being reported. There also seems to be a substantial difference of opinion among the clinicians relating to IVM. PCO and PCOS patients seem to be the ideal candidates for IVM; not only are they at the risk of OHSS but also they possess a huge number of resting follicles as compared to the non-PCO group. There is a huge cohort of growing follicles within the cortex and failure of dominance of a particular follicle. It is not uncommon to find ≥20 small- to medium-sized antral follicles in this group.

It was suggested that oocytes from patients with PCOS would be suboptimal as they are in an abnormal endocrine environment with stasis of follicular growth.[16] It is interesting to note that most of the oocytes obtained from these follicles do not show atresia or reduced developmental competence.[17] It has been reported and has been our experience as well that oocytes recovered during the cesarean section can also mature in vitro and form embryos and blastocysts.[18,19]

In natural cycle IVM, the regular baseline scan is done on day 2 or day 3 of periods. Between day 6 and day 8, another scan is done to assess not only the follicular size but also the endometrial thickness. Follicular aspiration is timed when the dominant follicle reaches 12 mm but does not exceed 14 mm in size. This would usually be seen between day 8 and day 10 of the cycle. Human chorionic gonadotropin (hCG) trigger may or may not be given though there are obvious benefits of administering hCG. The endometrium at least needs to be 5–6 mm on the day of oocyte pickup (OPU).[17] Some investigators also believe that if the leading follicle is >10 mm, the blastocyst developmental potential is impaired.[20,21] The pregnancy rates can be low in cycles where dominant follicle was >13 mm.[22]

Controlled ovarian hyperstimulation for IVM cycles has involved the use of clomiphene citrate, letrozole, recombinant or urinary FSH, or human menopausal gonadotropin (hMG). COH protocol involving hMG or FSH priming and hCG trigger seems to have a better maturation rate and developmental competence.[23] Gonadotropin priming improves the maturation rate and adds to rapid progression of meiosis I and improves the first polar body extrusion rate.[1,24,25] However, not all studies were able to prove any beneficial effect of gonadotropin priming on maturation rate and fertilization rate on embryo development.[26]

In vitro maturation done with mild ovarian stimulation involves a baseline scan followed by 75 IU of gonadotropin for 4–6 days. This dose can be continued till the follicles reach 11–12 mm in size. On an average, a total dose of 300–450 IU may be required. Physiologically, FSH priming with or without insulin-sensitizing agents would be a better choice to overcome the androgenic intrafollicular environment that causes ovulatory dysfunction in patients with PCOS. hCG trigger is given at 11–12 mm follicle size and aspiration is done 35–36 hours post-hCG administration.

Endometrial preparation is considered mandatory as the follicular phase length is reduced due to reduced exposure to estradiol (E2) in the proliferative phase. Also, the nonexisting corpus luteum can lead to loss of hormonal support in the secretory phase of the endometrium. For endometrial preparation, patients receive E2 valerate daily (6–10 mg orally in divided doses) beginning on the day of oocyte retrieval. This is followed by progesterone support (600 mg/day of micronized progesterone per vaginally) beginning on day after retrieval. Starting E2 very early in the follicular phase may reduce the maturation and the cleavage rates.[27] Child et al.[28] found the endometrial thickness at the time of ET to be different in pregnancy cycles as 10.2 ± 2.0 mm versus that in nonpregnancy cycles (9.4 ± 2.1 mm).

If the endometrial buildup is not satisfactory, then the decision to freeze the embryos can be considered. All freeze cycles are being practiced in many centers and recommending it for IVM cycles seems appropriate.

Triggering before Oocyte Pickup

Both hCG and gonadotropin-releasing hormone agonist (GnRHa) can be used for the final trigger, though most of the available data is related to hCG. The dose of hCG is 10,000 units and there seems to be no dose-dependent effect on the maturation rate between 10,000 and 20,000 IU.[29] But other embryo developmental parameters need to be studied. Controlled ovarian stimulation (COS) with FSH and an hCG trigger is considered as a "truncated IVF" cycle.

The number of oocytes retrieved with dispersed cumulus complex seemed higher (64.3%) when oocytes were exposed to hCG for 38 hours as compared to the 35-hour group (37.5%).[30] In this study, the number of oocytes matured in vivo and in vitro on day 1 of culture was higher in the 38-hour group and so was the clinical pregnancy rate. The authors concluded that the better pregnancy rate in the 38-hour group is attributed to an increase in the quantity of embryos produced from oocytes matured in vivo and matured faster in vitro.

The hypothesis is that hCG may promote initiation of oocyte maturation in vivo and hasten the rate of maturation in vitro. This may also improve the pregnancy rates. It loosens the cumulus contact with the follicular wall, hence making aspiration of the smaller follicles easier and thus increasing the oocyte retrieval rate. In studies comparing different protocols of IVM in PCOS, hCG priming which was not dose-dependent raised the maturation rate from 69 to 84%, fertilization rate from 45 to 80%, pregnancy rate from 31 to 38.5%, and live birth rate (LBR) to 33%.[31]

However, a recent Cochrane review found no conclusive evidence of the beneficial effect of hCG trigger on the clinical pregnancy rate and LBR.[32] In a randomized controlled trial (RCT) involving 172 cancer patients comparing no trigger, hCG trigger, and GnRH agonist trigger, the authors found no difference in the oocyte retrieval rate or the maturation rate between these three interventions.[33]

IN VITRO MATURATION ASPIRATION

Specially designed 17-gauge single-lumen aspiration needles are used which may be single or double lumen. These needles are more rigid with a shorter bevel and of a lesser length as compared to the conventional needle. The shorter bevel prevents the needle from going through the small-diameter follicles aspirated in IVM. The shorter length of

the needle helps to accumulate less aspirate volume. The aspiration pressure is reduced to 50–80 mm Hg. Higher aspiration pressure poses the risk of disrupting the immature oocyte of the granulosa cells. Flushing follicles may lead to reduced retrieval rate due to loss of these oocytes. It is not uncommon to have a blood-stained aspirate, and frequent flushing and rinsing of the needle may be needed to avoid blocking. Unlike in conventional IVF, the visual collapse of aspirated follicles is not readily seen in IVM retrievals and one needs to apply multiple passes of the needle in a back-and-forth motion while also simultaneously rotating the bevel of the needle.

OOCYTE IDENTIFICATION

The follicular aspirates are collected in tubes containing HEPES-buffered media with heparin (2–5 IU/mL). As follicles of smaller diameter are aspirated for IVM, it is not unusual to find most of the aspirates to be smaller in volume with greater proportion of blood products. The blood products are due to the ovarian trauma during aspiration. Hence, addition of heparin to the media is extremely important to prevent the formation of blood clots. Secondly, unlike in conventional IVF aspiration, multiple needle punctures may be needed in IVM, again predisposing the aspirates to be extremely blood stained **(Figs. 1A and B)**.

Once the tubes containing the follicular aspirates are passed on to the laboratory, identification of the OCC forms the next important step. This can be the most frustrating part of IVM. These OCCs do not have the typical mucoid and "sun ray" appearance. Identification of these IVM OCCs needs to be done meticulously and patiently.

There are two ways of doing this. First, the follicular aspirates are directly poured into the Petri dish and examined under the microscope; they are most likely to sink to the bottom of the dish or tube. Hence, pouring the aspirates into Petri dishes and waiting for the OCCs to sink to the bottom will help in identification. These dishes with the follicular aspirate can be kept in the incubator for a few minutes prior to observing them under the microscope. The disadvantage of this method, however, is the time factor and the longer interaction of the OCCs with the blood clots which may be detrimental.

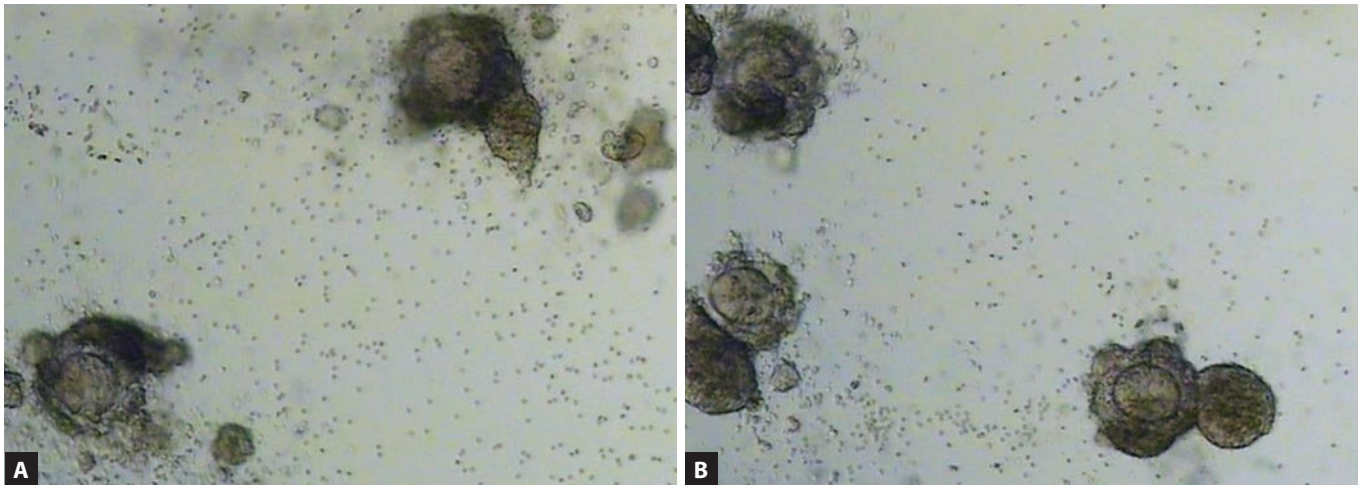
The second method is by using a cell strainer device made of nylon mesh, the pore size being 70 µm.[17,34] The follicular aspirates are filtered through this strainer. These collected aspirates can be washed to remove the red blood cells (RBCs) and small cells and then screened under the microscope to identify the OCCs.

Each laboratory will have its own protocol; some might utilize both methods. In protocols involving hCG priming, identification by the first method is possible as the cumulus is dispersed. However, in non-hCG-primed cycles, the cumulus will be more compact and their identification by the cell filter method is a better and faster option.

Special attention should be given to temperature and pH settings during multiple manipulations done during IVM as this can affect the protein synthesis and spindle morphology.

IN VITRO MATURATION CULTURE

There is very little data available on the composition of culture media for human IVM. Experience gained from IVM on mammalian species is what forms the basis for the composition of media used for human IVM. Historically simple salt solutions were used. Complex culture media such as tissue culture media 199 (TCM-199), Ham's F-10, P-1, Chang's medium, and Eagle's minimum essential media (EMEM) have been widely used. These media are supplemented with serum. Owing to potential sources of infectious agents, it was preferred to use patient's own serum. Human serum albumin (HSA) or synthetic serum has also been used as substitute for protein supplementation. Significantly higher maturation pregnancy and implantation rates were obtained in media supplemented with serum as compared to HSA. This could indicate that factors other



Figs. 1A and B: Immature oocytes obtained during in vitro maturation aspiration.

than albumin in the maternal serum may play a role in the maturation and embryo development.[35] Several other factors such as epidermal growth factor (EGF), activin, and inhibin may also be present in the serum which may play a role in the maturation process.[36] Hence, the addition of EGF could be a useful supplementation in the IVM media. Some IVM protocols also suggest supplementation of media with FSH and/or luteinizing hormone (LH); their effects on embryonic development, however, are still controversial. Media supplemented with FSH and LH in the ratio of 1:10 resulted in significantly higher developmental competent embryos with increased development to blastocyst stage in vitro as compared with FSH alone or no gonadotropins.[37] Addition of hCG in the culture media seems to have no effect on the maturation rate and further embryonic development.[21] Further studies are indicated to clarify the role of gonadotropins and other supplements used in the culture media for IVM. Of late, commercially made IVM media are available.

ASSESSMENT OF OOCYTE MATURITY

Assessment of the oocyte maturity immediately after retrieval is required to separate the metaphase II (MII) from the immature oocytes. It is not uncommon to obtain MII eggs in hCG-primed cycles, especially if the trigger is given at >12 mm follicle diameter. The tight cumulus makes the identification of maturity a difficult task. However, this can be identified by sliding method or spreading method.[21,38]

The sliding method involves allowing the OCCs to slide from one end to the other at the bottom of the Petri dish; tilting of the dish can make identification easier. The spreading method allows for spreading of the cumulus complex with Pasteur pipette with minimal media or follicular aspirate retained in the Petri dish. This will allow easy spreading of the cumulus, so as to allow observation of the oocyte cytoplasm under the dissecting microscope. Different radiate appearances can be observed in oocytes collected from different sizes of follicles and the maturity of these oocytes can still be at MII stage. Hence, it is very important to identify the in vivo matured oocytes in hCG-primed cycles immediately after retrieval. If this check is not done, the MII oocytes would be aged at the next check which would be 24 hours later and affect the further developmental competence.[35]

The hours of culture required for maturation could be one of the most important criteria deciding the outcome of that oocyte. Most of the IVM studies have shown 40–60% maturation rates after 24–30 hours of culture.[21,39] It is important to assess the oocyte maturity after 1-day culture. There might be some oocytes arrested at MII stage for more than 24 hours before insemination and this could reflect in poor fertilization rates. This was seen in earlier studies in which oocytes were inseminated at 48 or 56 hours without assessing the oocyte maturity between 24 and 30 hours of culture.[6,40]

FERTILIZATION OF IN VITRO MATURATION OOCYTES

Most of the studies prefer intracytoplasmic sperm injection (ICSI) even in the absence of male factor, due to the concerns regarding zona hardening as an effect of prolonged hours of culture. Denuding of the oocytes for ICSI also helps to identify the maturation status of the oocyte. Fertilization rates seem to be higher with ICSI as compared to IVF.[41]

Irrespective of the method of insemination, the developmental potential of the fertilized oocyte did not show any significant difference. Söderström-Anttila et al.[42] reported a higher fertilization rate with ICSI compared to IVF, but a higher pregnancy and implantation rate with IVF as compared to ICSI. Hence, it is not clear as to which is the best form of inseminating the IVM oocytes in the absence of a male factor.

In vitro maturation oocytes obtained from COH cycles are sensitive to postmaturation aging, and delayed ICSI can result in abnormal fertilization, pronucleus size asynchrony, and cleavage failure.[43] Hence, determining the optimal interval between the first polar body extrusion and ICSI is important to obtain normal fertilization and embryo development.

Human oocytes matured in vitro needed at least 1 hour after the extrusion of the first polar body to complete nuclear maturation.[44] Spindle imaging system could be a useful device in deciding the timing of ICSI for IVM oocytes. Source of immature oocytes, primed or nonprimed cycles (FSH and/or hCG), patient categories, and the IVM culture systems could all affect the nuclear maturation and hence the timing of the first polar body extrusion.

EMBRYO DEVELOPMENT

Most studies suggest ET being done on day 2 or day 3. This could be because of poor quality and quantity of embryos formed. IVM embryos may show a higher incidence of cleavage arrest as compared to the conventional IVF embryos. They also seem to show an increase in multinucleation owing to cell division arrest. Son et al.[38] in their studies obtained a good blastocyst formation (41.6%), clinical pregnancy (51.9%), and implantation (26.8%) in IVM patients who had more than seven zygotes and three or more good-quality embryos on day 3.

Use of assisted hatching can also be considered and frozen ETs using IVM oocytes have also been used successfully. The numbers with both these techniques are too low to accurately predict outcomes **(Table 1)**.

PROTEIN SYNTHESIS

During the period of oocyte growth, a large number of genes are transcripted and translated. During oocyte maturation, the protein translation activity continues and these

TABLE 1: Clinical aspects of in vitro maturation.

(ICSI: intracytoplasmic sperm injection; NR: not reported)

play an integral role in meiotic progression and embryo developmental competence.

Studies have revealed that in vitro matured MII human oocytes obtained from ovaries of untreated women have reduced protein content as compared to in vivo matured MII oocytes obtained from gonadotropin-treated patients.[6] Similar reduction in oocyte protein content has also been reported in bovine oocytes matured in vitro.[49] The role of these protein deficiencies and their impact on transcriptional inadequacies or translational defects is unknown. Further studies on the specific protein content and their role need to be assessed.

PREGNANCY RATES WITH IN VITRO MATURATION

Pregnancy rates per transfer vary between 4 and 27% and implantation rates between 2 and 14%. The reasons for the lower pregnancy rates have not been a subject of randomized trial. Some of the reasons suggested are nuclear and cytoplasmic asynchrony wherein the nuclear maturation is achieved without the cytoplasm undergoing maturation, thus resulting in poor embryo quality and higher pregnancy loss. Other factors contributing could be inadequate culture conditions inherent or induced abnormalities, failure of the embryonic gene expression, suboptimal timing of insemination, and asynchronous endometrium.[50,51]

Fresh or Freeze-only Embryo Transfer

Due to a shorter follicular phase, the endometrial exposure to estradiol is truncated in IVM cycles. This short proliferative phase and insufficient exposure to progesterone impact the endometrial receptivity by altering the expression pattern of the steroid receptors and deficient midluteal phase.[52] The LBR in frozen transfers was significantly higher compared to the fresh ET as reported by an RCT in non-hCG IVM cycles.[53] Thus, it appears that the endometrium in non-hCG cycles is suboptimal; hence, a freeze-all strategy should be considered.

SAFETY OF IN VITRO MATURATION

It is estimated that approximately 400 babies have been born through the procedure of IVM. A report by Buckett et al.[8] in 2007 did not find any increased incidence of malformation or disturbed development in babies born through the procedure of IVM as compared to that following natural conception. There have been reports of increased chromosomal abnormalities in embryos derived from IVM.[54-56] Comparison of the aneuploidy rate in the IVF and IVM embryos in 2010 was reassuring as it concluded that it was similar in both the groups (58.7% IVM vs. 57.4% IVF).[57] Another point highlighted by the study was that based on the maturation time of the IVM oocytes, the oocyte that matured early (<24 hours) had lesser incidence of aneuploidy as compared to those matured late (>48 hours). These studies do have a few limitations; the number of probes used is limited and different studies use different methods for assessment of aneuploidy. The patient population and selection of patient vary in different studies.

Cha et al.[58] reported 20 singletons and four twin live births; three congenital anomalies (7.9%) were noted, including two major congenital anomalies (5.3%) detected by ultrasonography: hydrops fetalis (n = 1), omphalocele (n = 1), and cleft palate (n = 1). Hydrops fetalis was associated

with normal chromosomes. Mikkelsen[59] reported 47 births. No specific abnormalities were related to IVM procedure. One 46,XX with *CCNH* gene variation, inherited paternally (no clinical significance), one intrauterine death (IUD), induction failure, and asphyxia were reported. Söderström-Anttila et al.[60] reported 40 singletons and three sets of twins. At the age of 12 months, eight children (19%) expressed minor developmental problems and one girl was found to have optical glioma. At 2 years of age, neuropsychological development was within the normal range. Fadini et al.[61] in 2012 reported the birth of 200 IVM babies, none of them with any major congenital anomalies.

We need to be cautious as the numbers of babies born are low, and there is no standardization of protocols on both the clinical and embryology front. The information available on their long-term development is scanty. Prolonged culture may instill certain epigenetic alterations. However, the findings from a recent meta-analysis regarding neonatal outcomes, including preterm birth, iatrogenic or spontaneous, low or high birth rate, and large for gestational age, have been reassuring.[62]

Recent Advances in In Vitro Maturation

A recent development has been the introduction of biphasic IVM. The prematuration step (24 hours) involves culture in presence of C-type natriuretic peptide (CNP) followed by maturation step (30 hours) in the presence of FSH and amphiregulin (AREG). The basic principle here is to maintain the oocyte meiotically arrested in the germinal vesicle (GV) stage in vitro while retaining their physical contact with the cumulus cells to facilitate an environment which allows the OCCs to acquire developmental competence followed by introducing an environment similar to post-LH surge, which will elicit maturation. A first prospective study by Sanchez et al.[63] involving sibling oocytes from 15 PCOS patients to study the impact of IVM culture on embryo yield in comparison to standard IVM protocol was followed by a second prospective study on 15 PCOS patients. The latter study involved evaluation of oocyte meiotic arrest, oocyte chromatin configuration, preservation of cumulus-oocyte transzonal projections, and cumulus cell apoptosis. Oocyte developmental assessment 24 and 46-hour prematuration culture (PMC) + IVM along with aneuploidy rate in 20 good blastocysts by next-generation sequencing (NGS) was analyzed.

This method showed a significant increase in maturation rate in comparison to standard IVM (70 vs. 49%; $p \geq 0.001$).

Also, the number of good-quality day 3 embryos and blastocysts was higher with no increase in aneuploidy rates.

KEY POINTS

- The optimization of IVM is ongoing.
- Although it may be premature to offer IVM to all types of infertility patients at this time, it does offer huge promise in the field of oncofertility.
- The practice of IVM requires flexibility and adjustment in the routine IVF program in the clinic.
- IVM holds a great promise as another type of assisted reproductive technology when fully developed.
- Further research and understanding of the human oocyte within the follicular environment are crucial for the advancement of IVM.

CHAPTER 115

Ovarian Tissue Cryopreservation and its Eventual Transplantation: Is it Proficient Fertility Preservation Program?

Pankaj Talwar, Pooja Awasthi

INTRODUCTION

Cryopreservation has proven as a boon for all the panoramas of reproductive medicine. A well-established program, tagged with proven medical laboratory protocol is required as an alternative to assist cases of women and adolescent girls facing urgent prerequisite for treatment of cancer and simultaneous management of their fertility preservation (FP). This section of the reproductive age group woman and adolescent girls suffering from various types of cancer may experience impaired fertility or hormone production as a result of their exposure to gonadotoxic chemoradiotherapy prior to or during the course of combating cancer.[1-3]

In current scenario, *ovarian tissue cryopreservation (OTC),* also known as ovarian cortex freezing, is considered as one of the best suited options that has gained substantial recognition as experimental tag has been removed from it recently in the year 2019. OTC is the only FP option that is readily available now in cases of cancer patients in whom traditional management such as oocyte and or embryo cryopreservation cannot be cogitated due to socio-psycho-medico issues. The main objective is the maintenance of the ovarian structure, physiology and endocrinology, benefiting multiple target patients facing different treatment and medical management situations.

Moreover, OTC is the only fertility preservation alternative for prepubertal patients, since in these cases, as neither the ovarian stimulation protocols nor oocyte collection can be applied.[4] Patients with benign conditions such as recurrent ovarian cysts, ovarian torsion, endocrine disorders, and autoimmune diseases may also benefit from this promising technique. Sometimes, individuals who wish to undergo gender affirmation surgery may also ask for preserving their ovarian cortex or whole ovary to be dissected into small pieces and cryopreserved.[5,6] However, some cases of women for whom surgery that requires removal of ovaries for medical condition or disease, e.g., prophylactic oophorectomy in BRCA patients and also for the patients who underwent previous treatment for cancer still has ovarian function is acceptable for choosing OTC. As the best suited option of their FP. OTC can also be indicated for postponing menopause.[7,8]

The main objective of OTC is to reimplant a few thawed cortical strips into the patient (i.e., auto transplantation) once the patient has completed cancer treatment, is disease free, and desires pregnancy. Pieces of ovarian cortex can be grafted to orthotopic (pelvis) or heterotopic (subcutaneous) sites, each having distinguished advantages and disadvantages. Very first pregnancy after orthotopic transplantation of OTC and live birth was reported in 2004 and according to the more recent literature, the number of live births after ovarian tissue cryopreservation exceeded 200 in 2020,[9] while the pregnancy and live birth rates reached 50 and 41%, respectively.[10] Though live births have also been reported by heterotopic transplantation,[11,12] the exact numbers are still unclear.

After eventual autotransplantation, success rates are high regarding the re-establishment of ovarian activity (63.9%) and natural live births (57.5%), according to a meta-analysis performed in 2017.[13] OTC requires a multidisciplinary approach to preserve the fertility in cases of females where necessity of husband or partner or donor sperms can be eradicated completely.[14] Concerted multidisciplinary discussions between hematologists, assisted reproductive technology (ART) teams and surgeons are required to improve the quality of patient information[15] in terms of procedures and measures for achieving OTC successfully. Radiosensitivity of the human ovary that leads to the loss of 50% of primordial follicles (LD50) is estimated to be 2 Gy.[16-18] The possibility of ovarian failure is also determined by the regimen and type of chemotherapy where block of DNA replication, double stranded (ds) DNA breaks, and induction of apoptosis primarily in the stroma and the granulosa cells of growing follicles occur.[19,20]

Ovarian tissue is collected surgically (laparoscopy or laparotomy) prior or during exposure of the young women to chemoradiotherapy. Afterwards, these strips

are cryopreserved. Follicular viability and integrity of tissue compartments and cell-to-cell contacts must be ensured by the cryopreservation procedures.[21] Thus, studies investigating the most favorable cooling rates and dehydration times have been conducted. It is now well-established that for obtaining satisfactory results, adequate penetration of cryoprotectant through the stroma and granulosa cells to the oocytes is required.[22] Slow freezing[23-25] and vitrification techniques[26,27] are two proven methods applied. However, when compared to vitrification, very few reports of successful births were reported in comparison to implementing the slow freezing method for OTC based FP. Although OTC is expected to bridge an important gap in FP in the field of oncofertility in cases where it is impossible to create embryos for cryopreservation, especially in pediatric oncology mostly among young girls prior to adolescence.[27,28]

Ovarian tissue cryopreservation comes with four key components that involve: (1) ovarian surgical procurement, (2) ovarian tissue processing, (3) tissue cryopreservation, and (4) Storage followed by ovarian tissue transplantation (OTT). Ethically, providing inadequate information about OTC/OTT including surgeries, procedures and probabilities of success, should be obstructed and informed consent form should be taken from the patients. In cases of adolescent girls, written and signed informed consent form should be taken from both patient and her parents/guardian stating all uncertainty specially related to the long-term complications and benefits of the procedures. A unique feature of OTC is that in future, the patient can choose to reimplant the ovarian cortical tissue orthotopically or heterotrophically for fertility purposes or to restore ovarian endocrine function. We as an expert are not only suggesting and recommending OTC as FP method that is being applied to benefit cancer patients, but also the women who want to postpone their fertility and menopause can opt OTC.[29]

In 1999, the first successful autotransplantation of frozen-thawed ovarian cortical tissue was performed, but it was not until 2006 when Meirow et al. reported the first live birth obtained from OTC.[30] However, claims of the first live human birth coming from ovarian tissue which was cryopreserved using the slow freeze technique and then transplanted was described by Donnez et al.[31] Orthotopic transplantation is more frequently used approach but reports of live births from heterotopic autotransplantation methodology has also been started to serve the society.[32-35] Since orthotopic transplantation can allow both live birth and the recovery of endocrine function more efficiently but the reimplantation of malignant cells is always a major risk and should always be considered in serious manner. It was suggested that the histological analysis, immunohistochemical studies and molecular methods, are needed in order to improve the search for malignant cells before transplantation of ovarian tissue. OTC/OTT appears to be a method with specific benefits, indications and risks which can be an important tool in terms of preserving fertility in younger women and adolescent girls.[36-38]

OTC in turner syndrome is under investigation but there is no published report showing any success in such cases.[39] The medical, surgical and laboratory techniques/methodology are required to be improved further to advance the technology for intensification of the reach of OTC for different groups of needy women where no other options are relatable, to offer OTC as FP in an efficient manner.[40]

Though, the cryopreservation and reimplantation of whole ovaries are areas where extensive research needs to be performed prior to offering such high-end medical service to the necessitous, in future.

A well-focused effort in terms of research work also needs to be conducted where more attention needs to be given to clarify criteria and establishment of guidelines for accurate selection of the patients to offer OTC. From technical point of view, it is advisable to optimize the protocol of OTC (slow freezing or rapid vitrification) to achieve higher follicular survival. Ultimately, the surgical technique for revascularization of thawed/warmed ovarian tissue and whole ovary are required to be sharpened. The present stance of OTC is hopeful for young cancer sufferer females and future perspective of OTC/OTT seems to be promising enough, to help the society specially cancer victims. However, OTC along with its subsequent thawing/warming and eventual transplantation techniques are relatively new. The long term associated and unseen risks of metastasis in young female patients with malignancies who had ovarian cortex reimplanted is still a matter of research and concern and needs to be explored.

CHAPTER 116

Polarization Microscopy and its Clinical Applications

Taswin Kaur, Mir Jaffar

INTRODUCTION

There is great importance in searching for parameters that can improve the assessment of the quality and the developmental potential of the human gametes and the embryos for a good implantation and a healthy viable pregnancy. Many microscope technologies are available to visualize the subcellular structures. One such revolutionary technology is the polarization microscopy.

Polarized light was used to investigate the structure and the development of skeletal and cellular components in animal cells by Schmidt about a century ago. Microtubule-dependent birefringence of the mitotic spindle has been visualized by polarized microscopy half a decade ago. Polarized light microscopy provides a unique window to view the internal structures of a cell.

PRINCIPLE

The polarization microscopy works on a principle that when two orthogonally polarized light rays passes through orderly arranged filamentous structures; they exhibit birefringence.

Birefringence is known as double refraction. It is a property that is exhibited when a ray of light passes through an anisotropic material and gets split by polarization into two unequal waves (traveling at different velocities). This phenomenon was first described in 1669 by a Danish scientist, Rasmus Bartholin. Light entering an isotropic substance passes through the substance with a single velocity at a constant angle. On the other hand, anisotropic substances have a nonuniform spatial distribution of properties. When light enters these substances at a nonequivalent axis, it is reflected into two rays, each traveling at different velocities. This is exhibited either to a greater or to a lesser degree in all anisotropic substances **(Figs. 1 and 2)**.

Retardance is the relative measure of optical path difference. In other words, it is the measured path length between the two exciting beams of light as they pass through the birefringent structure. It is usually measured in nanometers and is the primary quantity measure by a polarizing microscope. The retardance measured is directly proportional to the density of the structures in the cell, i.e., greater the density of the microtubules in the oocyte, greater the retardance **(Figs. 3 and 4)**.

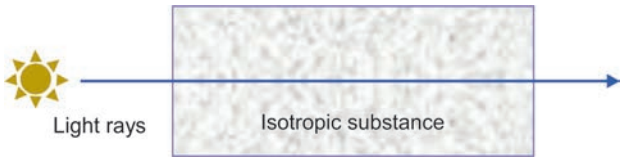

Fig. 1: Birefringence effect—when the light beam passes through an isotropic structure, no birefringence is seen. This is because light passes at a single velocity without being polarized.

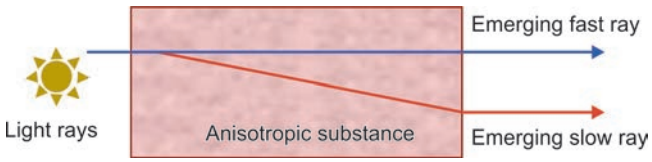

Fig. 2: Light rays passing through an anisotropic structure is split into two rays—an emerging fast and a slow ray.

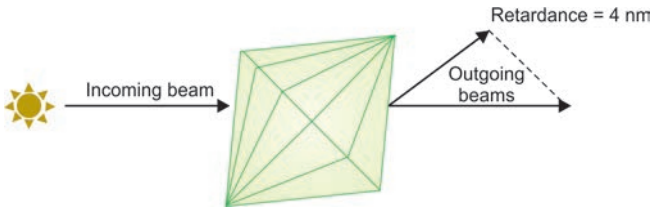

Fig. 3: Example of a spindle with a high birefringence. The spindle has a higher degree of molecular order.

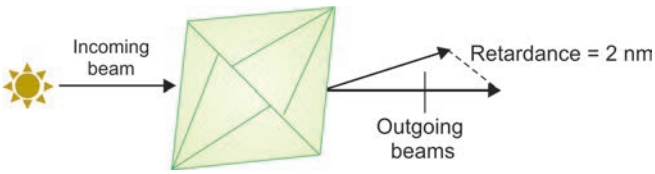

Fig. 4: Example of a spindle with low birefringence. These spindles have a lower degree of molecular order and are potentially less viable.

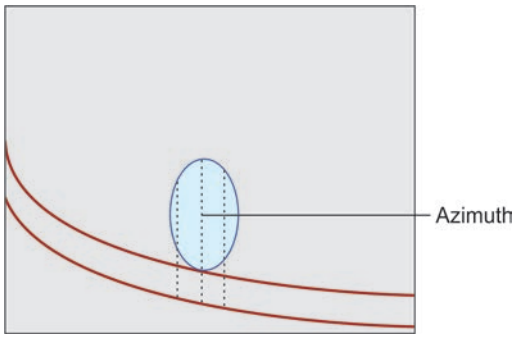

Fig. 5: Azimuth/orientation of a normal barrel-shaped spindle.

Azimuth is an angle, which refers to the orientation of the slow axis of a uniformly birefringent region. It is measured from the horizontal orientation with angles ranging from 0° to 180°. In case of the spindle apparatus, the azimuth follows the long axis of the spindle fibers. Therefore, normal and abnormal orientations can be identified **(Fig. 5)**.[1]

DEVICE

A polarized microscope system has been designed to observe an optically anisotropic specimen. This specialized microscope has been developed as a variant adjustment of the standard light microscope equipped with a polarizer, motorized micromanipulator, and an analyzer **(Table 1)**.

Polarized light microscopy enhances the contrast between the cell and the background, which then helps to reveal specific important information about the structure and the composition of the substance. In the field of reproductive medicine, the oocyte appears translucent and appears to have little or no details when they are back illuminated by white light using a simple light microscope. However, when polarized light passes these same tissues (oocytes), there is splitting of the light beam and a shift in the plane of birefringence and retardance, causing the internal structures to become visible and therefore analyzed and seen on the computer screen as grayscale values. The polarizing microscope has a sensitivity of 0.1 nm of retardance **(Flowchart 1)**.[2]

In the market, both the traditional and the liquid crystal (LC) polarizing microscopes are available. The LC polarizing microscopes usually include an LC-based compensator, a circular polarizer, camera, and computer software for image rendering and processing **(Box 1)**.[3] The modifications done in a polarizing microscope from the traditional microscope are as follows:

- LC-based compensator is used instead of the traditional compensator.
- Specimen is illuminated with nearly circular polarized light.
- Magnitude and orientation of the birefringence are measured without mechanical movement of the specimen or the instrument.

TABLE 1: Components of polarization microscope and its functions.

Components	*Function*
Eye piece	• Fitted with a cross wire reticule to mark the center of the field view • "Bertrand" lens are used—specialized lens mounted within the observation tube
Compensator/ retardation plate	• Inserted between the cross polarizer • Enhances the optical path difference in the specimen
Graduated circular rotating stage	• 360° rotating specimen stage • Facilitates orientation with centralization of the objective and stage with the microscope's optical axis
Polarizer	Confines white light to vibrate in one plane when light passes through it
Analyzer	Image obtained is colorful

Flowchart 1: Pathway of working system of a polarizing microscope.

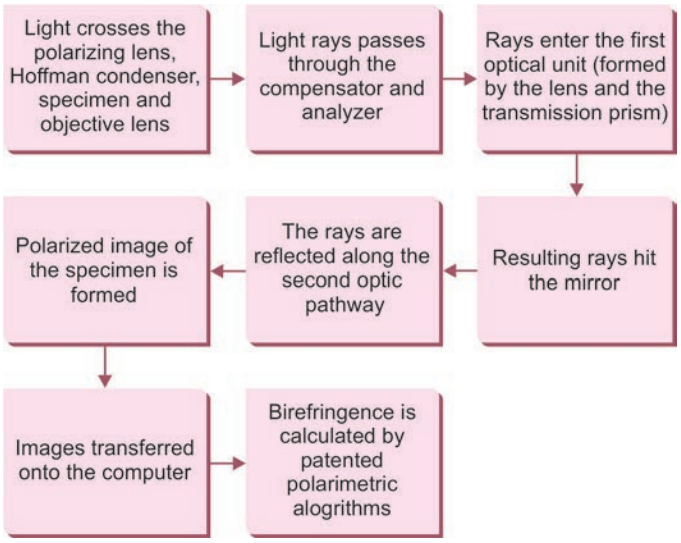

TABLE 2: Differences between the simple and polarizing microscopes.

Parameters	*Simple microscope*	*Polarizing microscope*
Polarizer and analyzer	No	Yes
Working principle	Reflection and refraction	Interference
Specimen used	Any specimen	Optically anisotropic specimen
Image color	Not same as that of the specimen	Colorful image/grayscale image is obtained due to interference
Dishes used	Plastic/glass	Only glass dishes or slides

Polarization microscopy is a new noninvasive tool to analyze the cell structures, mainly the meiotic spindle, zona pellucida, and the sperm acrosome **(Table 3)**.

BOX 1: Factors affecting the polarization microscope image.

- Orientation of the specimen
- Thickness of the specimen
- Orientation of the polarizer and analyzer with respect to each other
- Path difference between the two rays of light

TABLE 3: Advantages and disadvantages of the polarizing microscope.

Advantage	*Disadvantage*
Noninvasive	The oocyte and the sperm have to be assessed separately and not as an embryo
No usage of exogenous dyes or labels	Can be only used with ICSI as the cumulus mass surrounding the oocyte has been stripped away
Allows spindle visualization in living oocytes	
Optimizes thermodynamic stability of the oocytes during ICSI	
Enables the dynamic architecture of the meiotic spindles	

(ICSI: intracytoplasmic sperm injection)

FUNCTIONS OF POLARIZING MICROSCOPE

The functions of a polarizing microscope are:

- Stage of meiosis
- Location of meiotic spindle during intracytoplasmic sperm injection (ICSI)
- Timing of ICSI
- Quality of the oocyte
- Laboratory conditions
- Sperm quality.

APPLICATION OF POLARIZING MICROSCOPE

Spindle Imaging

Spindle Dynamics in the Meiotic Cycle

Oocyte maturation is a complex process involving both the nuclear and the cytoplasm maturation. Oocytes are arrested at the prophase of the first meiotic division. Post puberty, under the stimuli of the luteinizing hormone (LH) surge, via its action on the granulosa cells, there is a decrease in the cyclic adenosine monophosphate (cAMP) concentration. This in turn leads to the resumption of meiosis I followed by the extrusion of the first polar body. Oocyte nuclear maturity begins when the meiosis resumes from the diplotene stage, and this is determined by the absence of a germinal vesicle and the expulsion of the first polar body present in the perivitelline space.

The metaphase spindle organizes leading to an unequal division of the cytoplasm with the expulsion of the first polar body. Post expulsion, there is reorganization of the metaphase spindle preparing for the second meiotic division. In any standard ovarian stimulation cycle, around 85% of the denuded oocytes show presence of the first polar body in the perivitelline space and are classified as metaphase II (MII) oocytes. Around 10% of the oocytes are germinal vesicles where they are surrounded by an intact nuclear membrane. In the MII stage, the chromosomes are arranged at the equatorial margin of the meiotic spindle.

Determination of Stage of Meiosis

The meiotic spindle is a highly dynamic structure, which changes during the transition from metaphase I (MI) to MII. It is made up of microtubules that are nucleated from the spindle polar bodies. Under the regular light microscope, the extrusion and the presence of the first polar body are synonymous with a mature MII oocyte. However, this scenario under a few circumstances may be false when these oocytes are viewed under a polarizing light. With the advent and examination of these oocytes under a PolScope, some of these oocytes were found to be in the early telophase I stage where the spindle forms a connecting strand between the ooplasm and the first polar body. For around 40–60 minutes, the spindle disappears in telophase I and then reappears followed by the formation of a MII oocyte.[4]

Presence of the Meiotic Spindle

It is known that without the help of the PolScope, it is almost impossible to identify the presence of the meiotic spindle and hence to clearly identify the oocytes undergoing the important maturational transition from MI to MII. With the advent of video cinematography, it is known that spindle disappearance in the cell cycle lasts for around an hour. Hence, it is important to reexamine the oocytes that did not have a spindle after 2–3 hours to avoid a misdiagnosis of an absent spindle as a result of this kinetic behavior. This is done to confirm the diagnosis of an absent spindle or that the oocyte was in the transition phase of late telophase I.

A study by Montag et al. showed that almost 50% of oocytes with an absent spindle initially displayed a meiotic spindle after an additional 2 hours of culture.[5] In ICSI procedures, studies have shown a positive correlation with the fertilization rate when the sperm injection was done in oocytes with a visible meiotic spindle.[6-8]

A meta-analysis by Petersen et al. evaluated the influence of the meiotic spindle visualization in human oocytes on the outcome of ICSI. The authors included 10 trials and concluded that the presence of the birefringent spindle was associated with a better fertilization rate and embryo development.[9] However, there was no benefit noted on the pregnancy or implantation rates.

A retrospective analysis done by Picinato et al. reported that there was an increased fertilization rate with the use of a polarization microscope, but a reduced cleavage rate and top-quality embryos were observed.[10]

Location of the Meiotic Spindle

Majority of the spindles are located in the same equatorial plane as the first polar body, with the highest frequency of it being directly adjacent to the polar body, indicating that the position of the first polar body can be taken as a crude marker of spindle position. The vast availability of spindle imaging across in vitro fertilization (IVF) laboratories raised the question of the need of locating the position of the meiotic spindle during ICSI. The visualization of the spindle stamped that the location of the first polar body is not a reliable reference or predictor for the MII spindle location. The significance of the angle of meiotic spindle from the polar body position has been defined by various authors.[7,11] However, the association of the location of the meiotic spindle for the outcomes of ICSI has been investigated and debated in many publications with contradictory results in terms of fertilization rates, competent cleavage-stage embryos, blastocyst formation rates, and pregnancy or implantation rates.[3,12]

To avoid damaging the spindle during the ICSI procedure, the oocyte is usually rotated based on the position of the first polar body. However, we seldom realize that there may be possible movement of the polar body in the perivitelline space due to stress or physical displacement during oocyte denudation or the migration of the spindle in the oocyte. Hence, the relationship between these two structures is altered, leading to an impaired spindle if microinjection is done. Special care is usually taken not to damage the meiotic spindle when an isolated sperm is injected into the oocyte during ICSI.[13,14] Hence, the use of the PolScope is a useful tool in ICSI to allow the perfect orientation of the oocyte with the identification of the spindle, and not in relation to the polar body, thus, being as far as possible to the injection needle **(Fig. 6)**.

A recent study by Asa et al. reported that a close position of the meiotic spindle to the polar body was correlated with better fertilization and cleavage rates of the embryo.[15] This finding was consistent with the previous study by Rienzi et al., which demonstrated that oocytes with a spindle deviation of >90° from the polar body position had lower fertilization rates.[16] Kilani et al. demonstrated that spindle assessment was an early predictor of the pregnancy potential of that oocyte, especially in recurrent implantation failure patients.[17,18] However, on the other hand, in some researches, there was no significant correlation between spindle retardance and fertilization rates.[6,19]

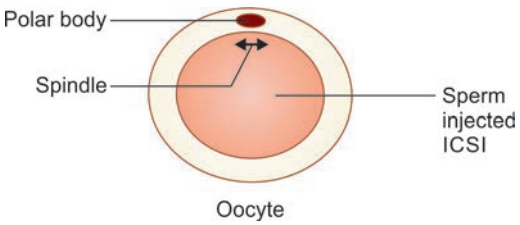

Fig. 6: Intracytoplasmic sperm injection (ICSI) injection site in relation to meiotic spindle and polar body.

Quality of Oocytes

Spindle birefringence is contributed by the microtubules, and a positive correlation has been recorded between the spindle retardance and the microtubule density. Raju et al. observed that oocytes with a higher spindle retardance (>3 nm) and those with a longer spindle length (>12 nm) seemed to have a better-quality embryo and subsequently progressed to blastocyst.[20]

With an increasing age, there are changes in the spindle integrity leading to a decreased oocyte quality and ultimately a rise in aneuploidy rates.[21,22] Therefore, low retardance due to spindle abnormality is synonymous with an aged oocyte and thus an early predictor for a compromised oocyte quality and hence a deficient embryo.

In a recent study by Revelli et al., the increase of the meiotic spindle size has been found to be associated with an increased ovarian resistance to follicle-stimulating hormone (FSH), hence, translating to stimulation like a patient of increased reproductive age.[23]

Prediction of Aneuploidy

The normal meiotic spindle is an important checkpoint in the cell cycle.[24] Its structure and function are crucial in mediating the mechanical alignment and segregation of chromosomes during MI and MII stages.

The noninvasive morphological assessment of these meiotic spindles by polarizing light microscopy identifies the oocytes with the greatest reproductive potential and least aneuploidy.[25] Five different types of oocyte spindle morphology—normal, dysmorphic, telophase, translucent, or no visible spindle—have been recently classified in a publication by Tilia et al. There were a higher percentage of aneuploid embryos with the presence of a translucent or absence of the meiotic spindle as compared to those with a dysmorphic spindle.[26] Hence, spindle visualization may be an important tool to predict better embryo outcomes.[27,28]

Cryopreserved Oocytes

The meiotic spindle is the most obvious manifestation of the polarity of the mature oocyte. It is of central importance in the cell during chromatid segregation in the second meiotic division. Unfortunately, this cytoskeletal component is very sensitive, especially to temperature.[29]

Oocyte cryopreservation had not gained much limelight previously due to the poor survival rate of these frozen–thawed oocytes. With the introduction of slow cooling and recent vitrification protocols, there is a high recovery percentage of the thawed viable oocytes.[30]

Freezing of the MII oocyte to nonphysiological temperatures may result in depolymerization and damage to the oocyte. Repolymerization causes swelling of the cell back to the original state and is believed to be time dependent. The translucent structures of the oocyte can be viewed under a polarizing light post thawing and the time taken for the spindle to reform to its original length and birefringence has been studied.

In the first few initial studies when spindle-positive oocytes were subjected to the standard freeze–thaw cycles, around 50% of the oocytes repolymerized and spindles reappeared within 3–5 hours post warming.[31,32]

Along the years, multiple publications reported on the various slow-freezing methodologies, especially after increasing the sucrose content in the freeze–thaw solutions which has showed to improve the survival rates.[33,34] There is >80% spindle reformation of the frozen–thawed oocytes within 1 hour after warming in an efficient slow-freezing protocol.[35]

Vitrification is an alternative technique for cryopreservation of oocytes. Oocytes rewarmed post-vitrification were found to have the same fertilization and cleavage as a fresh gamete insemination.[36] Slow-freezing method has been found to be inferior to the vitrified human oocytes. Vitrification causes less damage to the spindle integrity and the chromosome alignment.[37,38]

A study by Chen et al. suggested that most of the spindle was visualized within an hour of vitrification and only in about 25% of cases the spindle of intact thawed oocytes was found to be undetected.[39]

In vitro Matured Oocytes

Immature oocytes can be cultured in vitro to subsequent embryonic development, pregnancy, and a healthy live birth.[40] The timing of ICSI can be precisely determined by imaging the meiotic spindle under the polarizing microscope.[41] These in vitro matured oocytes show a varied time course compared to oocytes from stimulated cycles and develop faster.

Rescue Intracytoplasmic Sperm Injection

Failed fertilization after ICSI can be emotionally disturbing to the couple. A rescue ICSI can be performed on these 1-day-old oocytes.[42] This procedure may reduce the cycle cancellation rate but has been reported to result in morphologically and genetically abnormal embryos. However, a few studies have reported a successful live birth after a rescue ICSI.[43] Polarization microscope allows the accurate visualization of the meiotic spindle.

Spindle Imaging as a Tool for Quality Assessment of Laboratory Parameters

Microtubules are in the polymerized–depolymerized state. Oocyte meiotic spindle shows depolymerization to pH and temperature. The proper setting of laboratory parameters can be analyzed by these biochemical properties of the meiotic spindle.

Meiotic spindles start to disintegrate at the critical temperature of 33°C, and if the temperature falls below 25°C, repolymerization of the spindles is very unlikely.[44] Reassembly of the spindle depends on the minimum temperature and the duration that the microtubule was exposed to these harsh temperatures.[45,46] Hence, using this concept, the polarization microscope can be used to monitor the effects of cooling and rewarming not only in the oocytes but also in the laboratory. Therefore, the maintenance of the temperature at 37°C while oocyte manipulation is of utmost importance.

The meiotic spindle can also be disrupted by nonphysiological pH. Spindle disassembly can occur within 8–10 minutes of exposing the oocyte to an unbuffered culture.

If the meiotic spindles are consistently absent in most of the oocytes (>30%), it may be a wise decision to carefully monitor and troubleshoot the laboratory conditions.

Zona Imaging

Visualizing under the conventional light microscopy, the zona pellucida appears as a uniform layer surrounding the oocyte. The same zona pellucida when visualized under a polarization microscope exhibits a multilaminar structure that can be distinguished by their birefringent properties **(Fig. 7)**.[47,48]

Oocytes with a higher zona birefringence reflect a better oocyte quality and are an indirect indication for a good follicular development.[49,50] There was a higher fertilization rate and higher conception cycles noted with oocytes, which had a higher birefringence in their inner zona layer.[51,52] According to a study by Cheng et al. and Safian et al., oocytes with a high birefringence were negatively correlated with the women's age.[53,54]

The potential of an embryo to progress and to develop into a blastocyst was higher when there was a retardance of >3 nm and a thickness between 10 and 12 nm in the zona inner layer.[20]

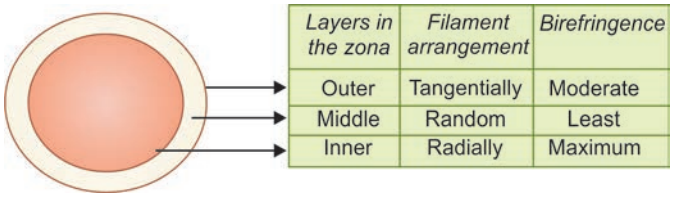

Fig. 7: Zona pellucida layers in an oocyte.

Sperm Selection

Advanced sperm selection techniques are gaining importance in assisted reproductive technique cycles, especially cycles utilizing ICSI.[55] The use of polarization microscopy could assist the embryologist in selecting the most viable spermatozoa without an adverse effect on the sperm motility or membrane integrity.[56]

The polarization microscope is equipped with a 63× objective and the images obtained can be further enhanced by digital imaging on a screen. There is total magnification zoom of 2,500× and 5,500× and these specific birefringence characteristics can be visualized and measured in real time.

The anisotropic structure within the nuclear and the acrosome region of the sperm head exhibits birefringence. The protein filaments arranged longitudinally contribute to the acrosome birefringence.

Three types of birefringent patterns in the sperm head have been distinguished:[57]

1. Spermatozoa with totally birefringent head—represents sperms with an intact acrosome.
2. Spermatozoa with a partially birefringent head (localized at the postacrosomal region)—sperm cell that has undergone an acrosome reaction.
3. Sperm head with abnormal patterns of birefringence—due to presence of vacuoles, absence of birefringence, localized areas of birefringence in the acrosome or nuclear area.

A study by Vermey et al. reported that the optimum sperm retardance was between 0.56 and 0.91 nm. A low sperm birefringence is associated with better pregnancy outcomes.[58]

The selection of sperms with partial birefringence increases the probability of selecting a sperm with a lower deoxyribonucleic acid (DNA) fragmentation. Therefore, selecting a sperm with a higher birefringence prior to ICSI may result in poor fertilization and pregnancy outcomes.[59,60] Visualization of retardance of the spermatozoa prior to ICSI, especially in patients with severe male factor infertility, may yield a better embryo development, implantation, and pregnancy.[61,62] Hence, sperm birefringence can be a real-time robust indicator for a healthy sperm.

CONCLUSION

The PolScope has been proven to be a boon for assessing the oocyte as well as the sperm. It is a real-time, noninvasive method that can be easily applied in an IVF–ICSI cycle. The use of this specialized microscope is a valuable add-on technique to identify the oocyte or the sperm that has the highest chance in developing a competent embryo, ultimately to reach the goal of a single healthy pregnancy.

CHAPTER 117

OMICS in Assisted Reproductive Technology

Syed Waseem Andrabi, Nivita Gugnani

INTRODUCTION

Approximately 15% of couples in the reproductive age are affected by infertility, which not only has significant medical and financial, but also many social implications. The number of couples opting for assisted reproductive technology (ART) is steadily increasing, to an extent, that, nearly four million babies have been born since the born of first in vitro fertilization (IVF) baby back in 1978. Although, ART does not overcome infertility completely, but it is like that light at the end of the tunnel for couples struggling to achieve their dream of parenthood.

The outcome of any ART procedure depends on multiple factors but, its ultimately the embryos, cultured inside the laboratory which are transferred into the female partner that play an important role in determining the overall outcome. Although, assessment of gametes and embryos can provide an idea about the overall outcome, however, even best of the best embryos with top grades, do not necessarily implant and vice-versa. Therefore, it is impossible to determine morphologically whether an embryo will result into a successful pregnancy or not.

The overall understanding of molecular physiology of endometrium, germ cells, embryo, and culture conditions is still very limited, but advancement in biotechnology over the last two decades has led to the emergence of new high-throughput techniques, generally grouped under the term "OMICS". Successful implantation of any embryo involves multiple events and is a consequence of regulated expression of embryonic and endometrial gene product. Diagnostic methods based on molecular interactions might be an encouraging tool for such assessments. So, owing to the simultaneous analysis of thousands of molecules in a single biological sample, OMICS approaches offer a global view of different biological processes, wherein particularly functional genomics is being used to determine information about the DNA sequence (Genomics), the mRNA (Transcriptomics), proteins encoded by mRNA (Proteomics) and the metabolic products (Metabolomics) **(Fig. 1)**. This, in

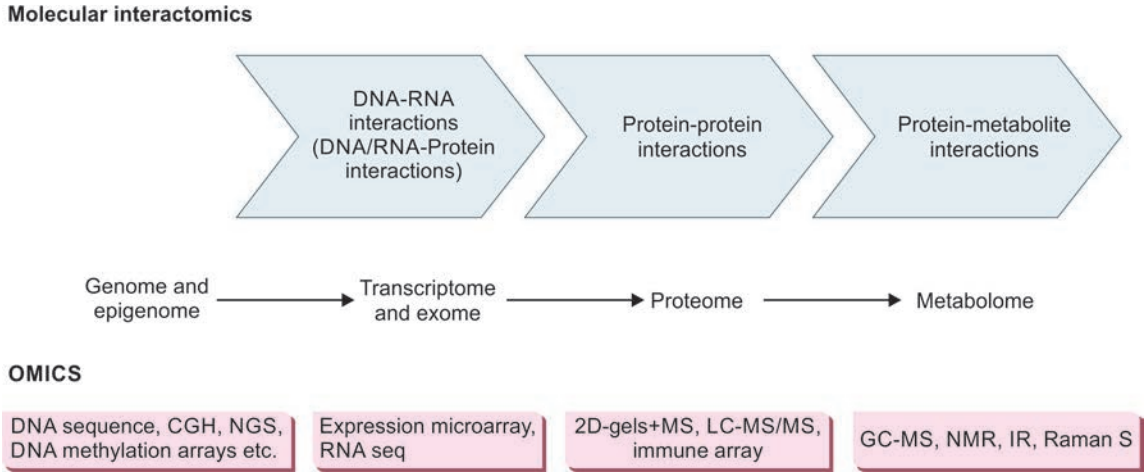

Fig. 1: Basic overview of OMICS.
(CGH: comparative genomic hybridization; GC: gas chromatography; IR: infrared spectroscopy; LC: liquid chromatography; MS: mass spectrometry; NGS: next generation sequencing; NMR: nuclear magnetic resonance)

turn is helping in decoding the complexity and behavior of biological systems.

The applications of OMICS in ART have become feasible due to the sensitivity, resolution and throughput of OMICS based assays, with the three most developed OMICS technologies being transcriptomics, proteomics and metabolomics. These technologies provide the platform to analyses all classes of biological molecules at different levels, that is, messenger RNA, proteins and metabolites using various techniques such as DNA sequencing for genomics; mass spectroscopy and protein microarray for proteomics; DNA microarray and real-time polymerase chain reaction (RTPCR) for transcriptomics; and Raman's infrared, proton nuclear magnetic resonance, near-infrared spectroscopy (NIR), and mass spectrometry (MS) technique for metabolites. Among these, metabolomic and proteomic approaches are emerging as promising noninvasive technologies for the evaluation of embryo viability.

The most important factor in any technology is the management of data, which in turn not only require proper planning but also great precision in order to produce reproducible data which can be easily translated into something biologically significant and OMICS fits this criterion through its expanding and more functional approaches. The example being exomics (analysis of exons), epigenomics (assessment of epigenetic modifications), secretomics (analysis of secreted products) and lipidomics (large-scale analysis of the whole lipid species).[1]

Studies of the interactome (entire network of molecular interactions in a system) and more integrative approaches, such as systems biology, are becoming increasingly significant in understanding the biological system and its activities as a whole, rather than a distinct component. OMICS and more broadly systems biology, are critical for the development of better diagnostic tools and treatments as they allow simultaneous investigation of numerous molecules. They are crucial not only in the determination of disease biomarkers, but they also provide information for a better knowledge of embryo implantation and pathological circumstances, with the goal of better patient care.[2]

GENOMIC ANALYSIS

Analysis of embryonic DNA composition can provide insight into embryo viability by examining the number of chromosomes and their integrity. An abnormal chromosome in the form of aneuploidy in preimplantation embryos is believed to be the basic cause of implantation failure or embryo loss. Female age plays an important role in the outcome of any ART procedure, as advance age is directly linked to increase in incidence of aneuploidy in both oocytes and embryos.[3] Identifying and excluding aneuploid embryos can improve IVF results.

The three main methods for obtaining nuclear material for genetic analysis are polar body biopsy, the removal of one or two blastomeres from early embryos (cleavage stage biopsy) and biopsy of 5–10 cells from trophectoderm of an expanded day 5/6 blastocyst (trophectoderm biopsy). European Society for Human Reproduction and Embryology (ESHRE) labeled these techniques as preimplantation genetic testing (PGT).

Fluorescent In-situ Hybridization

Previously, FISH, CGH, SNP-based arrays, and PCR SNP allele ratio analysis were methods used to study genomics. FISH was a frequently used method for chromosomal analysis, and the polymerase chain reaction (PCR) for the analysis of genes in cases of monogenic diseases. FISH was originally introduced in the clinic in 1992 using X and Y chromosome probes to treat families at risk of transmission of sex-linked disorders and to determine embryonic sex as an alternative to a PCR-based approach. In late 1993, the first FISH application for aneuploidy screening was run, and the number of chromosome copies of X, Y, 13, 18, and 21 chromosomes were evaluated as these chromosomal aneuploidies were mostly associated with birth defects. However, one limitation to this method was that the number of chromosomes that could be screened and the spectral resolution of the fluorescent dyes (red, yellow, green, light blue, blue). The chromosomes (16 and 22) most commonly associated with spontaneous abortion were then included with another set.[4] Irrespective of the stage of embryo biopsy, FISH technique has many drawbacks, one being that, FISH screens only up to 9–12 chromosomes and can detect only 60–80% of all aneuploid embryos. Given that aneuploidy does affect any chromosome, FISH cannot reliably detect a significant proportion of aneuploidy and segmental abnormalities present in the embryo. ESHRE and ASRM both stated that PGT with FISH was unjustified.

This problem was further solved by conventional comparative genomic hybridization array (CGH) where all 23 pairs of chromosomes were tested and copy number and entire chromosomal length details were analyzed. This comprehensive approach then provided a basis for array comparative genomic hybridization array (aCGH) technology and subsequently next-generation sequencing (NGS).

Comparative Genomic Hybridization

Comparative genomic hybridization employs FISH principles by cohybridizing differentially labeled test and reference DNAs with normal metaphase chromosomes. But, in contrast to FISH, it allows for the assessment of chromosome copy number across the entire karyotype,[5] but with limited resolution.[6,7] This technique was first

successfully applied to blastomeres in an IVF setting,[8] but was later described as tedious and time-consuming.[9] On the other hand, an aCGH (array CGH) involves whole genome amplification (WGA) and fluorescent labeling of samples where hybridization takes place on microarray (bacterial artificial chromosomes or synthetic oligonucleotides) instead of metaphase chromosomes and the results are further analyzed with specialized software such as Illumina. This method is not only fully automated and rapid but is also compatible with trophectoderm biopsy and subsequently allows fresh transfer. This has further been applied to polar body (PB) and cleavage stage biopsies as well (4).

Next Generation Sequencing

Next generation sequencing (NGS) method is based on Omics technologies used to screen the entire embryonic genome with high accuracy, preventing the transfer of aneuploid (and possibly nonviable) embryos in poor-prognosis patients. NGS has slowly replaced CGH due to scalability and various other advantages such as assessment of aneuploidy, translocations, single-gene diseases, modest copy number variations, and low-level mosaicism (up to 25%) from the same biopsy sample while using the same platform technology. In this technique, WGA is followed by a barcoding step which allows embryo-specific sequences to be identified,[10] after which the amplified product is broken down into short sequence-ready fragments. For aneuploidy screening, these fragments are subsequently submitted to massively parallel sequencing with limited coverage. The number of reads per chromosome (binning) are then related to the number of copies on each chromosome, which is further used to determine aneuploidy. NGS allows a large number of samples to be evaluated at the same time, hence lowering costs and workload.[4]

Next generation sequencing has an advantage over aCGH in detecting mosaicism and triploidy and is an improved method with a positive impact on the clinical outcomes in terms of a decrease in the miscarriage rate.[11] In addition, it also collects both nuclear and mitochondrial DNA (mtDNA) in the same sequencing run.[12] Mitochondrial DNA has been proposed as a biomarker linked to implantation and embryo viability, as lower levels of mtDNA are being linked to higher embryo implantation rates.

Epigenomics

Epigenetics, which is defined as changes in gene expression that occur without any changes in gene sequence can also be used in analysis of embryo viability biomarkers. With a major focus on long noncoding RNAs (lncRNAs) or microRNAs (miRNA), studies have analyzed some epigenetic modifications, wherein noncoding RNAs act as regulators of many target genes.[13] In a study of the expression profile of 12 miRNAs, it was found that aberrant miRNA in transferable blastocyst was linked to implantation failure associated with some specific infertility diagnosis. Data from a few studies also suggested that miRNAs might be an early indicator of the prognosis for human embryos of their development and that lncRNA has a regulatory role in embryo development and can be used as a marker of human embryo developmental potential.[14]

TRANSCRIPTOMICS

Transcriptomics is the study of the level of mRNA expression in a specific cell population, which is commonly done using a high-throughput technique based on DNA microarray technology. Transcriptomics includes studying of almost fifty thousand known genes that are translated into RNA molecules. But, scarcity of human embryo material for research, particularly mRNA from a single biopsied cell has restricted transcriptomic research into the human embryos. Other probable reasons include plasticity of the embryonic transcriptome and the invasiveness of the process to obtain the biopsied sample.[15]

Microarray technology is a viable option and more recently, NGS has advanced the whole transcriptional analysis of an individual embryo. Exploiting these technologies, various studies have discovered distinct transcriptomes for each stage of preimplantation development in human embryos, with noteworthy changes before and after the maternal-to-zygote transition.[16-18]

While early maternal transcripts are primarily involved in the regulation of cellular processes necessary for the transition, those found in the blastocyst are mostly involved in cell proliferation and differentiation, as well as implantation pathways. In addition, a difference in transcriptomic analysis was observed between human aneuploid and euploid embryos.[19,20]

On the other hand, oocytes are delicate and examining gene expression profiles should be done in a way that does not harm them. Cumulus cells and granulosa cells, which are connected with the oocyte, can be investigated using a noninvasive oocyte mRNA microarray. Checking cumulus gene expression in oocytes serves as a marker and offers transcriptomics information about good quality oocytes, embryo potential, and successful pregnancy. BCL2L11, PCK1, and NFIB gene expression was discovered to be different in the cumulus of good morphology embryos that proceed into pregnancy, while VCAN, PTGS2, GREM1, and PFKP gene expression was linked to good quality oocytes, and oocyte quality can be predicted by the presence of cathepsins mRNA.[21]

Recently, several studies have also looked up at the transcriptome of SFC (somatic follicular cells) to see if there are any new biomarkers that can predict oocyte and embryo competency and/or pregnancy outcome.[22] This is one

indirect but noninvasive approach suggesting that follicular environment, which is important for the maturation and acquisition of competence of a growing oocyte is influenced by bi-directional communication between the oocyte and its surrounding SFCs. These SFCs are exposed to the same environment as the oocytes they are linked with, which likely determines their transcriptome signature.[23]

PROTEOMICS

Proteomics refers to the large-scale study of proteins, also defined as the "PROTEin complement of the genOME". Proteome is a complex and dynamic system that is always changing due to internal and external interactions and stimuli. It is made up of all the proteins that are translated from the transcriptome of a cell and are further responsible for the cellular activities. In order to attain a complete understanding of the cellular function and comprehend biological processes, it is important to investigate a cell's active proteome. Hence, various studies on changes in protein expression have revealed the underlying molecular mechanisms of physiological processes and disease states.[24] Because of the low protein concentration and huge number of proteins to be analyzed, embryonic proteome analyzation is extremely difficult. This, combined with a lack of sensitivity in proteomic platforms, has limited proteome investigations to the identification of specific proteins produced into the medium by the embryo.[25]

These problems have been addressed by some advances in MS as a result of which some sensitive, high-throughput methods have enabled the analysis of complete human embryonic proteome, detecting even the low molecular weight proteins. MS consists of an ion source that generates charged species in the gas phase and an analyzer that separates the ions based on their mass-to-charge (m/z) ratio. Electrospray ionization (ESI) and matrix assisted laser desorption/ionization (MALDI) are the two more commonly used ionization methods for MS analysis. The analyzer used in MS includes TOF, quadrupole, or ion trap. Ions that have been properly aligned by the mass analyzer are then detected and amplified, with the resulting data being processed through databases that predict the identity of the molecules based on their m/z ratio. Tandem mass spectrometry (MS/MS) provides more information about specific ions and is commonly used for protein sequencing.[24]

This technology is utilized as a proteomic platform to study the developing preimplantation embryo. Variation in protein profiles have been observed in early and expanded stage blastocysts as well as developing blastocysts and degenerate embryos.[25] In another study conducted on the protein profiles of human blastocyst lysates, it was discovered that degenerated embryos had a different proteome profile than growing blastocysts.[26]

Microarray Analysis of the Proteomic Embryonic Secretome

In a study conducted by Dominguez and colleagues, to check the differential expression of protein in the secretome of implanted and the nonimplanted blastocysts using protein microarray, it was discovered that two proteins (CXCL-13, GM-CSF) were presumably consumed by implanted blastocyst.[27]

Subsequently, the same group conducted another study in which they proposed that, viable blastocysts consumed more IL-6 (Interleukin-6) than blastocysts that failed to implant, suggesting that IL-6 could be used as a potential predictor of good quality viable embryos.[28] Further, proteomic fingerprinting of individual human implanted embryos has also recently been combined with time-lapse morphokinetic analysis to create a superior embryo selection tool.[29]

Targeted Protein-based Approach

When comparing ongoing blastocysts to arrested embryos, some proteins such as ubiquitin, apolipoprotein A1 and different hCG isoforms have been found to be differentially expressed in the secretome. However, the relationship between these proteins levels and implantation outcomes were not studied in these cases, so, additional validation studies are required before including their analysis in a noninvasive embryo viability assay.[2] A recent study also found that caspase-3 levels in the secretome could predict IVF outcome after transfer of day-2 cultured embryos. In future, it will be interesting to see if it can be a part of the decision-making process regarding which embryo to transfer for a positive pregnancy outcome. However, more research is needed to understand how these markers can be used in this context.[30]

METABOLOMICS

The nutritional requirements and metabolic products of the preimplantation embryo at various stages of development have been studied, and their influence on the implantation process has been discovered. Therefore, human embryo metabolism has been extensively analyzed over the last three decades in order to help predict embryo potential. The majority of research has focused on the noninvasive quantification of a specific class of known metabolites used by the embryo, such as carbohydrates and amino acids. In the case of carbohydrate metabolism, while both pyruvate and glucose uptakes appear to correlate with blastocyst stage development, their relationship to implantation or pregnancy outcome is highly uncertain.[31,32] Hence, it was agreed that, carbohydrate metabolism cannot be considered as a suitable biomarker for embryo selection in clinical use.

Because of the differences in metabolic profile observed between embryos that grew into blastocysts and those that got arrested, specific quantification of amino acid turnover has also been proposed for selecting a competent embryo. Furthermore, some amino acids in culture media or the relative amino acid concentration are linked to the ploidy status of human embryos, as well as clinical pregnancy and live birth.[33,34] This correlation of metabolomic profile with the embryo viability has been validated in studies using media from embryos at different developmental stages after single or multiple embryo transfers. Fertilization rates and pregnancy outcomes were also linked to metabolic profiles of spent culture media from oocytes and follicular fluid.[2]

One of the most promising noninvasive methods for assessing embryo viability is based on measuring metabolite content in spent culture media as a clear reflection of its physiological or pathological status. Various platforms have been used to analyze the embryo metabolism. These include, gas or liquid chromatography (GC and LC, respectively) and/or MALDI coupled to MS, as well as nuclear magnetic resonance (NMR), Raman, or near infrared (NIR) spectroscopy. But due to the complex nature of embryo culture medium and low available sample volume, MS-based methods are considered ideal for this analysis. Vibrational spectroscopy is another technique for analyzing the metabolomic profile which is easily applicable for clinical use.[15] NMR is an efficient nondestructive analytical tool used for biomarker analysis, as it detects and quantifies specific metabolites within biological fluid or tissues. However, low sensitivity, high sample requirement and cost are some limitations associated with this technique.[32] Vibrational spectroscopy utilizes two approaches namely, Raman and IR, wherein scattering of electromagnetic radiation is measured by Raman spectroscopy while absorption of electromagnetic radiation results in an IR spectrum. Vibrational spectroscopy begins with exposing the sample to electromagnetic radiations which leads to the energy absorption by molecule's chemical bonds resulting in vibration to a large extent.[32]

Follicular Fluid

Though NMR and tandem MS have been the methods of choice for the characterization of follicular fluid metabolome, but tandem MS has been found to be more sensitive and with the addition of different chromatographic methods, the number of metabolites that can be detected in the sample is increased. Studies have shown a significant correlation between low amino acid turnover in spent media of 4 to 8 cell embryos and development to blastocyst stage, while high turnover has been found to be an indicator of metabolic stress involved in the repair of damaged DNA, RNA and protein during development, further leading to embryo arrest. Furthermore, when individual amino acids were assessed, it was discovered that there is an abundance of glutamate metabolism in follicular fluid of oocytes that formed blastocyst. As glutamate is one of the main components of fluid in the fallopian tube, therefore it also promotes blastocyst formation.

Overall, the majority of the statistically significant metabolites have been observed to be downregulated in the follicular fluid of embryos that formed a blastocyst, hence supporting the "quiet embryo hypothesis" which states the importance of endogenous resources over nutrient supplementation in embryo survival.[35]

Metabolomics and Semen

Seminal plasma has been the major area of focus for all the metabolomic studies of male infertility. It consists of proteins, amino acids, enzymes, fructose and other carbohydrates, lipids and major minerals and trace elements (such as Zn^{2+}, Mg^{2+}, Ca^{2+}, K^{+} and Na^{+}) secreted by the testes, epididymis, and accessory sex glands and can be used as potential biomarkers for sperm quality. High levels of tyrosine, and phenylalanine and lower levels of alanine, citrate and GPC, and have been related to oligozoospermia (decreased sperm number in the ejaculate), while reduced levels of metabolites involved in phospholipid (choline), cholesterol, and nucleoside metabolism, as well as the Krebs cycle, have been linked to asthenozoospermia (decreased sperm motility). Furthermore, higher levels of citric acid, choline, D-glucose, tyrosine, alanine, proline, leucine, lysine, myoinositol, lactic acid, threonine, pyruvate, glutamine, valine, and isoleucine have been linked to teratozoospermia (an increase in sperm abnormalities),[36] but still more studies are needed to establish a list of sperm metabolites that can be widely used as biomarkers of male fertility.

Recent meta-analysis has shown that these methods such as near infrared spectroscopy in addition to morphology, do not really improve the live birth rate when compared to embryo selection by morphology alone.[37] According to a recent systematic review, there is no evidence to support the use of metabolomics in clinical practice to improve fertility outcomes.[38]

Also, despite the numerous published articles and their complexity, OMICS techniques have not been employed in IVF to identify good quality sperm. The procedures used to search for proteome or metabolomics fingerprints differ, and reproducible results remain a promise rather than an actuality, with clear diagnostic and/or quality signals still to be discovered.

CONCLUSION

Despite the vast amount of biomarker data supplied by OMICS, there is still insufficient evidence to link data from all OMICS to better implantation outcomes. OMICS are reshaping our understanding of these complex processes by

significantly increasing the identification of new potential biomarkers to characterize viable embryos and providing a large number of key molecules that can be used to help identify the molecular causes of implantation failures and other disorders. The use of next-generation technology in less invasive techniques, together with new complicated and integrative computer analysis, will most likely aid in the adoption of OMICS assays. As a result, OMICS technologies may aid in improving the likelihood of embryo implantation, resulting in much higher pregnancy rates and live birth rate while reducing pregnancy losses.

CHAPTER 118

Intracytoplasmic Morphologically Selected Sperm Injection, Physiological Intracytoplasmic Sperm Injection, and its Clinical Significance

Mohammed Ashraf C

INTRODUCTION

The selection of a single spermatozoon, its immobilization, aspiration with a microinjection needle, and injection into the cytoplasm of the oocyte began with the introduction of intracytoplasmic sperm injection (ICSI) in 1992 by Palermo et al.[1] Since then, ICSI is being widely used for the treatment of subfertility and is the treatment of choice for male factor infertility. The primary concern with regard to ICSI is the selection of spermatozoon presenting both motility and normal morphology based on the evaluation of its head, neck, and tail.

In ICSI, the selection of sperm is performed under an overall magnification of 400×, which makes it possible to detect in the living state, most of the sperm anomalies recognized by the conventional basic semen analysis, performed on fixed and stained samples. This magnification only allows the observation of sperms with major morphological defects, while sperms with minor morphological defects go undetected. This poses a major drawback as it affects ICSI outcome.

As a result, spermatozoon that appears to be morphologically normal under this magnification could still have numerous structural abnormalities[2] affecting the development of embryos and implantation rates **(Figs. 1A and B)**.[3]

In the literature, only a few studies have reported that there is no correlation between the percentage of morphologically normal spermatozoon and ICSI outcome.[4,5] This may be attributable to a lack of correspondence between the morphological evaluation of seminal fluid performed on random cells obtained from original semen or from the motile fraction and the real morphological aspect of the single spermatozoon selected for microinjection. Starting from these assumptions, it would therefore seem sufficient to identify at least one single morphologically normal spermatozoon for each oocyte insemination to optimize ICSI outcome.

Studies show that ICSI outcomes are significantly influenced by individual sperm morphology.[6] De Vos and colleagues reported that when individual sperm morphology was assessed at the time of ICSI, it had an effect

Figs. 1A and B: (A) Intracytoplasmic sperm injection (ICSI) at 400×; (B) Intracytoplasmic morphologically selected sperm injection at 8,000×. *Source:* Adapted from Center for Infertility and Human Reproduction (CIRH). Barcelona, SPAIN.

on the fertilization rate but showed no effects on the embryo development. Implantation rates were lower only when injected with abnormal spermatozoon. This assumption is very important because it can reflect the embryo chromosomal defects of probable paternal origin and was recently confirmed in a shared oocyte model.[3,7,8]

Bartoov et al. in 2002 developed a new method of unstained, realtime, highmagnification motile sperm organelle morphology examination known as MSOME.[2] In MSOME, an inverted light microscope fitted with a high-power Nomarski differential interference contrast optics enhanced by digital imaging is used for achieving a very high magnification of 6,600×. MSOME when used with a micromanipulation system allows for the retrieval of a single motile spermatozoon with a welldefined morphologically normal nucleus to be injected into the oocytes. Since sperms cells are selected based on the morphology, this modified in vitro fertilization (IVF) procedure was named intracytoplasmic morphologically selected sperm injection (IMSI).[9]

INTRACYTOPLASMIC MORPHOLOGICALLY SELECTED SPERM INJECTION

Procedure

For semen sample preparation, the density gradient technique is preferred, and the motile sperm fraction was employed for further retrieval based on MSOME. Part of the motile sperm suspension (2–4 μL) is transferred to a 4 μL of a polyvinylpyrrolidone (PVP) medium and placed in a sterile, glassbottomed dish (GWSt1000; Biosoft International, Amsterdam, the Netherlands) covered with mineral oil. Adjustments of sample temperature and PVP concentration were made according to the intensity of sperm motility. When sperm motility was low, the sample temperature was raised to 37°C and no PVP was used, while 6% human serum albumin was added to the recipient droplet.[2] When the sample showed high sperm motility, the suspension temperature was reduced to 20°C, and PVP was added to a final concentration of 8%. In order to gain control of the moving sperms and facilitate their morphological evaluation, Bartoov created a series of small bays, extruding from the rim of the droplets, to block the heads of the motile spermatozoa **(Fig. 2A)**. Microdroplets containing sperm suspensions are subsequently observed under immersion oil under an inverted microscope.[2,9]

Microscope Equipment

Bartoov used an inverted microscope equipped with Nomarski differential contrast optics, an UplanApo oil/1.35 objective lens, and a 0.55 numerical aperture (NA) condenser lens. This system is coupled with an image capturing high-definition color video camera, with a 0.5 inch, three-chip power holeaccumulation diode chargecoupled device (HAD CCD) containing some 380,000 pixels and a high-definition color video monitor for morphological assessment. The resulting magnification is based on four parameters:

1. Objective magnification 100×
2. Magnification selector 1.5×
3. Video coupler magnification 0.99×
4. Calculated video magnification (CCD × monitor diagonal dimension) 44.45×.

Therefore, total magnification = 100 × 1.5 × 0.99 × 44.45 = 6,600x.[2]

Motile Sperm Organelle Morphology Examination Criteria for Intracytoplasmic Morphologically Selected Sperm Injection

A spermatozoon selected for IMSI is classified as morphologically normal if it exhibited a normal nucleus as well as an acrosome, a postacrosomal lamina, a neck, and a tail and did not present a cytoplasmic droplet or cytoplasm around the head.[2,9] The subcellular organelles were morphologically classified based on the presence of specific abnormalities, defined according to the arbitrary descriptive approach reported by Bartoov et al., by using transmission and scanning electron microscopy **(Table 1)**. The estimates of transmission electron microscopy suggest that the shape and content of chromatin determine the morphologically normal state of the nucleus. The criterion for the normality of nuclear form was a smooth, symmetric, and oval configuration. The estimates for normal means for length and width were 4.75 ± 2.8 and 3.28 ± 0.20, respectively. When the form presented a variation of two standard deviations in one of the axes (length: ≥5.31 μm or ≤4.19 μm; width >3.7 μm or <2.9 μm), it was classified as abnormal **(Figs. 2A and B)**. For rapid evaluation of the nuclear form, a fixed transparent, celluloid form of a sperm nucleus fitting the criteria was superimposed on the examined cell (chablon construction based on the ASTM E 19512). Similarly, a nuclear form was considered to be abnormal if one or more vacuoles occupied >4% of the nuclear area (visual evaluation was aided by a celluloid form of a large vacuole superimposed on the examined cell, if necessary). Finally, when the nuclear form and chromatin content are normal, a nucleus is considered to be normal.

In the first study by Bartoov's group, MSOME was applied on the leftover motile sperms fraction of 100 random couples seeking ICSI treatment. The mean incidence of morphological normalcy was 3.3% (±0.55), showing a significant positive correlation with the fertilization rates following the standard ICSI procedure ($p < 0.01$). The result was also confirmed by dividing patients according to their fertilization rates. A significantly higher incidence of morphologically normal spermatozoa was observed in the normal fertilization group (>60%, $n = 53$) than in the low fertilization group (<60%, $n = 47$, $p < 0.01$) **(Fig. 3)**.

TABLE 1: Specific sperm morphological abnormalities at the subcellular level according to motile sperm organelle morphology examination (MSOME) criteria.

Nucleus		*Acrosome*	*Postacrosomal lamina*	*Mitochondria*	*Neck*	*Tail*
Shape	***Chromatin content***					
Small oval	Vacuolar area >4% or the entire nuclear area	Lack	Lack	Lack	Abaxial disorder	Lack
Large oval		Partial	Vesiculated	Partial		Coiled
Narrow (<2.9 µm in width)		Vesiculated	Disorganization		Cytoplasmic droplet	Broken
Wide (>3.7 µm in width)						Multi
Short (<4.2 µm in width)						Short
Regional disorder

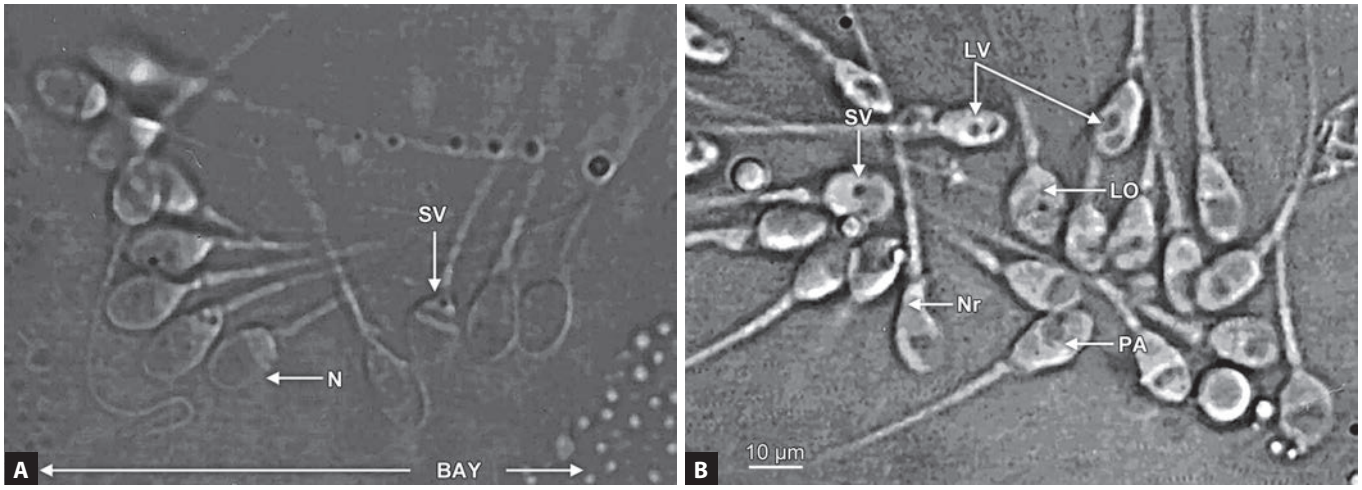

Figs. 2A and B: High-power light microscope micrograph of motile sperm (6,500×). The sperm heads were captured in small bays (BAY) extruding from the rim of the droplets.
(LO: large oval sperm cells; LV: large nuclear vacuoles; N: morphologically normal spermatozoa; Nr: spermatozoa with a narrow postacrosomal region; PA: partial acrosome; SV: small nuclear vacuoles)

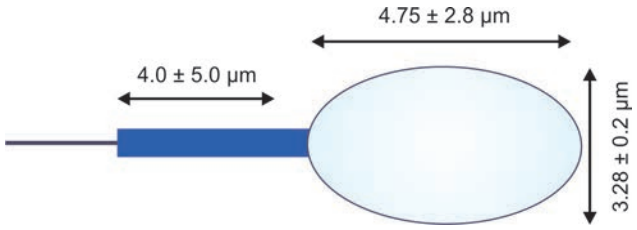

Fig. 3: Schematic representation of dimensions of normal spermatozoa according to Bartoov criteria.

The authors demonstrated that among the group of subcellular organelles examined by MSOME, only the morphological normalcy of the sperm nucleus had a positive correlation with fertilization.

Selection of Vacuole-Free Sperm (Pathological Aspects of Nuclear Vacuoles)

Vacuoles are similar to liquid bubbles observed in the nucleus of a sperm's head. Their presence has been correlated with deoxyribonucleic acid (DNA) anomalies. Vacuole is a sign of molecular defects caused by abnormalities of sperm chromatin packaging and anomalous chromatin remodeling during sperm maturation;[10,11] such defects make the spermatozoa more susceptible to DNA damage. Research shows that the integrity of the chromatin is correlated with the presence or absence of vacuoles in the head of spermatozoa, and defective chromatin compaction makes DNA more susceptible to reactive oxygen species.[12,13] Patients with teratozoospermia index have sperm vacuoles exclusively in the nucleus and are preferentially situated in the anterior part of the sperm head.[14] The chromatin containing large vacuoles was unusually decondensed and showed a high level of immaturity.

Midpiece Selection

Motile sperm organelle morphology examination allows the detection of midpiece selection and other abnormalities leading to infertility. Ugajin et al. were able to demarcate

between a straightshaped and taperingshaped midpiece.[15] The taperingshaped midpiece is a result of aberrant microtubule organization and is thus associated with abnormal centrosomal function,[16] stated that after the nucleus, the centriole plays a vital role in the initiation of the intracytoplasmic fertilization process, as it is responsible for the development of the sperm aster. The dysfunction of centrosomes results in fertilization failure due to the absence of a sperm aster. IMSI allows for the selection of sperms with morphologically straight midpiece where the sperms will have functional centrosomes and therefore increases the rate of fertilization and enhances embryo development post ICSI.

Vacuoles and Embryo Development (Full Benefit of Intracytoplasmic Morphologically Selected Sperm Injection is Attained with Blastocyst)

The selection of morphologically good-quality spermatozoa by IMSI yields a better embryo quality and higher blastocyst per cycle.[17] The nuclear vacuoles can have a negative impact on human embryo development as the presence of these vacuoles is related to sperm DNA damage. Hence, the embryo development, pregnancy, miscarriage, and malformation are affected by the selected spermatozoa.

Intracytoplasmic morphologically selected sperm injection reduces abortion rates by 50%. Prolonging embryo culture till blastocyst stage (5 days) can serve as a strong diagnostic tool, reflecting genomic activation and providing information on the implantation potential of human embryos.[17,18]

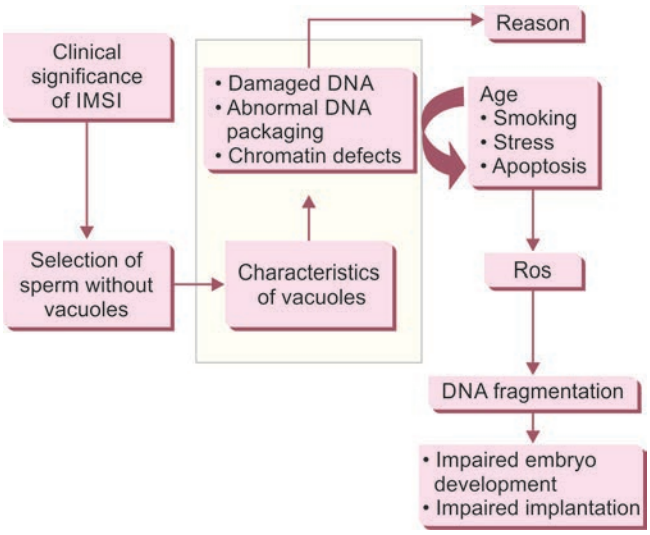
Clinical Significance of Intracytoplasmic Morphologically Selected Sperm Injection

Many studies report that the morphological quality of the spermatozoa used plays a vital role in the fertilization, implantation, and pregnancy rates in ICSI cycles **(Flowchart 1)**.[6,19]

According to Berkovitz et al., the use of the best ultrastructural morphology sperm in IMSI showed a significant difference in the clinical results over conventional ICSI. The morphological features that had the most detrimental effect on the clinical outcome were the presence of large vacuoles.[20,21]

In a recent metaanalysis comparing ICSI versus IMSI outcome,[22] three studies comprising 357 IMSI cycles and 349 ICSI cycles[9,20,23] were considered. Only the fertilization rate was comparable between the ICSI and IMSI groups (76.7 vs. 75.7%) [odds ratio (OR) 0.95; 95% confidence interval (CI) 0.81–1.11]. The overall results of metaanalysis for topquality embryo (27.7 vs. 41.2%, OR 1.83; 95% CI 1.50–2.24), implantation rate (10.5 vs. 21.9%, OR 1.50–4.95),

Flowchart 1: Clinical significance of intracytoplasmic morphologically selected sperm injection (IMSI).



(DNA: deoxyribonucleic acid; ROS: reactive oxygen species)

pregnancy rate (26.6 vs. 47.6%, OR 3.12; 95% CI 1.55–6.26), and miscarriage rate (29 vs. 14.7%, OR 0.42; 95% CI 23–0.78) were all in favor of IMSI.

The weakness of this metaanalysis is the variable study's characteristics. Only one randomized control study was included in this analysis.

In a recent prospective randomized study, 24 a comparison between the clinical outcome of 87 IMSI cycles and 81 ICSI cycles in an unselected infertile population showed that IMSI did not provide any significant improvement in the clinical outcome in comparison with the ICSI cycles. However, the IMSI group showed trends in higher implantation (28.9 vs. 19.5%), clinical pregnancy (54 vs. 44.4%), and live birth rates (43.7 vs. 38.3%). The significantly higher implantation rates, when compared with the ICSI groups (26.9 vs. 15.2%, $p = 0.01$), show that patients with severe male factor infertility benefit from the IMSI procedure.

Intracytoplasmic Morphologically Selected Sperm Injection for All

Although IMSI is useful in selected patients, routine IMSI for all patients is not shown to be useful.[24,25]

Intracytoplasmic Morphologically Selected Sperm Injection and Severe Male Factor Infertility

In a prospective randomized trial, the potential of IMSI over ICSI was assessed in the management of 446 couples with severe oligoasthenoteratozoospermia without considering the previous failed attempts. IMSI yielded a significantly higher implantation and pregnancy rates than those for ICSI (17.3 vs. 11.3%, $p = 0.007$ and 39.2 vs. 26.5%, $p = 0.004$,

respectively) in cases where patients suffered from severe male factor infertility.[18] In subgroup analysis, the group with at least two previous failed ICSI attempts benefitted from the IMSI procedure in terms of clinical pregnancy rates (29.9 vs. 12.9%, $p = 0.017$). These results are even more valuable when there is restriction in the number of oocytes that were injected.

Spermatozoa showing nuclear normalcy were found to be significantly associated with the lower incidence of aneuploidy in derived embryos, resulting in lower rates of cycle cancellation.[26]

Intracytoplasmic Morphologically Selected Sperm Injection in Globozoospermia

Globozoospermia is a condition involving premature elimination of acrosomal structures during spermiogenesis. Phospholipase C zeta (PLCζ), which is a decisive factor for the activation of oocytes by inducing Ca^{2+} oscillations, will be absent in most of the globozoospermic cases and in turn results in fertilization failure. Some globozoospermic spermatozoa will have an acrosomal bud that possesses the total amount of PLCζ and is not invariably different from fertile controls, can be detailed with IMSI, and helps to achieve successful oocyte activation and fertilization.[27,28]

Intracytoplasmic Morphologically Selected Sperm Injection in Previous Intracytoplasmic Sperm Injection Failure Patients

Klement et al. conducted a cohort study to find out the advantage of IMSI versus ICSI in the first assisted reproductive technology (ART) cycle and in consecutive cycles in male factor infertility patients requiring micromanipulation. A total of 1,891 IVF–ICSI and 577 IVF–IMSI cycles were included. The first cycle of IVF treatment showed pregnancy rates of 46 and 47% and delivery rates of 23 versus 30%, respectively. The second cycle following a failed ICSI cycle showed a significant rise in pregnancy and delivery rates in patients that opted an IMSI technique over a second ICSI cycle (56 vs. 38% pregnancy rates and 28 vs. 18% delivery rates). A multivariate analysis showed an approximately threefold increase in the chance for both pregnancy and delivery rates in couples opting IMSI after a failed ICSI attempt.[29]

In a prospective study of 200 couples with at least two prior unsuccessful ICSI, clinical outcomes were evaluated between 100 couples who were assigned to IMSI and 100 couples who were assigned to routine ICSI.[30] There were no significant differences between the two groups with regard to the rate of fertilization, implantation, and pregnancy rate/cycle. However, there is no statistically significant miscarriage rate (IMSI 15.3% vs. ICSI 31.7%), ongoing pregnancy rates (IMSI 22% vs. ICSI 13%), and live birth (IMSI 21% vs. ICSI 12%); the IMSI group showed better clinical outcomes.

Intracytoplasmic Morphologically Selected Sperm Injection and Sperm DNA Fragmentation

The integrity of DNA is an important factor in the success of human reproduction. It has been clinically proven that the sperm DNA damage has a negative effect on reproductive outcomes. Studies show that the spermatozoa from infertile men possess significantly more DNA damage in comparison with fertile men.

A study by Franco et al.[31] evaluated the amount of DNA fragmentation in 30 unselected patients [by TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling) assay] and the prevalence of singlestranded or doublestranded DNA (by acridine orange) in sperm cells with large nuclear vacuoles and in strictly morphologically normal sperms both selected at high magnification (8,400×). A significantly high DNA fragmentation was reported in large nuclear vacuole sperms than in normal sperms (29.1 vs. 15.9%, $p < 0.001$). When compared with normal sperms, the large nuclear vacuole group also showed a significant increase in the amount of single-stranded DNA damage (67.9 vs. 33.1%, $p < 0.001$). Hence with better sperm selection with IMSI, pregnancy outcomes can be improved in semen samples with high sperm DNA fragmentation.

Intracytoplasmic Morphologically Selected Sperm Injection and Routine Semen Analysis

The correlation between MSOME and much commonly used morphological assessment by Tygerberg criteria was compared[30] by regression analysis of 97 randomly selected semen samples. It was postulated that despite high positive correlation between these two assessments, MSOME provides a much more strict evaluation criterion for sperm morphology since magnification at 6,600× reveals more fine nuclear assessment. In addition, MSOME focuses on motile sperm fraction only, and hence provides information on the fertilization and developmental potential of fraction referred for ART.

Intracytoplasmic Morphologically Selected Sperm Injection and Prolonged Sperm Manipulation

As IMSI based on MSOME is a time-consuming procedure (average 1–1.5 hours),[10] a study was undertaken to verify whether the prolonged exposure at 37°C could impair the morphological integrity of the sperm nuclei. The morphological normalcy of sperm nuclei was significantly impaired after 2 hours of incubation at 37°C compared with

initial rates (4.7 ± 2.8% vs. 6.8 ± 3.5%, $p < 0.01$). A similar detrimental effect was reported for the percentage of sperms with vacuolated nuclei, which was significantly higher than before (80.8 ± 7.2% vs. 75.0 ± 7.6%, $p < 0.01$).

On the other hand, prolonged incubation of sperms at a lower temperature (21°C) did not produce any significant morphological impairment. Hence, an incubation temperature of 21°C is preferred in case of extended sperm manipulation during MSOME.

PHYSIOLOGICAL INTRACYTOPLASMIC SPERM INJECTION

Physiological intracytoplasmic sperm injection (PICSI) is a technique in which physiologically mature spermatozoa are selected based on their capacity to bind hyaluronic acid **(Fig. 4)**.

Hyaluronan is the primary constituent of cumulus oophorus layer that encloses the human oocyte. It is a biopolymer (polysaccharide) and is found in every human cell. Hyaluronanspecific ligand receptors are present in a mature sperm head that facilitates the sperm to unite to hyaluronan. In comparison, immature sperms do not tend to unite to hyaluronan as they lack these receptors. However, this advancement does not imitate the genomic integrity of the spermatozoa and its aptitude to deliver the best paternal contribution to the zygote.[32]

Advantages of Physiological Intracytoplasmic Sperm Injection

Selection of sperm based solely on facade and appearance can be flawed as sperms that appear healthy could have chromosomal imperfections. Hyaluronic acid-bound spermatozoa have enhanced morphology and it could reduce the chances of aneuploidies.

Fig. 4: Selection of hyaluronic acid (HA) bound sperms with injection pipette.

Disadvantages of Physiological Intracytoplasmic Sperm Injection

In case of testicular sperm aspiration (TESA) sample, PICSI cannot be performed as immotile sperms are present and also in cases where occasional sperms are present (sperm counts ≤1 million/mL).

PHYSIOLOGICAL INTRACYTOPLASMIC MORPHOLOGICALLY SELECTED SPERM INJECTION

Intracytoplasmic morphologically selected sperm injection is a technique that allows the selection of spermatozoa based solely on morphology, wherein highresolution optics and digital analysis are used to reveal morphological abnormalities in the spermatozoa,[33] while in PICSI, the sperm selection is based on the physiological maturity of sperm based on their capacity to bind hyaluronic acid. Wilding et al. in 2012 combined these two techniques and named physiological IMSI (PIMSI).[34]

The application of hyaluronic acid sperm selection techniques and morphological selection of spermatozoa with IMSI are not mutually exclusive. Therefore, they were combined into a new technique termed "PIMSI".

Idiopathic infertility continues to remain a "pathology" that is difficult to treat with ARTs. The main challenge in such cases is the selection of unfragmented DNA from an ejaculate containing high levels of fragmented DNA. In such cases, PIMSI can take a leading role by selecting the matured ones at first followed by performing their morphological assessment.[35]

KEY POINTS

- Highpower morphological selection of sperms is rather a new technique offering an advanced mode of sperm selection. This becomes more important when the production of supernumerary embryos needs to be overcome for ethical, religious, or legal reasons.
- This procedure which is costly and time consuming has been mainly applied in a selected population of patients.
- The evidence at present shows that patients with previous failed IVF–ICSI cycles, severe male factor patients, and those with high sperm DNA fragmentation may benefit from IMSI compared to conventional ICSI by yielding higher pregnancy rates and lowering miscarriage rates.
- In addition, the PIMSI technique has the potential to be instrumental in treating patients suffering from idiopathic infertility.
- However, there is a need for more prospective randomized studies to confirm and correctly identify the group of patients that could benefit from these methods.

CHAPTER 119

Microfluidics in Assisted Reproductive Technology

José María de los Santos, Thamara Viloria, Ana Cobo, Josep Lluís Romero, Marcos Meseguer

INTRODUCTION

In the last 30 years, human-assisted reproductive technology (ART) has profoundly changed. It is now a scientific field where novel research works continuously emerge, and it is becoming an exciting area to investigate and work in. Since the first in vitro fertilization (IVF) birth,[1] IVF cycles exceed 600,000/year and are performed in more than 50 countries.[2] Despite novel techniques and procedures, such as sperm isolation,[3] intracytoplasmic sperm injection (ICSI),[4] thawed embryo transfer,[5] optimal culture conditions assessment,[6] preimplantation genetic diagnosis (PGD),[7] oocyte vitrification,[8] and timelapse embryo quality assessment,[9] having improved from the very beginning, there are not many approaches that mimic in vivo conditions such as female genital tract and physiological changes. Indeed, the most commonly used culture system is microdrop medium culture with oil overlay in Petri dishes. Perhaps, for this reason, in vitro human embryo culture is inefficient. Although many efforts have been made to improve culture media and optimal microenvironment, physics parameters have not been considered in the majority of these studies. Moreover, the incubators, dishes and plates, and other devices currently used in human IVF have been rescued from cell culture procedures and have not been designed specifically for this objective. Microfluidics chip devices may be a new approach to solve this problem and might replace conventional human embryo culture in microdrops in the future.

At the beginning, microfluidic systems appeared as miniaturized devices designed for chemistry analyses and certain molecular biology procedures and were later used as cell culture platforms. However, some studies showed that it is possible to use them as an alternative to conventional ART; basically, these include sperm isolation, oocyte decumulation, IVF, embryo culture, and even microdevices in all the earlier steps.

Although microdrop culture allows autocrine factors retention around the embryo, it does not provide mechanical stimulation. The main property whereby a microfluidic system is advantageous as compared to conventional culture platforms is its behavior at the microscopic level. Turbulent fluid flow is usually observed on a normal environment scale; therefore, stream of fluid is unpredictable. However, if the physics parameters (density, viscosity, and velocity) are adequate and the microfluidic device is produced to take them into account, laminar fluid flow can be achieved. In this way, it is foreseeable to track a particle through it. Thereby, a continuous interface between different density fluids can be achieved by acting as an ideal surface to exchange gases, growth factors, and even cell isolation. The introduction of microfluidics into gamete or embryo culture systems is a change of paradigm as gametes or embryos stay in the same place throughout the process, while the culture media surrounding them can change continuously, thus minimizing harm to them, such as temperature or pH oscillation, osmolarity changes, shear stress, and preserving microenvironments around gametes or embryos.

Furthermore, there are some disadvantages involved due to excessive flow rate and the washing of autocrine or paracrine factors released for embryos, shear stress, osmolarity changes for culture media evaporation, etc. For this reason, it is very important to achieve a correct flow pattern, the complete refreshing or recirculation of the culture media, and the cell surface interactions required to correctly handle these microfluidic devices, which can be responsible for earlier unsuccessful experiences with such platforms.[10-12] Furthermore as regards culture media composition, efforts must be made because, nowadays, these culture media are designed for microdrop static culture systems. Thus, a new composition (subtracts, hormones, and growth factors) is required to improve those results. Currently, these platforms aim to operate along wide-ranging times with no manipulation, automatic fluid flow,

and culture media control for each embryo development step (as with gravity-driven flow, syringe pump, and piezo-Braille pin actuation). An ultimate aim is to employ a system that is capable of combining the aforementioned qualities and which is, at the same time, able to use a video timelapse system for morphokinetics embryo assessment.

The objective of this chapter is to explain the different areas of ART where microfluidic devices have been used. Moreover, the authors attempt to summarize their design, results, and possibilities for future human ART use. They pay attention to those studies which they believe are the most interesting and didactic for students.

MANUFACTURING MICROFLUIDIC DEVICES

Although a wide range of materials to construct micro-devices, including microfluidic platforms, have been used, plastic polymer platforms are currently the best option because they are easy to handle and are cheaper to produce as compared with other materials.[13] Specifically, the use of polydimethylsiloxane (PDMS) became the first option because its physical properties render it suitable for rapid prototyping and aqueous applications, and its use is compatible with biological systems. PDMS is nontoxic, chemically inert, colorless, and allows gas exchange. A commonly used microfluidic fabrication technique is polymer casting, also known as soft lithography or replica molding. Briefly, the steps to be taken are: (1) Casting a PDMS mixture on a silicon master, (2) curing by heat (65°C/2 h) and demolding PDMS, (3) bonding (O_2 plasma/30 s), and (4) adding glass slides and placing connectors for inlet and outlet ports.[13] Moreover, PDMS platforms have been tested to assess potential harm to mammalian and human gametes and embryos. These studies found no significant differences as compared with traditional culture performed by microdrops systems.[14-16]

However, there are certain restricting PDMS properties such as deformation, evaporation, leaching, hydrophobic recovery, and absorption that discourage its use in cell culture and ART, at least at naïve status.[17] For this reason, different PDMS pretreatments have been developed to solve these problems. On the other hand, bypassing the previous inconveniences, some authors argue thermoplastics as the solution. One of the most interesting examples is polystyrene (PS), widely used for cell culture and ART. The PS handicaps include mold fabrication, hot embossing, thermal bonding, and inlet ports/outlet port creation, raising final production costs.[17] Some efforts have been made to reduce these inconveniences, and currently, there are some procedures able to have the best things of both options making PS platforms and devices of an efficient manner.[18]

SPERM ISOLATION

Nowadays, two sperm isolation techniques, swim up and density gradient separation,[19] are used. However, there are studies that report deoxyribonucleic acid (DNA) damage and reactive oxygen species (ROS) release by these procedures.[20] Some attempts have been made to replace them with microfluidics prototypes, but we focus on what most interests us.[16] This microfluidic device is formed by two inlet ports and two outlet ports which, in turn, form one area with two parallel laminar flow streams. A gravity-driven pump generates fluid flow. It places the sample in the first inlet port, and it places fresh culture media in the second inlet port. Therefore, an interface appears between the two flows, which only allows particles to pass by diffusion or by active movement such as motile sperm. In this way, the first outlet port obtains debris, round cells, and nonmotile sperm, while the second port acquires motile sperm **(Fig. 1)**. To test this microfluidic platform, unprocessed human semen, which was artificially enriched with debris and round cells, was placed in the first inlet port (44% of sperm motility and an approximate 10/1 round cells/sperm ratio). As a result,

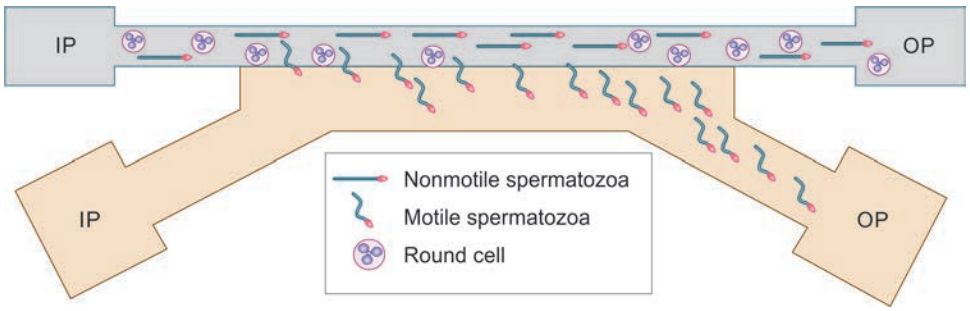

Fig. 1: Model showing a microfluidic device that is formed by two inlet ports and two outlet ports. It places the sample in the first inlet port (upper port, at left), and it places fresh culture media in the second inlet port (lower port, at left). A gravity-driven pump generates fluid flow. Motile sperm are able to swim between parallel laminar flow streams interface. In the first outlet port (upper port, at right), debris, round cells, and nonmotile sperm are obtained and in the second outlet port (lower port, at right), motile sperm is acquired. Model is not at a real scale. (IP: inlet port; OP: outlet port)

the sperm motility in the second outlet port was increased to 98%, and the round cells/sperm ratio was lowered to 1/33. Therefore, this novel device can act as a sperm isolation alternative because, at the same time, it was able to achieve both increased morphology and decreased debris/round cells. Nevertheless, its main limitation was its low volume processing at a rate of 20–40 µL/h. Although ICSI does not need total semen sample processing because the total sperm cell required for microinjection is low, we can consider that this device needs to be improved to be an alternative to other techniques.

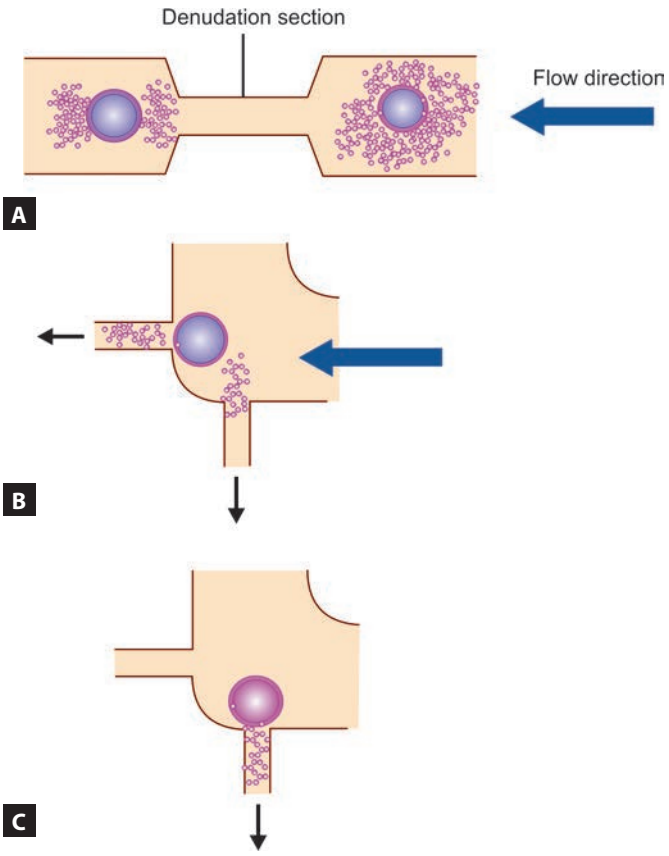
OOCYTES DENUDATION

Inevitably, the oocytes employed to perform conventional IVF or ICSI must be denuded. Basically, the oocytes retrieved after ovum pickup are cultured for around 4 hours. If ICSI is performed, oocytes are denuded to assess maturity and are microinjected as soon as possible.

Following conventional IVF, oocytes must be denuded at around 18 hours postinsemination to assess fertilization success. In any case, denudation implies stress to oocytes, so this is carried out by gentle repeated aspiration through several glass or plastic pipettes to mechanically remove cumulus and corona radiata cells. To reduce such stress, some microfluidics devices have been designed. Some experiences have been performed in bovine oocytes rendering good results.[15] These oocytes were placed on this platform 22 hours after conventional IVF by a standard pipetting procedure. The oocytes placed in the inlet port flow along the microchannel, and they consecutively pass through the contrition-conditioning areas. Then systematically, cumulus and corona radiata cells were trapped or aspirated by constricted microchannels or twin microchannels placed at a 90° angle to each other **(Figs. 2A to C)**. As a result, 90% of these zygotes were successfully denuded, and the mean time taken was only 20 s/oocyte. Moreover, these oocytes were apparently not injured because subsequent embryo development was not affected.

IN VITRO FERTILIZATION

Conventional IVF is an easy procedure because if the sperm parameters are good, it is necessary to only adjust the sperm concentration correctly and then perform the insemination. Microdrops in Petri dishes and well-plate platforms with an oil overlay are widely used. The sperm concentration used in human IVF is around 1×10^5 motile sperm/mL, but total motile sperm depends on the total volume used. Thus, if we use 50 µL drops, the ratio is 5,000, this being the total number of motile sperm per oocyte. Thanks to this "easy-to-use" procedure, no drastic changes take place at all. However, is it the best microenvironment for oocyte integrity and future embryo competence. Many sources can produce ROS,



Figs. 2A to C: Model presenting a microfluidic platform for oocyte denuding. The oocyte placed in the inlet port (not shown in the figure) flows along the microchannel and it is denuded by the action of contrition-conditioning areas (A) or aspiration by twin microchannels placed at a 90° angle to each other (B and C). Model is not at real scale.

such as oocyte or sperm metabolism, granulosa or corona radiata cells, and culture media.[21] ROS accumulation occurs during the insemination period because sperm and oocytes were coincubated for around 18 hours until fertilization assessment. In fact, DNA damage[22] and high ROS levels on the fertilization day were related to low pregnancy rates when conventional IVF was performed.[23] When performing conventional IVF, possible solutions for this problem can include a reduced coincubation time[24] or the use of microfluidics platforms as they offer certain advantages as compared with traditional systems (e.g., reduced total motile sperm required and diminished polyspermic zygotes formation).

One of these platforms consists in a funnel inlet port for media and gametes.[14] A microchannel (500 µm wide × 180 µm high) allows continuous media and sperm flow, retains oocytes, and at the same time avoids possible harm from oocyte deformation. Negative pressure and a gravity-driven pump acting by silicon tubes from the outlet port generate the fluid flow. To perform this IVF test, mice-denuded oocytes and capacitated sperm were used. Oocytes were pipetted to the inlet port, and flow was transported and

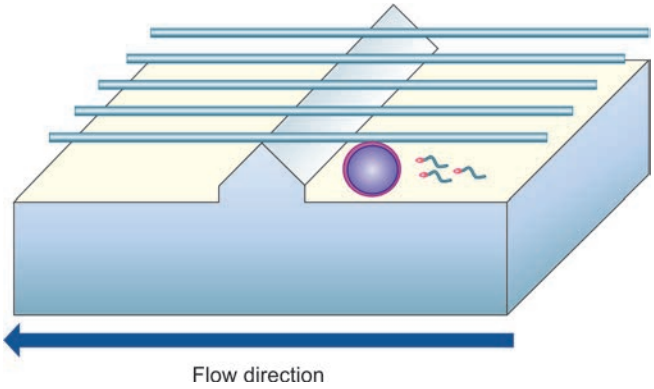


Fig. 3: This platform consists in a funnel inlet port for culture media and gametes. Negative pressure and gravity-driven pump acting by silicon tubes from the outlet port generate the fluid flow. Oocytes are pipetted to the inlet port (not shown in the figure), and the flow transports and retains them at the microchannel gate (as shown in the figure). Sperm is also loaded in the same inlet port and flows to oocytes along the microchannel. Static coincubation lapses are carried out to improve the interaction with them. Model is not at real scale.

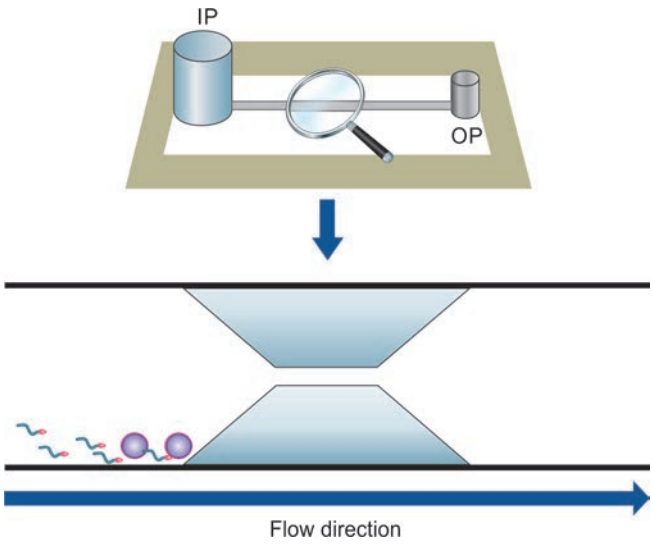

Fig. 4: Device consists in two opposite glass reservoirs, the inlet funnel port and the outlet port (upper picture). A microchannel is combined with them to allow sperm and oocytes' flow by a gravity-driven pump. Oocytes are located in the middle of the microchannel to be stopped by a constricted area. Capacitated sperm are placed in the inlet port and are carried to the trapped oocytes. Model is not at a real scale. (IP: inlet port; OP: outlet port)

retained at the microchannel gate **(Fig. 3)**. Sperm was also loaded in the same inlet port, the flow to oocytes goes along the microchannel (the total media volume used was 50 µL), and static coincubation lapses were carried out to improve the interaction with them. Conventional IVF in center-well Petri dishes was used as the negative control (the total media volume used was 500 µL). Moreover, to assess the potential harm of PDMS to oocytes or sperm, parallel conventional IVF was done with this material present, and no significant differences in the respective fertilization rates (42% without PDMS vs. 41% with PDMS) were observed. However, the fertilization rate in conventional IVF center-well Petri dishes using a standard sperm concentration (1×10^6 sperm mL^{-1}) was higher than in the microfluidic device (43 vs. 12%, respectively). Interestingly, the microfluidic platform proves the best option to achieve better fertilization rates when the sperm concentration lowers, showing a plateau when concentrations between 8×10^4 sperm mL^{-1} (10% conventional IVF vs. 27.1% microfluidics conventional IVF, respectively) and 2×10^4 sperm mL^{-1} (10% conventional IVF vs. 27.4% microfluidics, respectively) were used. Knowledge of this phenomenon is interesting mainly for microdevice improvement and for future use in human IVF. Thus, it can offer possibilities to perform IVF to patients who can currently choose only ICSI because a decreasing volume with a constant sperm concentration reduces the total number of sperm required to carry it out.

Another problem encountered when using conventional IVF is polyspermic zygote formation[25] because it can achieve low polyspermic formation rates for microfluidics platforms as compared with conventional IVF.[26] For this study, porcine-capacitated sperm and in vitro matured denuded oocytes were used. Basically, the inlet funnel port and the outlet port device consist in two opposite glass reservoirs (10 × 10 mm). A microchannel (100 mm wide × 250 µm tall × 38 µm long) is combined with them to allow sperm flow by a gravity-driven pump, and at the same time, oocytes are located in the middle of the microchannel to be stopped by a constricted area. In this way, the microchannel allows sperm flow and mimics the oviduct tract. Oocytes were pipetted to the inlet funnel port, dropped to the channel, and rolled into the constricted area **(Fig. 4)**. During this time, 200 µm of capacitated sperm (6×10^5 sperm mL^{-1}) were placed in the inlet port and were carried to the trapped oocytes by a gravity-driven flow to be mixed with 200 µL of fertilization medium in the microchannel. As a negative control, conventional IVF was performed by microdrop in Petri dishes with an oil overlay by adding 50 µL of the same sperm solution (6×10^5 sperm mL^{-1}) to 50 µL of the fertilization medium drops. Therefore, the final concentration in both systems was 3×10^5 sperm mL^{-1}. When comparing 10 or 15 oocytes inseminated at the same time in both experiments, the results obtained were similar. The sperm penetration rate was comparable (96% microdrop vs. 88% microfluidics; 97% microdrop vs. 87% microfluidics), but the monospermic rate increased significantly when the microfluidic system was employed (22% microdrop vs. 55% microfluidics; 22% microdrop vs. 63% microfluidics) and gave a comparable male pronucleus formation rate (78% microdrop vs. 82% microfluidics; 80% microdrop vs. 73% microfluidics). Moreover, the mean sperm in the penetrated oocytes was significantly higher in the microdrop than in the microfluidic system (6.47 sperm/oocyte in microdrop vs.

2.03 sperm/oocytes in microfluidics; 7.39 sperm/oocyte in microdrop vs. 1.66 sperm/oocytes in microfluidics). Thus, this microfluidic system allows comparable penetration and male pronucleus formation rates, but significantly reduces polyspermy when performing an IVF with porcine oocytes. Likewise, the physical microfluidic system parameters can be responsible for these results because presence of flow can change the behavior and dynamics of the sperm around the oocytes. Moreover, oocytes can be stimulated by fluid flow, and a tridimensional microenvironment can simulate an in vivo oviductal tract architecture.

EMBRYO CULTURE

We focus on one of the devices, presented as IVFLab 6, which uses microfluidics in an automated cell culture device for IVF **(Figs. 5A and B)**. The medium is automatically controlled to a flow rate of up to 20 µL/h, and two types of media can be used, which were automatically administered. Fresh medium is added to each well and waste products are removed. The flow conditions in the form of a shear strain rate and the local concentration of the new medium after 10 seconds of flow are presented in **Figures 6A to D**. The simulation is based on a hydrodynamic flow difference of 2 mm. **Figures 6A and B** illustrate the gentle conditions in relation to shear stress. By assuming that cells are placed in the middle and at the bottom of the well (level –2 mm, at the bottom of the yellow lines), the shear strain rates influencing cells are very low. **Figures 6C and D** show the local new medium concentrations (dimensionless). The graphs indicate the isosurface plots of different concentration levels and demonstrate how changing the medium in the wells is performed. The medium enters the wells along the least flow resistance path, meaning that the main stream is transported in and out through the channels, and that the transport which is perpendicular to the flow direction is a combination of diffusion transport and a slower drag flow. **Figure 6D** depicts the concentration plots for an imaginary axis in the middle of the well from the bottom (–2 mm) to the top (1.5 mm).

It is clear that the highest concentration is rapidly reached at the level of the channels. The transport to the bottom of the well links mainly to the diffusion process. As seen in **Figures 6A and C**, cells are placed in small wells; hence, there is a risk of high shear stress conditions and of reduced washing out of autocrine substances. When culturing cells to the blastocyst stage, many protocols facilitate the use of two different types of medium. The conventional way of changing the medium involves preparing a different Petri dish containing the new medium and then transferring embryos to the new dish by pipette. Moving embryos from one dish to another can prove harmful because cells are exposed to physical stress and changes from one medium to another are abrupt. **Figures 7A and B** show a computational fluid dynamics (CFD) simulation of the flow condition in a 200 µL pipette when manually changing the medium. It is assumed that it takes the user 2 seconds to fill the pipette, which results in a flow rate of 100 µL/s. The velocity field **(Fig. 7A)** and the shear strain rate field and a graph plot for the shear strain rate of 1 mm behind the inlet opening across the diameter **(Fig. 7B)** are presented. The highest velocities are reached at the smallest diameter close to the tip opening. Hence, the lowest shear strain rates are found in the center of the pipette. Yet, if we continue to compare the above levels reached, the rates are still about five times higher with the pipette.

Our research group tested this device (manuscript is still being actively written), analyzing 223 embryos from microdrops group and 234 from microfluidics dish, and we have observed that those who had optimal development on days 2 and 3, according to embryo culture dish, were statistically comparable (day 2: 56.9 vs. 52.56%; day 3: 57.14 vs. 55.45%, respectively). Optimal blastocyst quality

according to embryo culture dish was significantly improved on day 5: 33.5 vs. 42.31% ($p < 0.05$) and similar in day 6: 29.03 vs. 31.51%,. However, implantation rates (IRs) were not significantly different between both systems in both groups (64.7 vs. 44.4%; $p = 0.199$).[27]

Another platform we can attempt to do embryo culture and automatic medium changing is described below.[28] In this microfluidic device, zygotes or embryos are cultured in microfunnels. Culture media changes are achieved by pump computer-controlled piezoelectric movable pins on a commercial braille display. The pump controls the fresh media flow from the inlet port to the culture funnels and to the outlet port. Moreover, a computer simulation analysis was performed to analyze fluid flow, shear stress, biomolecules retention, and microchannel dimension. Thus, two parameters were used to ensure an optimum flow rate. First, the epidermal growth factor (EGF) was employed as a beneficial factor model, and ammonia was employed as a waste molecule to calculate the mass production rate. Second, by means of two beneficial factors such as EGF and insulin-like growth factor1 (IGF1), the diffusion coefficient flow rate was calculated, defined as the volume with ligands which are accessible for receptor binding on an embryo. The microchannel dimensions were 1.5 mm long × 1 mm wide × 0.11 mm high, and the microfunnel dimensions were 0.25 mm bottom radius × 1.77 mm top radius × 2.63 mm high **(Fig. 8)**. Mice zygotes were used; female mice were placed with male mice overnight.

If mating occurred, presumptive zygotes were retrieved and isolated from the oviduct, and were finally decumulated. Three options to culture these zygotes were randomly chosen and performed: (1) Microdrop culture in Petri dishes with overlay oil, (2) culture in the microfluidic chip device with no fluid flow, and (3) culture in the microfluidic chip device with a fluid flow. All the platforms were placed in the same incubator and cultured under the same culture conditions. Embryo development was assessed at 96 hours of culture using two parameters: First, blastocyst morphology; second, the total cell number of each blastocyst by staining them with Hoechst 33342. As a result, blastocyst development was improved under dynamic microfunnel culture conditions. Therefore, the best hatching or hatched blastocyst formation rate was observed in the microfunnel-pulsatile model as compared with the microfunnel-static control and microdrop control (71, 23, and 31%, respectively) ($p < 0.01$). Likewise, the mean total cell blastocyst number was significantly higher for the microfunnel-pulsatile model if compared with the microfunnel-static control and microdrop control (109 ± 5, 60 ± 3, and 67 ± 3, respectively) ($p < 0.01$). It is noteworthy that the total cell blastocyst number was related in a time-dependent manner by improving blastocyst development when at least half the embryonic development of embryos or blastocyst was performed under dynamic flow conditions. All the previous results were consistent with the following because the blastocyst culture done with the microfunnel-pulsatile model offered the best IR ($p < 0.05$). Furthermore, normal pregnancy or development parameters were observed when they were transferred to the uterus. Based on these results, the authors claim that this microfluidic platform seems a very good model given the results obtained, which ensure that dynamic culture can enhance embryo development, and can improve the microenvironment as it retains the beneficial factor and washes waste molecules. Moreover, it should be taken into account that flow can break the gradients formed around gametes or embryos and can help the exchange of gases or metabolites. Finally, the physical stimulation due to the media flow can act on them.

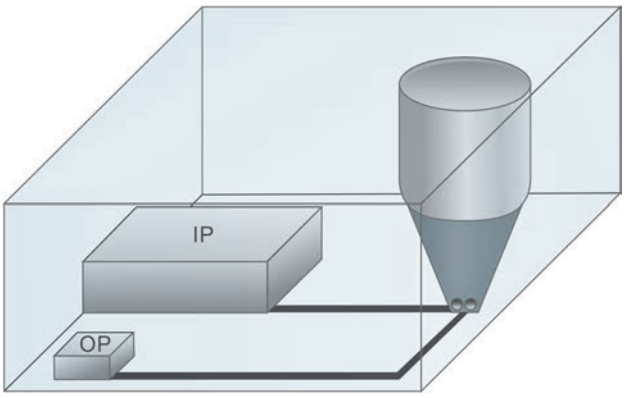

Fig. 8: In this microfluidic device, zygotes or embryos are cultured in microfunnels. Culture media changes are achieved by pump computer-controlled piezoelectric movable pins on a commercial braille display. The pump controls the fresh media flow from the inlet port to the culture funnels and to the outlet port. Model is not at real scale. (IP: inlet port; OP: outlet port)

INTEGRATED PLATFORMS

In Vitro Fertilization, Oocyte Positioning, Sperm Screening, Fertilization, Medium Replacement, and Embryo Culture by Microfluidics

Currently, there are very few microfluidic platforms that integrate all the IVF process steps. However, to achieve this goal, a research group is currently testing two microfluidic prototypes. The obtained design and results are promising. We now go on to look at how both experiments can prove to be the best attempt to integrate each step of the IVF process, oocyte positioning, sperm screening, fertilization, medium replacement, and embryo culture.

This first integrated microfluidic platform is described as follows.[29] A computational model for fluid flow analyses was performed to design it. Mice-denuded oocytes and capacitated sperm were utilized. A microchannel connects the inlet port and the outlet port which, in the middle, transforms into a microwell array area where oocytes/zygotes/embryos are positioned during insemination or

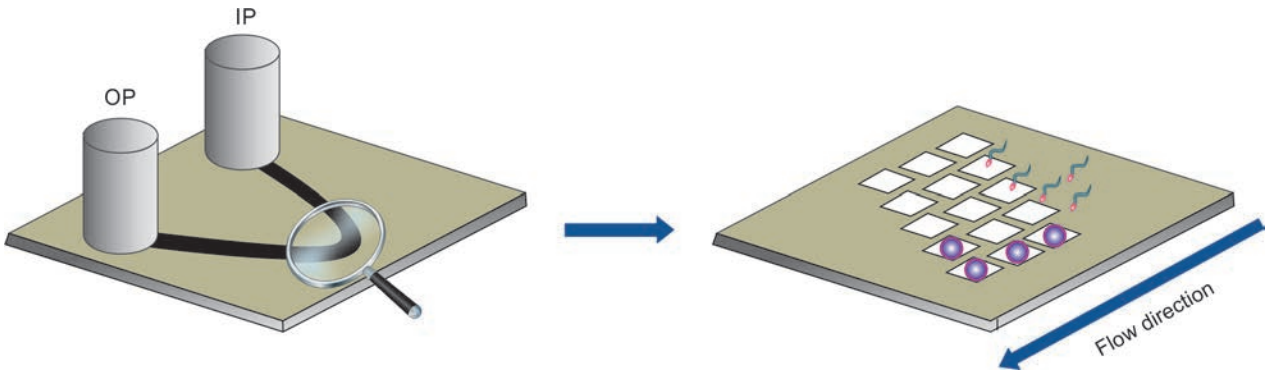

Fig. 9: A microchannel connects the inlet port and the outlet port which, in the middle, transforms into a microwell array area where oocytes/zygotes/embryos are positioned during insemination or fertilization and the culture process (at left). Thus, in the same place, fertilization occurs and embryo development becomes continuous (at right). Model is not at real scale.
(IP: inlet port; OP: outlet port)

fertilization and culture process. Thus, in the same place, fertilization occurs and embryo development becomes continuous. Microchannel dimensions were 1 mm wide × 200 μm deep. The microwell array area dimensions were 10 mm long × 3 mm wide **(Fig. 9)**. To assess how well the microwell performs to trap debris and to retain oocytes, several microwell depths were tested (50, 100, 150, and 200 μm). Therefore, after the culture media, the prefilling device was used, and oocytes or dead sperm samples were placed into the inlet port. The negative pressure-driven flow was achieved by a syringe pump connected to the outlet port to control flow culture media velocity. Consequently, the 50 μm and 100 mm depths did not allow high washing-out velocities to be observed when culture media or sperm were loaded in the inlet port. However, no significant difference was found between 150 and 200 μm when testing the debris trapping capacity, and the first size was unable to retain oocytes inside the microwell when velocity increased substantially.

Finally, the best size was 200 μm because it exhibited the best debris trapping capacity and it also retained oocytes at the fastest medium perfusion velocities. After completing these test trials, the IVF process was performed. For insemination purposes, a standard sperm concentration was used (1×10^6 sperm mL^{-1}) in both the microdrop system and the microfluidic device. Denuded oocytes were pipetted to the inlet port and placed inside the microwells array area by a gravity-driven flow generated by medium aspiration in the outlet port. After performing single oocyte positioning, sperm was added to the inlet port and was transported to the array area by the same gravity-driven flow, where fertilization is to occur later. As a negative control, conventional IVF was performed by microdrops in Petri dishes with an oil overlay at the same sperm concentration and under the same culture conditions. Fertilization assessment was done at 9 hours postinsemination by checking for the presence of two pronuclei. To perform an extended embryo culture, the media of two ports were depleted and changed for suitable fresh media. Embryo development was checked after 14, 48, 72, and 92 hours postinsemination. Finally, at 104 hours, an individual pickup of the obtained blastocysts was done and stained by Hoechst 33342 to assess normal development. As a result, the fertilization rate in both the microdrop system and the microfluidic device did not show a significant difference (71 vs. 69%, respectively). Similarly, embryo development was not affected by the microfluidics culture. Thus, two-cell, four-cell, morula, and the blastocyst formation rate were similar with no significant differences being found.

The second novel platform shares the same goals but improves the design of the previous prototype.[30] This platform has three regions: (1) Sperm inlet ports, (2) motility screening microchannel, and (3) an area for oocyte positioning. Four sperm inlet ports (4 mm diameter × 5 mm depth) surround the area of central oocyte positioning (6 mm diameter × 5 mm deep) and are connected by four microchannels (1.5 mm width × 9 mm length × 80 mm deep). At the bottom of the area for oocyte positioning, a 4 × 4 array structure allows to position oocytes individually, as well as their insemination and culture. For this purpose, each array unit is formed by a circular columnar structure (200 μm in diameter) and is laterally perforated by eight gaps (50 μm) **(Fig. 10)**. Mice-denuded oocytes and capacitated sperm were used. Oocytes were pipetted individually into each positioning unit. Then, sperm was loaded into the inlet ports (2.5×10^4 sperm/port). As a negative control, conventional IVF was performed by microdrops in Petri dishes with an oil overlay at the same sperm concentration and under the same culture conditions. Moreover, a parallel experiment was done to test sperm motility by comparing the percentage of the motile sperm between both insemination systems. A computational model was used to analyze the medium's behavior and to adjust medium replacement. The mineral oil and culture media of the four ports were removed and changed in accordance with the suitable culture conditions.

To track embryo development, an assessment was done every 24-hour postinsemination. The obtained blastocysts

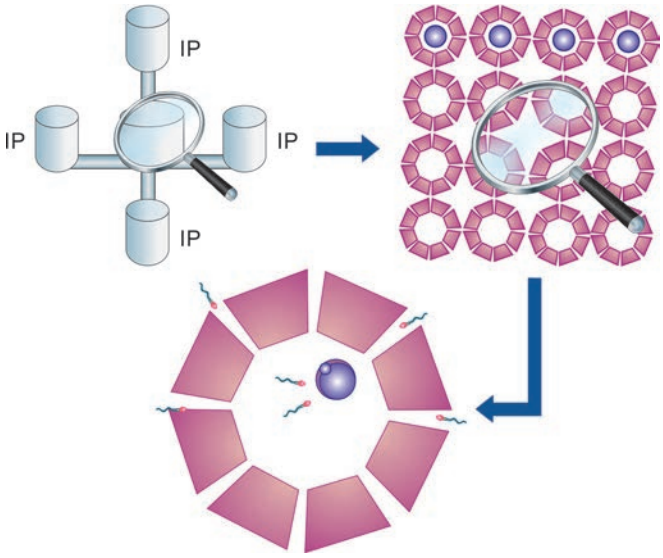

Fig. 10: This platform has three regions: (1) Sperm inlet ports, (2) motility screening microchannel, and (3) an area for oocyte positioning (upper picture, at left). Four sperm inlet ports surround the area of central oocyte positioning and are connected by four microchannels. At the bottom, the area for oocyte positioning allows to position oocytes individually, as well as their insemination and culture (upper picture, at right). Each array unit is formed by a circular columnar structure and is laterally perforated by eight gaps (lower picture). Model is not at real scale.
(IP: inlet port; OP: outlet port)

were Hoechst 33342 stained to assess normal development and the total cell number.

As a result, and in relation to sperm motility screening, the sperm motility rate in the central well device was significantly higher than the control group until 6 hours postload, when both rates were similar. The comparable cleavage rate (two-cell embryo formation) was observed between this microfluidic device and the conventional microdrop culture (64 vs. 61%, respectively). Likewise, the formation rate of four-cell embryos, morula and blastocyst, in accordance with the formation rate of the two-cell embryo, showed no significant differences. Finally, in situ fluorescent staining was done to assess the total cell number of obtained blastocysts, and no significant differences between the microfluidic device and the conventional microdrop culture (50.0 vs. 50.7, respectively) were observed.

In short, these two experiments provide similar results for the different platforms because they actually share many concepts and designs. They show similar conventional IVF and embryo development rates, and combine some daily IVF laboratory routine steps in the same platform.

MICROFLUIDICS FOR AUTOMATED VITRIFICATION

Another assisted reproduction area that may benefit from automation is oocytes and embryo cryopreservation.

Addition of cryoprotectants can be automated by microfluidity, and even vitrification can be either controlled or done simultaneously, particularly in the light of the recent progress made in vitrification techniques, which have become the most extended procedure for oocyte and embryo vitrification.[31]

In order to optimize cryopreservation protocols, microfluidic technology can be applied to minimize osmotic effects and to improve outcomes. A computer-controlled multichannel microfluidics device has been developed to systematically mix cryoprotectant agents and to produce smoother osmotic changes.

In fact, this researching group has comparable results compared with Cryotop method, the current manual "gold standard". This automated method is named Gavi and it allows automatic equilibration steps necessary for successful oocyte/zygote/embryo vitrification. Thus, for mouse zygotes, warming recovery rates were 97% using Gavi and 100% using Cryotop, and achieving the same rate of fully hatched blastocyst (43 and 57%, respectively, by D5 and D6). Warming recovery rates for mouse blastocysts were 99% in both methods, being 54% vitrified by Cryotop and 50% by Gavi, able to arrive at the fully hatched blastocyst stage 48 hours later. In the same way, results with mouse blastocysts showed 99% warming recovery rate for both methods and fully hatched blastocyst rate comparable between them. Finally, results with human blastocysts were similar, showing 100% of recovery rate and comparable rates for different blastocyst stage formations 24 and 48 hours later.[32] Apparently, this procedure is less time-consuming and offers minimal interembryologist variability for oocyte and embryo cryopreservation.[33]

KEY POINTS

- New technologies and approaches have been emerging since the last few years, changing our concept about ART. They are an exciting discovery that helped us to imagine so many different IVF laboratories in only few years. However, in the day-to-day life, we witness the difficulties that we face to change established concepts. Some reasons such as state regulatory laws, company's policy, ethical and research commission supervision, high cost, clinical ineffectiveness of novel culture platforms, and, obviously, the own embryologist's opposition are stopping these emerging methods. Even so, satisfactory experiences in humans show the way forward. Thus, embryologists, engineers, and researchers working as a multidisciplinary team aim to solve the challenges imposed by design, manufacturing, and daily use and work towards improvements of new platforms and devices.
- Currently, our vision of the introduction of microfluidic technology in ART is rather like a big jigsaw puzzle

with few connecting pieces. However, pieces will gradually join and we can imagine the future, IVF laboratories becoming a lab on a chip. Therefore, it is perfectly conceivable that future microfluidic devices with video timelapse systems can replace current IVF platforms. Moreover, microfluidic platform outlet ports could be connected to "omics" analyzers able to asses implantation and development potential of each cultured embryo without invasive assessments. Hence, the embryologist's tasks will possibly change in the future due to continuous gamete/embryo handling and culture, and the combination with automatic embryo assessment by timelapse video microscopy. New tasks should be clinically managed by the embryologists in these new IVF labs, such as surveillance of automated procedures, quality control assessment, and improving technology/scientific background, and they should do active research with the embryological data generated by these novel devices and platforms.

CHAPTER 120

Artificial Intelligence in Assisted Reproductive Technology

Krishna Chaitanya M, Durga G Rao, Ruchi Narula, Selva Karthick M, Sherin Theresa Mathew

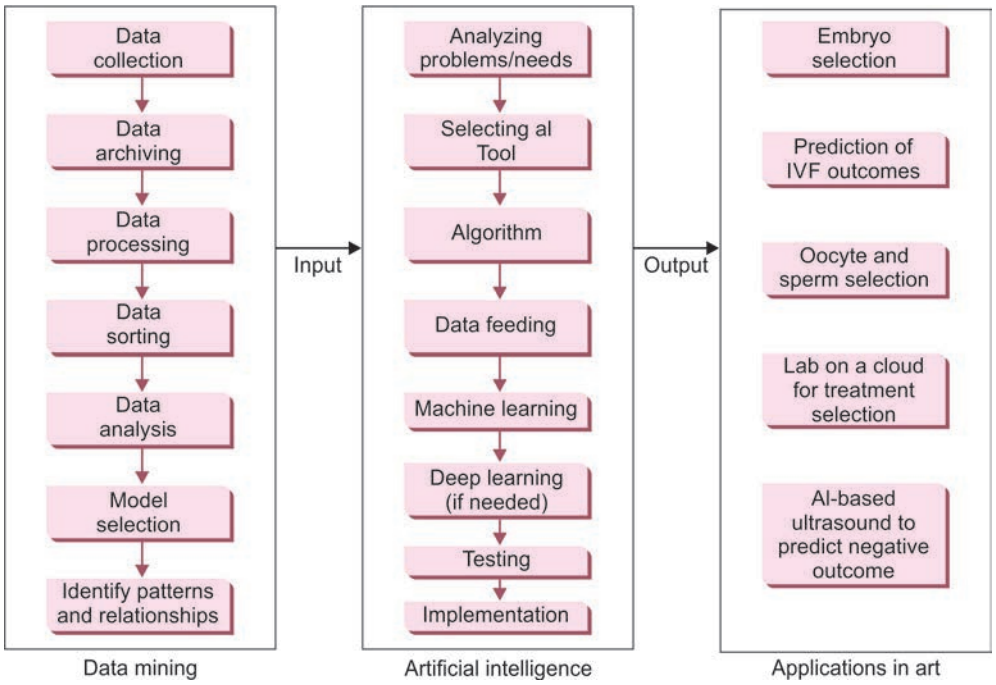
INTRODUCTION

Assisted reproductive technology (ART) has existed since 1978 to eliminate natural barriers in fertilization. ART procedures can be described as follows: Oocytes aspirated from ovaries using the surgical procedure and fertilized in vitro using the best sperm selected, and the embryo thus developed is introduced to the uterine cavity.[1] Now, ART has evolved with advanced techniques such as preimplantation genetic testing (PGT), time-lapse embryo monitoring method, and clinically advanced laparoscopic procedures. ART has some practical challenges: 100% success rates are not achieved with in vitro fertilization (IVF) procedures, cannot not eliminate human errors such as sample mismatches and culture mishandling, and complete automation of the process is not yet possible. In comparison with other fields of medicine and other sectors, ART has not seen any drastic improvements and advancements. Artificial intelligence (AI) is one of the methods to eliminate the challenges discussed and to introduce more automation in ART. AI is used in most of our daily activities; the easiest and most common example to understand about AI is the "image to text conversion" application: If the words are written in an unknown language, you can scan them using your mobile phone and translate them to your preferred language. In this chapter, we will discuss the following: (1) General AI infrastructure and currently available AI algorithms for ART practices such as embryo selection, gamete selection, prediction of clinical outcomes in IVF cycles, and advanced embryo monitoring techniques; (2) The reasons why we need a machine touch rather than using human intelligence and its possible limitations and disadvantages; (3) Our predictions in ART using AI were prepared it after consulting experts globally; (4) Lab on a cloud, where patient information is stored electronically and is used for statistics, studies, and machine learning (ML) models. In the current situation, we are not clear whether we can rely on the existing time-consuming process of embryologists/clinicians' decisions to decide upon the treatment type, selection of embryos and gametes, and time of transfers or we really need a machine to tell us the accurate choice and correct predictions for the same. We need to consider what would happen if AI applications took over humans, which then completely manipulates the information and provides us with incorrect predictions. To conclude, AI software needs more training to get very accurate results; it may take some more years and a huge amount of data to evolve.

ARTIFICIAL INTELLIGENCE ARCHITECTURE AND TOOLS USED IN ASSISTED REPRODUCTIVE TECHNOLOGY

The development of AI applications is a very long process with efficient planning; it needs a large amount of raw data, AI software engineers to write programs, and hardware resources. ML is one of the processes in AI that is mostly used in all medicine-related applications, and it is a mathematical model that analyses patterns in huge random data. A common example of an AI application is a self-driven car, where the algorithm is written to run the vehicle and to manage any outward incidences arising out of a mishap; also, it is programmed to update and learn from the situations regularly. Data collection is the first step in building an AI program. In the case of predicting IVF success rate, we need to feed multiple parameters such as age, medical history, administered drug details, previous live birth, and many others.[2] In the field of medicine, data can be obtained from the following sources: Patients' medical records and cloud-sharing hospital information. Data thus obtained will be segregated and fed to the system (input data) after process modifications. For example, in predicting a good embryo program, the embryo image has to be processed—dragging the image and keeping the embryo at the center, correcting image quality to obtain the best results. When we discuss the programming language, Python is a commonly used language in ML software. To build deep learning neural networks,

Flowchart 1: Artificial intelligence (AI) concept in the assisted reproductive technology (ART) field.



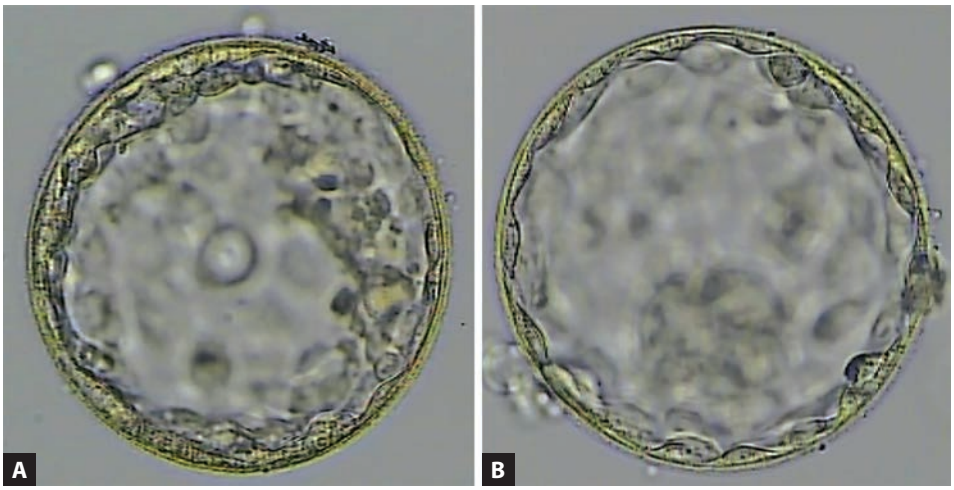
(IVF: in vitro fertilization)

we require a computer microprocessor with sufficient space to run and a graphics card to analyze the images. To implement the algorithm, basically called coding, we need architecture such as TensorFlow, Google's Inception, and Keras neural network library.

Artificial intelligence tools can be widely classified into two methods—supervised and unsupervised learning. In supervised learning, the labeled information predicts the test data, whereas in unsupervised learning, hidden structures in the input data are focused. Supervised learning can be used for image analysis, and unsupervised learning can be used to analyze complex multiple parameters to predict the output. Under supervised learning, commonly used tools are decision tree (DT) and random forest (RF), naïve Bayes classifier (NBS), and support vector machines (SVM). Neural networks and deep learning methods come under unsupervised learning. Based on the input/output, these tools can be generally classified into two types: white- and black-box models. In the white-box model, we can clearly explain the predictions, and in the black-box model, algorithms find patterns without being able to explain their methodology. Each tool has its own algorithms, advantages, and disadvantages. DT and RT have subclasses that have root nodes and decision nodes, and it is a white-box model that can be applied for oocyte cryopreservation and embryo transfer. NBS is a simple algorithm with good accuracy; it is used in the prediction of the outcome of IVF and intracytoplasmic sperm injection (ICSI). SVM is used in complex nonlinear relationships and is currently used for the prediction of the implantation outcome based on transferred embryos. Neural networks and deep learning are used when the problem is having many layers. It is a black-box model and is currently used for the prediction of ART outcomes from multiple parameters **(Flowchart 1)**.[3]

WHY DO WE NEED A MACHINE TOUCH?

The embryo evaluation and selection at the time of embryo transfer mark the success of the entire IVF process, where an embryologist aims to select the "best" embryo/embryos from the larger cohort of fertilized oocytes. **Figure 1(A)** is grade 3 embryo, which gives live birth, and **Figure 1(B)** is a grade 1 but resulted in a negative pregnancy. It is generally acknowledged that even after embryo selection based on morphology, time-lapse microscopy (TLM), or PGT screening, the implantation rate in humans is difficult to predict. While there has been a vast improvement in the embryo evaluation methods, IVF treatment still remains a gamete-inefficient and embryo-wasting process. The traditional method of morphological assessment for evaluating embryo quality and selecting the best embryo for transfer is a subjective method and leads to inter- and intra-observer variability, resulting in less than optimal IVF success rates. To overcome this factor and increase success rates, it has become a common practice to transfer more than one embryo, leading to a higher risk of multiple pregnancies. We still aim to have methods that enable the selection of both healthy sperm and oocytes and, finally, the selection of



Figs. 1A and B: Embryo images. (A) Grade 3 embryo with live birth; (B) Grade 1 embryo result with negative pregnancy.

the best embryos for transfer to optimize the IVF process and gamete efficiency.

Although PGT-A and time-lapse incubators have been introduced to help and increase the chances of live birth, the outcomes still remain less than ideal. The novel noninvasive embryo assessment methods promise to increase IVF efficiency and reduce embryo wastage. AI has long been utilized in other industries and has recently found its place in the field of ART as a noninvasive approach and use of computational applications tools in the IVF laboratory; however, it is just a beginning.

The inclusion of AI in the field of reproductive medicine is highly desirable for many reasons. AI shows good potential in enhancing the embryologist's decision-making ability. AI systems are trained on the vast pool of information and data and can thus make decisions based on facts and supporting data, thus making the decision process reproducible and repeatable versus a human decision which may depend on personnel's experience, training, and emotional states. Manual selection is prone to many types of biases,[4] and the decision is prone to stress, subjectivity, and fatigue; also, AI is smart and eliminates the human element and relies on objective analysis, and can learn to analyze complex patterns with increased resolution while analyzing a greater number of variables in comparison with humans who may not be able to consider multiple variables while taking a decision.[5] Well-trained automated systems can also be used for the training of embryologists on fixed standards. Such automated systems can also help in rapid diagnosis, thereby reducing the time required for evaluation by the embryologists helping them to even evaluate without the need to be physically present in the laboratory.

Artificial intelligence and its application have unlimited potential for development, but ultimately, it should reduce health care costs while improving outcomes, and it should be manageable and feasible without majorly disrupting the IVF laboratory's day-to-day function that strictly relies on morphological criteria for embryo selection. A big question that arises with the adoption of AI in regular IVF laboratory practices is that "Would the traditional manual approach of light microscopy evaluation be totally abandoned or could we simply combine both options?" Ideally, should the final decision be with the embryologist who takes into account the software ranking and the embryo quality as per standard grading techniques? Will AI replace reproductive medicine practitioners and embryologists? All of these are genuine considerations and deserve to be addressed.

Despite the majority of the current research showing that AI can meet or even exceed the performance of experts, AI has not established its role in the world of reproductive medicine, and it is crucial to remember that its role in improving outcomes is limited. Further research is required to prove the application of this approach in routine and its balance with the embryologists' role within the IVF laboratory. Further studies, ideally randomized controlled trials (RCT), are required to identify indicated use of AI. However, the existence of these techniques cannot be overlooked. Possibly, it may prove to be a revolutionary new milestone in the assisted reproduction service.

RECENT ADVANCES OF ARTIFICIAL INTELLIGENCE IN IN VITRO FERTILIZATION AND ASSISTED REPRODUCTIVE TECHNOLOGY

Artificial intelligence has the potential to soon assist doctors in creating patient-centric treatment regimens, both before and after oocyte collection, and also to reduce the risk of ovarian hyperstimulation syndrome (OHSS) and improve gamete and embryo selection for IVF cycles. The incorporation of this new technology is ideally positioned to improve IVF, predicting an increase in the present static success rate. AI is now being tested and applied in the

following ART processes: Live birth prediction prior to IVF, embryo and gamete selection, and treatment selection.

Gamete Selection and Screening

Conceiving a healthy live baby is the ultimate objective of an IVF cycle. Accurate prediction of IVF cycle outcomes still remains elusive despite several developments in the field of ART. Compared to the relatively limited number of oocytes that are available for selection in a treatment cycle, men mostly have millions of sperm for selection. The current practice of fertilizing all available oocytes limits the use of AI in oocyte selection.

Artificial Iintelligence Application on Sperm Selection

We currently use many techniques to select sperms, but the identification of the optimal sperm for ICSI mostly relies on the skill of an embryologist for selecting the best-looking sperm under the inverted microscope without any information regarding its fertility potential. These include microfluidics technology, which uses small fluid streams to sort the best sperms; magnetic-activated cell sorting (MACS), which uses a magnetically charged column that separates apoptotic and nonapoptotic spermatozoa based on the expression of phosphatidylserine; and fluorescence-activated cell sorting (FACS), where fluorescent-labeled cells are sorted based on the scatter from a laser.[6] These sperm-sorting techniques promise to help in the selection of sperms with optimal function from the ejaculate for treatment. Even with the presence of several technologies for sperm sorting, have we reached a point where we can predict the fertilization ability or deoxyribonucleic acid (DNA) integrity of sperm in real time before using it for insemination? Can AI help us to reach this point in the future? Let us look at the advances and developments in the field and come to a conclusion at the end.

Artificial intelligence is already applied in many fertility clinics and research laboratories to improve sperm analysis and selection along with gamete selection and for predicting the outcomes of IVF.[3] AI has been previously applied in semen analyses and has also helped to evaluate sperm morphology.[7,8] It has also been used to measure sperm DNA integrity.[9] A popular sperm analysis method called computer-aided sperm analysis (CASA) integrated a low-level AI ML system for automatic sperm evaluation.[10] Some attempts to apply AI in urology (based on a patient's clinical parameters) have already been reported. AI methods have also been developed to predict the likelihood of sperm extraction in azoospermic patients[11] and to reliably predict the male factor infertility.[12] The impact of lifestyle and environmental factors on fertility rates in men has also been explored using the data-mining methods.[13] The application of AI technologies has gone far ahead with the development of smartphone-based applications for semen analysis as well as sperm viability and DNA integrity.[14,15] CASA vector machine model has been used to classify human sperm into five kinetic classes based on sperm kinetics.[10] Another assay for sperm intracellular pH and sperm membrane potential offers a reliable assessment of sperm capacitation when compared to previous penetration assays. One of such techniques used AI with an assumption that capacitation is an indication of the fertilization potential for which they had introduced a Cap-Score and penetration assay (Androvia, Mountainside, New Jersey, United States).

Another application of AI in the field was pointed out by Gunderson et al. In a study where they used a DT ML to predict success accurately when conventional IVF was considered, they included multiple clinical and demographic variables for each partner, such as sperm intracellular pH, sperm hyperactivated motility, sperm membrane potential, sperm linearity coefficient, sperm lateral head displacement, and sperm curvilinear velocity.[16] The major target for the clinical application of AI in male infertility would be the identification of sperm cells in the microsurgical testicular samples of patients with severe male factor infertility, as identifying these rare sperm cells requires several hours and skills of the embryologists. The idea of developing such a system would require machine training and learning on a massive number of sperm images to correctly differentiate sperm from other types of tissue cells in testicular samples. Most importantly, this system will also need to be rapid and applicable in real time. In 2021, Wu et al. developed a new CASA system, which on testicular sperm extraction utilizes deep learning for near human-level performance.[17] This system helps to automate the identification of sperm in testicular biopsy samples. This study model was benchmarked against embryologists' performance on the detection task. This proposed method has promised to work in real time, but its speed is effectively limited only by the imaging speed of the microscope. The results of this study promise that deep learning-based technologies can improve the efficiency of finding sperm in testicular biopsy samples.

In conclusion, AI techniques for sperm selection that correlate with the fertilization potential and DNA integrity of sperm and, thereby, a successful IVF cycle are limited. Many AI techniques till now have tried to classify sperms based on kinetics, capacitation, and penetration, but none of these have aided in successfully selecting a sperm that can be used in real time for treatment. But all these techniques ultimately yielded sperms that cannot be used for treatment since they get destroyed or wasted. Going ahead, AI can help with newer technologies that help for rapid screening and selection of sperms without inducing cell damage and are usable in real time for treatment.[18] Another target, as discussed above, would be rapid identification and selection of sperms for ICSI in testicular biopsy samples. However, AI is yet to be

applied routinely to these sperm-sorting techniques to make the selection faster and smarter.

Artificial Intelligence Application on Oocyte Selection

The female gamete plays a crucial role in determining embryo competence and thus in the success of the IVF treatment. Most of the oocytes retrieved after the ovarian stimulation exhibit one or more types of dysmorphism; thus, finding an ideal oocyte after denudation is rare. There are many extra cytoplasmic anomalies [first polar body (PB), perivitelline space (PVS) size, irregularity of zona pellucida] and abnormal cytoplasmic inclusions [smooth endoplasmic reticulum (SER) centrally located cytoplasmic granulation (CLCG), vacuoles, refractile bodies] noted in the recovered oocytes. It has been speculated that these morphological anomalies, which can be easily identified under light microscopy, may be an indication of the compromised development potential of the oocytes. Rienzi et al. in a retrospective analysis evaluated the influence of different oocyte morphotypes on ICSI outcomes. They also generated an MII oocyte morphologic score (MOMS) capable of predicting the oocyte competence in terms of fertilization potential, pronuclear (PN) morphology, and embryo developmental ability.[19] Several other characteristics correlating with oocyte quality have been identified, such as the composition and amount of accumulated maternal messenger ribonucleic acids (mRNAs), the size of the oocyte and its zona pellucida, its cytoplasmic organization, or the existence of certain specific epigenetic alterations. However, there has never been an agreement on the individual power of these parameters to determine oocyte growth potential, and results are very often incongruous. ML can be used to address this issue since it can automatically identify essential features and consider multiple elements instantly. In both academics and in clinics, the use of computational tools to better characterize an oocyte's developmental potential is thus necessary. Let us go ahead and have an overview of the application of AI and advancements in oocyte selection.

In 2013, in a study by Manna et al., texture analysis of 269 oocyte images was performed, and the corresponding embryo development was tracked. Texture features were used with neural networks to predict the outcome of an IVF cycle.[20] In 2021, Targosz et al. analyzed 71 deep neural network models for semantic oocyte segmentation;[21] they trained their algorithm to classify the oocyte morphological features such as clear cytoplasm, dark cytoplasm, diffuse cytoplasmic granularity, smooth endoplasmic reticulum, vacuoles, first PB, multi-PB, fragmented PB, PVS, zona pellucida, cumulus cells, and the presence of germinal vesicle (GV). In this study, the training accuracy (acc) reached about 85 and 79% for training patterns and for validation, respectively. Kanakasabapathy and colleagues, in 2020, trained a convolutional neural network (CNN) to predict fertilization potential using oocyte images and then identify the oocytes with the highest fertilization potential.[22] A deep CNN was used in 2020 by Dickinson et al. to locate the first extruded PB, which allowed them to distinguish the mature metaphase II (MII) oocytes from metaphase I (MI) and GV stage oocytes. This algorithm also helped to pinpoint the location of the extruded PB, which can help to identify the correct location on the oocyte to inject spermatozoa for ICSI. Unfortunately, the available scoring systems have shown extreme variability regarding their types and methods for individual scoring of investigated features and outcome parameters. Hence, at present, they can only be regarded as diverse approaches to the same strategy, but their comparative evaluation is not possible. Experimental research procedures such as in vitro maturation (IVM) of oocytes, somatic cell nuclear transfer and reprogramming, in vitro gametogenesis (IVG), and others have a good potential to benefit from the introduction of the AI system. A study on the animal model has demonstrated that using an ML pipeline makes it possible to predict oocyte maturation with accuracy between 80 and 90%. Furthermore, scientists also identified two new features, the texture of the zona pellucida and the size of cytoplasmic particles, as good predictors of mouse oocyte maturation potential. They also defined a competence score to rank mouse oocytes by their capacity for maturation. Moreover, it has also shown that the zona pellucida texture could be a good predictor of human oocyte maturation potential and revealed a defect in the cytoplasmic activity in poor-quality oocytes. This ranking could be utilized to augment IVM protocols by identifying the most viable oocytes. Furthermore, the small increase in IVF efficiency in recent studies can mostly be credited to the use of a PolScope microscope for detecting zona retardance and presence, position, and retardance of the spindle, a technique that is used in a limited number of ART facilities around the world. The use of polarized light microscopy for imaging the spindle has been previously investigated, and it has been reported that there are associations between meiotic spindle morphology and oocyte quality. Thus, imaging of meiotic spindles might also provide useful information for selecting high-quality oocytes using AI tools trained on these concepts. In future, it would be interesting if the imaging of mitotic spindles in early embryos could provide additional information to help in identifying aneuploidy in embryos.

At present, comprehensive oocyte morphology scoring is not performed as a routine procedure, the morphological assessment of oocytes currently seems to be informative rather than predictive, and the use of AI for oocyte selection is limited due to the practice of fertilizing all available oocytes. Oocyte selection before insemination may have important benefits in certain situations; for example, in countries with legal restrictions where noninvasive AI methods can be used

to evaluate oocytes with the best competency can become an important selection and prediction tool to reduce the number of embryos created and wasted, and thus, it would lead to the overall efficiency of an IVF treatment cycle. Such tools would thus help to restrict supernumerary embryos and also provide patients with counseling over the prognosis of the success of an IVF cycle. Oocyte morphology assessment can be especially useful in oocyte donation cycles where we have restrictions on the number of oocytes to be allotted to a recipient during oocyte freezing for fertility preservation. Finally, objective oocyte scoring can be important in cases of very poor treatment outcomes as a tool for an explanation of results to the patient. Currently, there is a need for more intensive and coordinated research to reach a consensus and exploit fully the predictive potential of morphological examination of the oocytes.

Embryo Selection

Many studies are performed every year focused on individual variables, yet a clear cause cannot be identified in the majority of IVF failures. With the Istanbul consensus since 2011, the field of clinical embryology has made strides in relation to embryo selection. However, horizontal adoption of a consensus on embryo grading has yet to be achieved to a satisfactory extent and is commonly accepted and practiced, and unfortunately, there are many grading systems. Even with the "Gardner" system of grading, which is used universally, variations and deviations are seen quite commonly, and this subjective method leads to inter- and intra-observer variability, resulting in less optimal IVF success rates. To overcome the failures, it has become a common practice to transfer more than one embryo, resulting in high-risk multiple pregnancies. Even with the introduction of time-lapse incubators and preimplantation genetic testing for aneuploidy (PGT-A), the IVF outcomes remain less than ideal. The utilization of AI has been increasingly tried in the embryology laboratory to help improve IVF outcomes. Many studies investigating the use of AI as an automated and unbiased approach for embryo assessment have been published. Embryo selection is subjective and is based on developmental and morphological characteristics such as the granularity of cytoplasm, the color of cytoplasm, multinucleation, number of blastomeres, degree of fragmentation, size of blastocoel, the timing of cleavage and morphokinetics, roundness of oolemma, thickness of zona and more and already sufficient sets of qualities to judge an embryo have been explored. Numerous experimental methods have been developed to predict the implantation potential and live birth rate from images or videos of the embryos, including morphometric analysis by time-lapse imaging, mathematical-statistical tools, and computer-assisted scoring. AI is already being tried for embryo selection at various stages of development, such as the PN stage, cleavage stage, and blastocyst stage. We are going to discuss the AI application at these stages individually under the following subheadings and thereby try to get answers to some important questions such as, Is AI ready to replace the traditional manual assessment? Can we expect better lab work management with a cut down in time required in labs? Can we predict the euploidy status and development potential of embryos at the early stages of development so as to transfer or freeze at day 2 or day 3 by reducing the chance of epigenetic changes that may be caused by prolonged culture?

AI Application on Pronuclear-stage Embryos

Fertilization checks and embryo quality assessments require manual examination, status recording, and embryo development scoring. Manually scoring the zygotes is labor-intensive and subjective and also requires an embryologist's presence in the lab at the correct timeline. Dimitriadis and colleagues, in 2019, described a CNN that can distinguish between 2PN and non-2PN zygotes at 18 hours post-insemination with >90% accuracy.[23] This system can be used to help embryologists confirm the fertilization assessment of each oocyte and also monitor individual embryologists performing ICSI for advanced quality assurance to improve patient outcomes. Using AI, these predictive features can be incorporated into an embryo selection algorithm. Early parameters of zygotic (cytoplasmic movement) development, analyzed by AI-powered methods, have been shown to be predictive of blastocyst development. Compared to human evaluation and prediction using morphological parameters, AI-based methods using cytoplasmic kinetics showed, on average, 10% higher accuracy.[24] These studies collectively show that the use of AI in PN stage scoring can help in the prediction of blastocyst development and also save the time required for fertilization checks.

AI Application on Cleavage-stage Embryos

Cleavage-stage embryos are generally graded based on three features: Blastomere cell count, percentage of overall cytoplasmic fragmentation, and degree of asymmetry between the cells. These grades are mostly assigned by visual morphology examination and AI technology which is proposed as a solution to these labor constraints and the subjective nature of selection, including morphology and morphokinetic measurements. A deep learning CNN was used by Kanakasabapathy et al. to train and validate embryo assessments on day 3 embryo images based on embryo developmental outcomes observed on day 5 of culture. This algorithm was trained to make expected day 5 developmental predictions such as embryo arrest, morula, early blastocyst, full blastocyst, and high-quality blastocyst. Using a test set of 748 embryos, the accuracy of the algorithm in predicting blastocyst development was 71.9%.[25,26] This

was also the first AI-based system to be used to predict the developmental fate of cleavage-stage embryos. Some algorithms used cleavage-stage embryo images with DT methods and statistical analysis of features to determine the implantation potential of cleavage-stage embryos.[27,28] Using CNN, Meyer et al. in 2020 demonstrated the ability of CNN to identify noninvasive markers for detecting genetically abnormal embryos. They classified day 3 cleavage-stage embryo images as aneuploid or euploid with high specificity and were thus able to sufficiently identify 85.5% of aneuploid embryos.[29] Kelly and colleagues used CNN to identify safe regions on a cleavage-stage embryo to perform laser-assisted hatching.[30] These studies collectively show that a variety of AI techniques can be used to extract very important information from cleavage-stage embryos, which may be used for classification, assessment, and ranking, and thus, to aid in clinical decision making. Also, by prediction of the euploidy status and development potential of embryos at day 2 or day 3 itself, prolonged culture can be avoided, thereby reducing the chance of epigenetic changes that may be caused.

AI Application on Blastocyst-stage Embryos

The AI tools available for blastocyst stage assessment have been either trained on time-lapse microscope images or static images of blastocysts.

AI-based on TLM image analysis: The advances in time-lapse technologies have led to the development of embryo selection algorithms and the high-powered computer processing to analyze a large set of images along with the combination of some parameters which may be linked to embryonic viability. The first AI-based on time-lapse images developed a predictive algorithm capable of automatically quantifying the duration of cytokinesis and the time between mitoses.[31] This tool was marketed under the name of Early Embryo Viability Assessment (Eeva), the first clinically validated platform that integrates time-lapse, two predictive parameters, and automatic software. In another study, a different approach was used to predict blastocyst development using the TLM data up to D3 of embryo development. Two different AI algorithms were developed: An automatic morphokinetic data model and a TLM embryo image model, with both models having comparable predictive power, and when both were combined, the different weights were used to optimize the blastocyst prediction. More weight was given to the morphokinetic data compared to the image data. When compared to embryologists, the AI model performed better in terms of sensitivity and specificity.[32] In another unique approach in which AI measures the kinetics of blastocyst expansion and correlates it to the outcome, where faster-expanding blastocysts were seen to exhibit higher implantation potential.[33] Bori et al. presented a novel model utilizing AI to predict embryo implantation. The authors were able to make a high implantation prediction by combining AI image analysis and proteomic profile of the spent culture media from the PGT euploid embryo. Using AI image analysis combined with a proteomic profile on spent culture media from the PGT euploid embryo, the authors were able to demonstrate very high implantation prediction. Although the study is preliminary, it demonstrates the power of AI to combine different data points (proteins and morphology).[34]

AI-based on static image analysis of blastocysts: An AI deep learning model was studied in 2019 that can evaluate blastocyst quality, and in this AI-based prediction model, the blastocyst expansion followed by inner cell mass (ICM) and trophectoderm (TE) quality were important parameters. The precise time point used for the AI evaluation (at 110 hours) demonstrated the importance of embryo developmental kinetics for embryo prediction.[35] In a 2020 study, a CNN system by Bormann et al. was used to classify blastocysts based on the presence of the cavity and the morphological quality of the ICM and TE.[36] In another algorithm based on implantation outcomes of the images of blastocysts selected by humans for transfer, a blastocyst ranking system called the "blastocyst score" was established, which showed over 50% positive outcomes. The variations seen among the embryologists making decisions on vitrification and embryo biopsy based on standard morphological assessments can be significantly improved by using deep neural networks, according to Bormann et al. in their study.[37,38] Souter et al. in 2019 further demonstrated in their study that a deep learning CNN could be used with 96.3% specificity and 93.7% sensitivity to find which D3 assisted hatched embryos met D5 criteria for TE biopsy and cryopreservation. This validation study was the first to demonstrate that an embryo decision-making algorithm could be successfully applied to embryos that had been breached to promote herniation of TE cells for blastocyst-stage biopsy.[38] Thirumalaraju et al. in 2021 compared the use of eight different architectures to classify blastocyst-stage embryo images captured on a variety of imaging platforms and showed that "Xception" performed best in learning the embryo data and was able to accurately classify blastocysts based on their morphological quality, it could correctly classify >99.5% of the highest quality blastocysts, which is of critical importance, clinically, when identifying embryos suited for transfer.[39] In 2020, Eduardo et al. evaluated KIDScore as an algorithm for morphological assessment and preimplantation genetic testing for aneuploidies (PGT-A) to improve implantation and ongoing pregnancy rates. This algorithm can thus help in enhancing the embryologist's decision making capacity to choose the embryo with the greatest potential.[40] Vermilyea et al., in 2020, presented another study in which they used computer vision image annotation techniques to compose AI (The Life

Whisperer AI), providing a reliable and robust assessment of blastocysts with different types of cameras, microscopes, and focal planes. They concluded that in all these variables, the results suggest that this method of preprocessing and automatic annotation, as well as AI trained in a globally diverse dataset, creates a generalizable AI that is robust to the type of camera and focal configuration, regardless of hardware.[41]

To conclude, as of now, AI has still not reached an accuracy level so as to replace the manual grading completely as there are many doubts on the amount and quality of images the software is trained on. By using AI, it might be possible to strengthen the correlation between blastocyst assessment and outcome in a more objective manner. But we clearly see the benefit of AI only when we have multiple good-quality blastocysts to choose between, and if we have low egg and embryo numbers, then it probably will not be as useful. It will be necessary to perform a comparative prospective study to identify the (dis)agreement in blastocyst selection for transfer between AI models and embryologists. A question needs to be answered by existing AI applications, which have, till now, used both fixed and flexible time-based methods of evaluation because blastocyst development is a dynamic process: Should we evaluate and grade blastocysts when they are exhibiting the "best" appearance? Or should we evaluate them at a particular time? Also, the ability of AI blastocyst applications predicted by early developmental versus later developmental events needs to be explored.

Artificial Intelligence and Screening for Aneuploidy

Embryo euploidy has been an important consideration while selecting embryos for transfer. Although PGT-A has been available since the early 1990s, testing methods have evolved rapidly in terms of the types of chromosome abnormalities that may be identified and in the terms of accuracy that may be expected. PGT-A is a globally performed screening test for embryo euploidy; however, its role as an adjuvant in IVF treatment still remains controversial because the weight of evidence in support of improving delivery rates is still considered questionable. Also, a recent American Society for Reproductive Medicine (ASRM) committee opinion concluded that the effectiveness of PGT-A cannot yet be determined.[42] One serious limitation plaguing preimplantation genetic diagnosis (PGD) studies is the issue of mosaicism. It has been reported that up to 24% of embryos that are diagnosed with PGD may be mosaics.[44] Now, If AI can differentiate "normal" embryos from those that are chromosomally abnormal with higher accuracy and proficiency than the other types of PGT, it promises to reduce costs, miscarriage, and stillbirth rates and will also eliminate the invasive techniques ultimately. In the future, this technology could be valuable for patients who do not wish to subject their embryos to the invasive biopsy procedure or cannot afford PGT-A, and so on.

The various algorithms designed to accurately predict the embryo euploidy are based on the morphokinetical characteristics obtained through TLM.[45] Some algorithms have proposed to divide embryos into categories (low, medium, and high) on the basis of aneuploidy risk in association with the time required from insemination to reaching the blastocyst stage with demonstrated high prediction ability of 97% regarding embryos at high risk of being aneuploid, whereas low-risk embryos presented a 37% probability of aneuploidy.[46,47] However, it should be noted that the sample size in the studies was considerably small (<100 embryos each), highlighting the limitation. Another larger study proposed algorithm based on completely different morphokinetics with the evaluation of earlier stages of embryo development. This algorithm attempts to be statistically more efficient in terms of predicting embryo euploidy with the advantage of enabling embryo transfer on D3.[44] However, the statistical significance of the parameters considered has been argued.[46] Using CNN, Meyer et al. (in 2020) were able to classify D3 cleavage-stage embryo images as aneuploid or euploid with high specificity and thus were able to sufficiently identify 85.5% of aneuploid embryos. These results demonstrate the ability of CNN to identify noninvasive markers for detecting genetically abnormal embryos.[31] Based on AI, CooperGenomics has developed a completely new PGT-A data analysis platform named PGTai which promises to improve the accuracy of PGT-A interpretation and reporting while "removing subjectivity" in interpretation and avoiding reporting transcription errors by using a larger dataset for baseline than other available PGT-A software in use today.[48] Some AI start-ups and products are already claiming significant results, for example, the detection of chromosome 21 aneuploidy (by Life Whisperer and Ovation Fertility), where the companies have announced that it is possible to screen embryos for aneuploidy using AI embryo analysis, instead of aspirating the embryos for genetic testing. But without proper peer review, it is difficult to evaluate any of these claims, and another point to consider is whether we have enough images of aneuploid embryos to build a dataset huge enough to allow AI to detect an anomaly.

As of now, couples who have a large number of embryos available for testing may be able to save money by testing only the embryos with a moderate to high likelihood of genetic defects. Currently, AI is used in IVF laboratories as a tool to prescreen and identify viable embryos with a low likelihood of genetic defects before proceeding with PGT. The available prediction models for embryo euploidy are few, and the published studies indicate that substantial work is still needed before they can be used in ordinary clinical practice. Hence, we may be able to utilize these prediction

models in the future to help choose which embryos should undergo PGT-A screening because of their strong negative predictive values, but we are still not at the point where AI can reliably identify an embryo as euploid or aneuploid before transfer.

Artificial Intelligence in Prediction of Treatment Selection and Success Rate Prediction

In recent years, couples approaching test tube centers have become very common due to their lifestyle and stress levels, but IVF cycles are again a stress factor with their cost, continuous medication, and side effects. Currently, researchers are attempting to predict success rates using multiple parameters. The application of AI to choose treatment types is not much explored, and very little research has been published. Intrauterine insemination (IUI) success rate can be predicted using a neural network model with 71.92% accuracy results.[49] In this study, morphology, total motility, female factors, and underlying factors are fed to predict success rates. Another work predicts IVF success rates using multiple parameters; in their study, they have used 1,456 patient data using NBC and RF.[50] Siristatidis et al. proposed a new model to predict success rate using lifestyle, previous cycle details, the metabolomics profile of each embryo, transcriptomics of the oocyte and endometrium, reactive oxygen species in follicular fluid, micro RNA (miRNA) of the endometrium.[51] In this model, we can predict the clinical outcomes—miscarriage rate and live birth rate. Huang et al.[52] predicted the live birth outcome using a deep learning model from single embryo transfers. Xi et al.[53] developed a hierarchical model to understand the embryo implantation potential in double embryo transfers. Hassan et al. developed a prediction model with the help of multiple ML types using attributes such as antral follicle count, NbreM2, fertilization rate in vitro, follicles on D14, and others.[54] Durairaj et al. claimed 75% accuracy in success rate prediction using the artificial neural network (ANN) model.[55] These models are at the beginning level; many models have to be developed by involving all possible parameters to achieve >90% accuracy.

CURRENTLY AVAILABLE TOOLS AND APPLICATIONS

The first time-lapse system (TLS) for use in IVF labs was sold in 2008 (Primo Vision™, Vitrolife, Sweden), and today we have a lot of such systems available in the market, such as EmbryoScope and EmbryoScope Plus [Food and Drug Administration (FDA)-authorized, Vitrolife]; Miri (ESCO, Denmark); Geri (ESCO, Denmark) (GeneaBiomedx, Australia). Many experimental approaches, including morphokinetic studies available through the TLS, have been developed to examine the implantation potential and live birth rate of IVF embryos using photos and videos. Advances in TLS technology have resulted in the creation of embryo selection algorithms to address the subjective issues associated with manual scoring, such as blastocyst morphological evaluation and embryo selection.

The FDA-approved Eva test, which is driven by the updated Xtend algorithm (a standard multidimensional, static algorithm), can effectively predict which blastocyst has the better chance to develop into an embryo, based not only on its appearance but also on the combination of this new algorithm with traditional morphology grading attained by the embryologist and could actively promote Eset. KIDScore, also known as the implantation data score, is another time-lapse DT-based technique that includes morphokinetic characteristics as well as cell counts. The KIDScore algorithm outperformed the ALPHA/European Society of Human Reproduction and Embryology (ESHRE) rating system in terms of blastocyst development and quality prediction. A new version of the KIDScore contains a D5 decision support tool (KIDScore D5) that can only be used in culture systems with certain oxygen conditions. However, no consensus on these findings and the advantages associated with them has yet been published. Due to its relatively recent emergence and availability for only 2 years, the KIDScore has not been studied to the same level as Eeva. An Australia-based company, Life Whisperer, claims to have evaluated the embryo quality using AI so as to increase the success of implantation by 50% over manual grading by morphology alone. They use a database of embryo images, each with the embryologist assigned morphological grade, along with genetic screening results and pregnancy outcome data to train its AI system. It is a web-based decision tool with instant reporting where we simply upload pictures of the embryos and receive a scoring in real time. This company has also recently announced its ability to screen for aneuploidy. Another AI tool, "iDAScore," which integrates time-lapse monitoring and AI-based embryo evaluation in one workflow, is currently being tested in an international multicenter RCT. More recently, an AI, called Stork, was trained on over 12,000 images and eventually achieved a 97% accuracy rate for identifying healthy embryos that might produce a viable pregnancy and poor-quality embryos that might not.

Despite several studies which support the use of AI in embryo selection, there are also large number of excellent reviews which demonstrate that there is not enough data to differentiate between TLS and traditional incubation in cases of live delivery, miscarriage, stillbirth, or clinical pregnancy. As always, when applying new technologies, it is important that they are validated and should be used as supportive tools rather than a replacement for humans until we are confident that they operate in a reliable and safe manner. To this end, properly designed RCT are the way forward. AI comes with

the "black box" problem, this behavior of AI is something that even the engineers who create these AI fail to explain, and as a result, there is a significant amount of inadvertent bias connected with AI. Private companies are eager to sell their products in the market; these products currently available in the market are often without peer review, which in contrast to AI projects developed through research where the reviewers have full access to the source code, and the AI under development undergoes extensive peer review. It is crucial that the use of smart tools should not compromise the safety and efficiency of the clinic.

LAB ON A CLOUD

For two decades, the field of medicine has completely digitalized its documents, archiving patient records electronically, and information is stored on a cloud server. Electronic medical record (EMR) reduces our time and helps to conveniently retrieve the data wherever and whenever possible when provided with a suitable system to access and good internet connection. Lab on cloud is much used in research studies, where we can get numerous patient information within a short time. To build an AI model in ART, Lab on a cloud becomes an important and necessary tool to teach algorithms. Individual ART clinics have their own software to store their data, and it would be much appreciated if all this information is shared in a common platform so that we can develop a prediction model with more accuracy as the data will be huge. We propose in the future, all the national and international registries could initiate to archive data in a general linear form that is easy to access for the research.

POSSIBLE LIMITATIONS

Although AI has shown promising results, its use currently has certain limitations. Premature adoption of models without considering its limitations may be associated with risks in clinical practice. One such underlying reason behind the risks involved in wide-ranging applications is the fact that different IVF laboratories follow different practices, employ different criteria, and select embryos on different grounds, using different cutoff values. All users must be educated on how to evaluate AI system results and also to be aware of the limitations regarding validation procedures and the conditions of the model.

Reasons to Interpret Reproduction Artificial Intelligence Studies with Caution

- *Unbalanced data/intrinsic bias:* AI algorithms are trained on a specific set of data, and it performs their function based on that data only. Hence, when the training set is highly unbalanced, the model is prone to intrinsic bias; thus, the description of the algorithm should include the actions taken to avoid such bias.[56,57] It is very important that the IVF scientific community reaches a consensus on the algorithm's use and value as a prognostic tool in the IVF laboratory.
- *Lack of generalizability assessment:* Reproductive treatments at different clinical setups can vary widely. Ideally, an AI-based algorithm should be tested for generalizability across multiple clinics around the world and should include a wide spectrum of sample types available in clinical practice. However, the majority of the studies published to date have AI-based algorithms trained using data from a single clinic or with very narrow inclusion criteria (e.g., a single type of incubators, specific brand of culture media, category of patients, age group, study on only day 5 blastocysts), limiting their applicability in other conditions. An AI model's performance, to a large extent, is related to the quality of the database it was trained on. For example, on the type of images the AI model was trained on, suppose for training the images used were of day 3 embryos which were obtained after ICSI. Will this model be generalizable to images taken on day 3 or day 3.5? Will it be accurate for IVF-inseminated oocytes? Will it be applicable when different culture media are used? Hence, the clinic should access an AI system only if that was trained under conditions similar to those in the clinic where it would be implemented. A quality assurance test should be performed before the model is used in real cases. To date, there have been no prospective studies published in which the performance of an AI model is compared with standard clinical decisions, and the use of a universally commonly accepted, more evidence-based efficient algorithm remains the goal.
- *Sample size:* By nature, AI algorithms should be trained on large databases because a small sample size can compromise the model's performance and introduce overconfidence.[58] The creation of an efficient program would require a learning set consisting of a vast number of IVF cycles and an equally large testing dataset with known implantation data and pregnancy outcomes. If the training data sample size is small, the sample diversity is insufficient, or the ratio among samples is not balanced, this could lead to bias in the model regarding monitoring and learning, which would further result in the low generalization of the models with poor practical application effects.[59]
- *Controversy on its efficiency:* Even though there is an active ongoing controversy regarding the use and clinical efficacy of these systems,[23,60-62] advanced imaging techniques such as TLS have already obtained a significant market share of IVF-laboratories in the United States.[63] Other research subscribes to the view that the data on the merits of time-lapse services is yet insufficient to justify the device's and consumables' associated costs or

the major adjustments that must be made to IVF's usual operations. TLM-based embryo grading failed to make a statistically significant difference in enhancing clinical pregnancy or ongoing pregnancy rates when compared to regular embryo grading methods.[62] However, several validation studies revealed varying prediction capacities; hence, external validation on a large sample is required prior to the reproduction, acceptance, and horizontal application of the proposed models in order to identify the models' strengths and flaws.

- *Limited performance metrics reported:* Algorithms designed for AI, which are used in assisted reproduction, are largely classification systems that tell us whether a biological sample has a poor or good prognosis. Two most common metrics used to assess these classifiers are accuracy and area under the curve, but with these two metrics alone, a reader cannot execute a deeper performance analysis. Hence, other tests should be performed before the technology is implemented into daily practice.
- *High cost:* This technology is not widely used in clinics worldwide, and its cost initially seems to be remarkably high and can put an additional burden on the patients.
- *Increased workload:* This may come at the cost of increased workload (e.g., increased annotations) and may require the need for specific training on using this type of equipment.
- *Ethical issues:* Many patients will not allow or give consent to the uploading of their medical data online for intelligent analysis, as they would consider this as a threat to their privacy.
- *Images quality-related issues:* The transfer learning (TL) algorithms are mostly trained on high-quality image data. Different laboratory setups may have the provision of microscopes with cameras, and thus images range from low resolution to high resolution. The question is, would it be possible to train an AI system on high-resolution images and apply it to low-resolution images or vice versa? Also, a single image cannot be used to evaluate the dynamic process of embryo development or events, such as blastocoel collapse, which can potentially interfere with the assessment. Moreover, it is unclear how AI will perform with data it has never "seen before".
- *Need of RCTs:* Furthermore, before an AI model's clinical application, quality assurance should always be considered whenever a model is introduced into a new setting for the first time. This is in contrast to the complex logistics required for an RCT and the long time it takes from design and recruitment until publication. In other words, a 2-year RCT project could end up demonstrating that a 2.5-year-old version of an AI/ML model is good; by that time, the same ML model is already in its third or fourth version/update.[64,65]

FUTURE ASPECTS

Artificial intelligence will predominantly occupy the ART field; here are some possible predictions:

- Complete ART treatment planned using AI, based on their diagnosis and history, whether the patient can undergo IVF, ICSI, PGT, or IUI.
- Most accurate prediction model to check the pregnancy outcomes before undergoing the IVF treatment cycle.
- Exact uterine implantation time predicted by AI system.
- Proper embryo selection protocol to provide high success pregnancy rates.
- AI-based embryo culture system to prevent degeneration by addressing changes in any chemical, metabolites, and gaseous exchange parameters such as glucose, calcium, lactose, pH, pO_2, pCO_2, sodium, zinc, and others.
- Evaluation of embryo without embryologist presence. Prediction models can be improved if patient information is shared globally on a common platform.
- Extended blast cultures can be cut down if we can predict the embryo with a good success rate in implantation and live birth occurrence; by this, we could prevent epigenetic damage.

To pick the most morphologically normal sperm, software such as intracytoplasmic morphologically selected sperm injection (IMSI) and motile sperm organelle morphology examination (MSOME) are already available. CASA is a type of software that is frequently used for sperm analysis. Automated machines are being used routinely for embryo vitrification. The use of well-calibrated AI algorithms in ART will improve the efficiency with which sperms and oocytes are picked for IVF, which will, in turn, increase clinically achieved pregnancy rates. In the future, AI algorithms will aid clinicians in automating, systematizing, and improving IVF outcomes.

CONCLUSION

The use of AI in ART is steadily growing, and in the future, it may be possible to use AI and machine language to incorporate and analyze, all IVF-cycle-associated data from various clinics treating infertility, so as to significantly improve reproductive outcomes in infertile couples. However, at present, despite being around for a decade, advanced imaging techniques such as TLM have failed to earn the trust of embryologists, who strongly believe that the TLS is more of a curiosity but not a requirement. AI has not yet established a stronghold in the world of reproductive medicine, as it still has to prove its use in improving reproductive outcomes.

Despite all these hurdles, in the near future, AI is poised to boost and appreciably improve the present stagnant success rates, which have plagued fertility clinics for over a decade.

Laboratory Management

CHAPTER 121

Setting-up an ART Laboratory

R Suchindra, Anuja Kamath

INTRODUCTION

Over the last few decades, the services provide by an assisted-reproductive technology (ART) clinic have evolved. The types of treatment offered by an in vitro fertilization (IVF) clinic, today, include procedures like intrauterine insemination (IUI), IVF, intracytoplasmic sperm injection (ICSI), other micromanipulation techniques, cryopreservation, and preimplantation genetic diagnosis (PGD). The ART laboratory is the place where gametes, i.e., oocytes and sperms are handled to form an embryo. This requires a sterile, stable, and nontoxic environment. Therefore, it is very critical to setup an optimum ART laboratory. The infrastructure, equipment, and the design depend on the number and the type of ART cycles performed in the clinic.

LAYOUT OF AN ART LABORATORY

The layout of an ART laboratory is described in **Figure 1**.

A basic ART laboratory should have:

- A fully equipped operation theater (OT) for ovum pickup (OPU), embryo transfer (ET), and for surgical sperm retrievals [percutaneous epididymal sperm aspiration (PESA)/testicular sperm aspiration (TESA)/testicular sperm extraction (TESE), etc.].
- The embryology laboratory is like the *sanctum sanctorum*, the heart of the ART clinic and it should be located adjacent to the OT. The laboratory should have restricted access, and a pass window should be provided on the wall, which is shared between the OT and the embryology laboratory. The follicular fluid aspirated during OPU is passed to the embryology laboratory through the pass box, this minimizes the door opening and helps prevent the entry of outside air.
- Andrology laboratory for semen analysis and semen preparation should be located next to embryology laboratory. It should also have a semen collection room adjacent to it with a closed pass box on the wall common to andrology and collection room. This is to facilitate the transfer of samples from the collection room to the laboratory, minimizing the movement from the laboratory.
- Cryopreservation materials like liquid nitrogen, and stored samples container should be kept in a room adjacent to the embryology laboratory.
- Carbon dioxide and nitrogen cylinders used for the incubators should be kept in a separate area outside the laboratory creating a gas bank, from which gas should be supplied to the incubators through piped gas lines. This will prevent the interference in embryology laboratory, caused by the movement of the cylinders while changing them. An inline-activated charcoal (CODA) and high-efficiency particulate air (HEPA) filter should be always provided to filter out the volatile gas and particulate matter.
- IVF culture media should always be kept in a refrigerator, which should be exclusively used for embryology.
- Scrub area should be located at a convenient place.
- There should be a recovery room for patients, which can be used for preparation as well as post procedure.
- Changing rooms with toilets should be planned well.

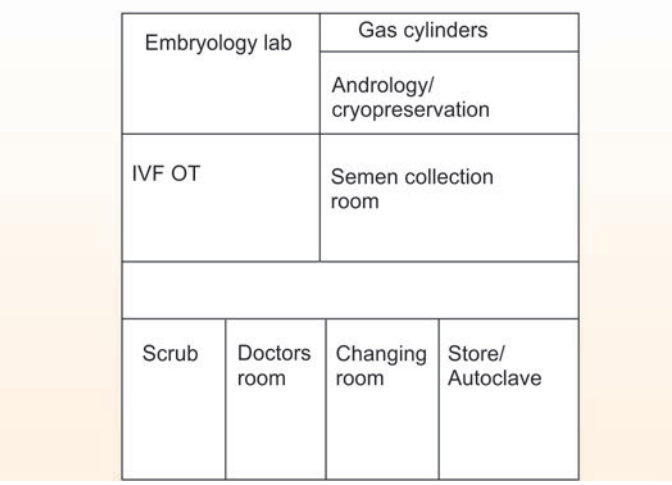

Fig. 1: Layout of an assisted-reproductive technology laboratory. (IVF: in vitro fertilization; OT: operation theater).

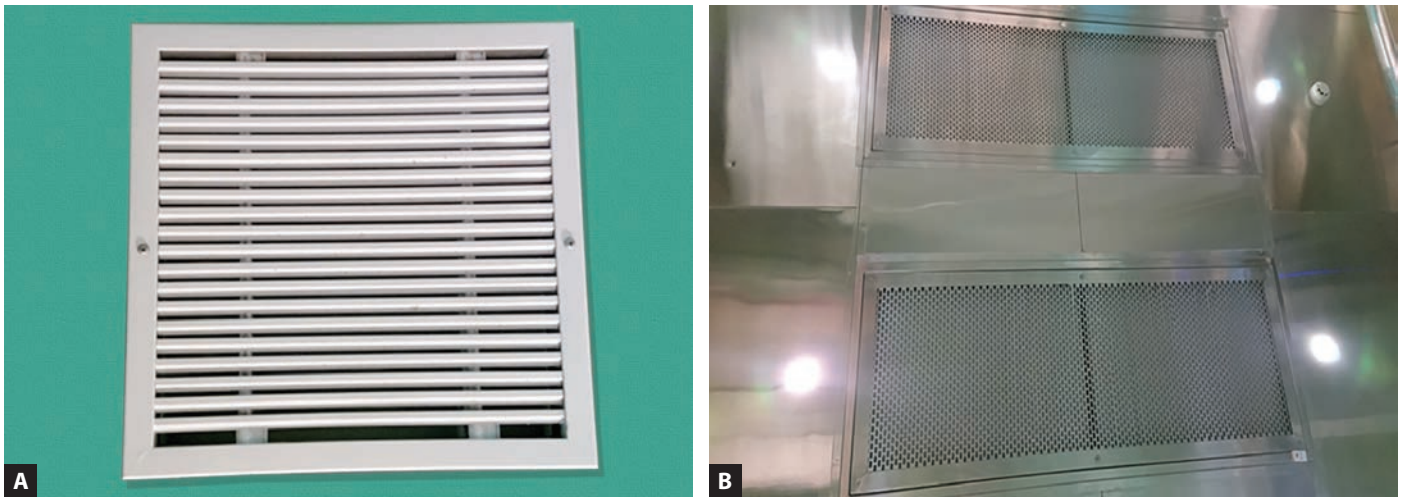


Figs. 2A and B: Heating, ventilation, and air-conditioning system.

- Stores for embryology consumables should be separate from others.
- Staff room, counseling room, and discussion rooms should also be planned accordingly.

INFRASTRUCTURE FOR NEW LABORATORY SET-UP

Site Suitability and Basic Design

The location of the building in which the IVF laboratory is to be set up is very important. Attention should be paid to possible sources of chemical and particulate pollution, e.g., foundries, petroleum processing units, vehicle garages etc. The IVF laboratory should have a supply of HEPA –filtered air similar to that of an operating theater.

Fig. 3: Coda mini tower as stand-alone.

Air Quality

- Particulates: Ideally should be less than 352,000 particles larger than 0.5–10 µm per m^3
- Micro-organisms: ideally should be less than 10 cfu/m^3 and less than 2 spores/m^3 "at rest".
- VOC: Ideally total VOCs should be less than 500 µg/m^3 (~400–800 ppb total VOC); aldehydes should be less than 5 µg/m^3.
- Air changes: Ideally 15 total air changes per hour (ACH), including three fresh air changes per hour (20% outside air)
- Positive Pressure: The ideal target is +38 to +50 Pa in the IVF laboratory (minimum recommended is at least +30 Pa).
- Temperature: Temperature in the IVF laboratory should be regulated by the HVAC system (**Figs. 2A and B**). The HVAC comprises of heating, ventilation, and air-conditioning. The temperature should be maintained in the range of 20–24°C (depending on region).[1]
- Humidity: The relative room humidity (RH) should be between 40 and 45%. Higher humidity helps growth of contamination like molds, while lower humidity may cause discomfort to the laboratory personnel, and also can cause higher evaporation of media during dish preparation, which may consequently affect osmolarity of the culture medium and be detrimental to the embryo quality **(Fig. 3)**.[2]
- General design and construction criteria
  - The IVF laboratory should be equipped with a dedicated AHU to prevent contamination of the cleanroom air with air from adjoining places. The HVAC system must run constantly, not just during working hours.
  - The fresh air inlet should be located away from sources of obnoxious fumes and it can be further prefiltered to increase the functional life of the filter systems.
  - The HVAC system should be incorporated with activated carbon or potassium permanganate filter for elimination of VOCs
  - The HVAC system should be equipped to provide adequate warming or cooling of incoming fresh air depending on the local climatic conditions.

- The HVAC system should also be able to totally isolate the laboratory air from the outside air, in case of emergencies like local construction works, repairs of the road works, which can generate high VOCs.
- Air supply vents should be placed in the ceiling and outlet return ducts should be placed close to the floor level.
- HEPA filters should be placed in a central position to avoid difficult access during their cleaning and maintenance.
- Ideally, pressure sensors should be installed on the side of the doorway to the IVF laboratory. This pressure gauge should display differential pressure.
- The exterior walls of the IVF laboratory should be a complete wall from the concrete floor to the roof with no perforations present on the wall
- The ceiling must be constructed with solid material like plasterboard, gypsum board, etc. Essential access panels should have air-tight, silicone gaskets.
- Light fittings must be air-tight, designed for cleanrooms and should be air tight.
- All electrical, gas, and data outputs should be sealed to prevent air loss through them.
- Doors must be tight-fitting with bottom "sweeps" and perimeter seals (top and edges). The view panels, if any, should also be installed using gaskets to make them air-tight.
- Pass boxes should be air-tight to preserve room positive air pressure.
- Construction materials: For walls steel modular panels or plasterboard coated with zero VOC paint or antimicrobial wall paper can be used. Floors can be covered with vinyl with impervious sealed joints. The floor of area where cryopreservation procedures will take place should be made of nonthermally fragile material like stainless-steel tread plate.
- Non-porous materials like epoxy, Corian, and Granite should be used for counter tops.
- Furniture like cabinets (under and over benches) should be powder-coated metal or stainless steel.
- Use of manufactured wood products and polish is not recommended, as they have all been demonstrated to be embryotoxic.

"Burn In" of an IVF Laboratory

- A newly constructed or renovated IVF laboratory will have a compromised air quality, due to the VOCs and other contaminants released from construction materials like paint.
- "Burn In" of an IVF involves increasing the laboratory temperature by 10–15°C and also increasing the air cycles for better ventilation, for at least 2–4 weeks before its operation.
- This facilitates offgassing from various building materials and also facilitates lowering of the VOCs.
- A final check of the air quality and VOCs should be done before commencing the work.

Equipment

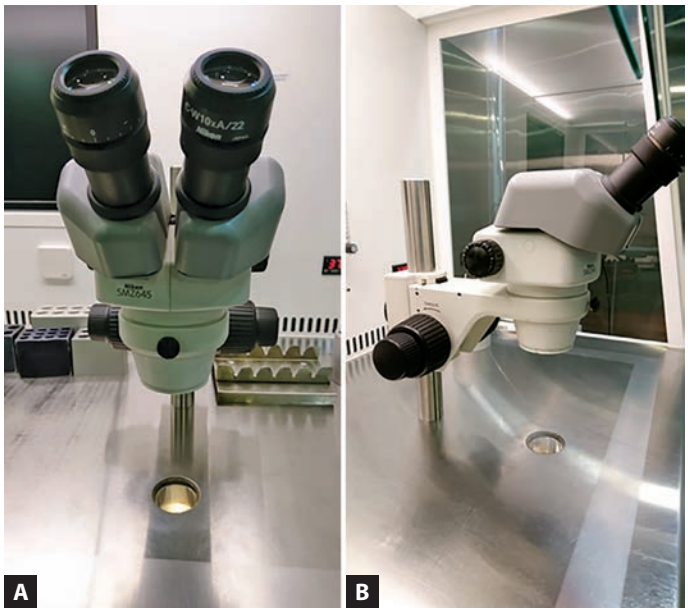
The equipment for an embryology laboratory depends on the number of cycles and the type of procedures offered by the clinic. The equipment can be classified into essential and optional.

- Essential equipment:
  - The integrated workstation (laminar air flow)
  - CO_2 incubator or box incubator
  - Trigas incubator or bench-top incubator
  - Micromanipulator with inverted microscope
  - Centrifuge
  - Makler chamber
  - Cryopreservation equipment (cryocans).
- Optional equipment:
  - Intracytoplasmic morphologically selected sperm injection (IMSI)
  - Laser
  - Timelapse imaging or embryoscope.

The Integrated Workstation or Laminar Air Flow

- The workstation should have a temperaturecontroled floor, maintained at 37°C. Temperature maintenance is of utmost importance for the spindle integrity in oocytes and also likely for normal fertilization and subsequent embryo development **(Fig. 4)**.[7]
- Also it should be equipped with a stereo zoom microscope (**Figs. 5A and B**), 10× or 15× magnifications for screening of oocytes, denudation, and then visualizing the embryos.

Fig. 4: In vitro fertilization workstation with laminar air flow.



Figs. 5A and B: Stereozoom microscope.

Fig. 6: Box type CO_2 incubator (Heracell).

- The size of the workstation depends on the workload, 3*2 is the most common size.
- Turbulence pattern of the flow differs in horizontal and vertical laminar flow, therefore a vertical flow is preferred.[8]
- Ideally two workstations are required, one for sperm preparation and another one for preparing culture dishes, screening and grading of oocytes and embryos, and loading embryos into catheters for transfer.

CO_2 Incubator or Box Incubator

- CO_2 incubators provide optimum environment for the culture of embryos **(Fig. 6)**.
- These are used to incubate media, holding the oocytes after screening, for semen preparation, and to hold embryos before ET.
- The box incubators usually control concentration of one gas, i.e., CO_2. The concentration of CO_2 depends on the bicarbonate concentration in the culture media.
- The door of the incubator is also heated, so as to maintain the temperature inside, and also facilitate quick recovery of temperature after closing the door. Also there will be a gas tight door inside, which prevents the gas leak. Preferably incubator with more chambers should be preferred as the recovery of temperature and pH will be faster.
- The incubators should be equipped with infrared sensors for CO_2 monitoring.
- Medical grade CO_2 should be provided and should pass through inline filters, to eliminate all contaminants present in the gas.
- The incubator should be equipped with failure alarm, and also there should be provision to install independent probes, remote alarm system, and uninterrupted power supply (UPS).
- "Burn in" of the incubators before starting the operations is necessary, absence of "burn in" of incubators before use resulted in stress to embryos possibly via induction of VOCs thus producing a significant difference in the ART outcome.[9]

Tri-gas Incubator or Benchtop Incubator

- A benchtop incubator combine optimal embryo growth conditions due to individual chambers and also have advanced user control (**Figs. 7A and B**). They minimize the pH and temperature fluctuations.
- O_2 concentrations can be reduced to 5%, the reduced O_2 tension in the gas mixture closely mimics physiological circumstances[10] and minimizes oxidative stress to the embryos that may arise at 20% O_2.[11,12]
- Embryos cultured in a 5% O_2 environment consistently resulted in higher rates of implantation and live births when compared with rates among women whose embryos were cultured in an atmospheric O_2 environment.
- They may require a premix gas, e.g., MINC, Planar, or there might be integrated gas mixing unit in the incubator, e.g., K System, ESCO.

Micromanipulator with Inverted Microscope

- Micromanipulator is an integrated system with inverted microscope, used for micromanipulation of oocytes with sperm, also known as ICSI **(Fig. 8)**.
- The inverted microscope is used for detailed examination of oocytes and embryos. Interference optics such as Hoffman and Nomarski are preferable as they permit the best measure of detail and depth.

Figs. 7A and B: Benchtop incubator.

Fig. 8: Micromanipulator.

- The manipulator is equipped with a stage heater to maintain temperature in culture dishes during ICSI, pronuclear check, embryo development check, LAH, and biopsy for preimplantation genetic screening or PGD.
- Rigorous thermal control produced by a heating system stabilized spindles and increased fertilization, embryo development, and clinical pregnancy rates achieved after ICSI.[13]
- The inverted microscope should be equipped with a *still camera and/or video camera and monitor*, to capture images which can be analyzed after returning the gametes to the incubator. It also helps in training new embryologist and allows placement of still photos in patient file.
- *Micromanipulator* should be equipped with microtool holders for bilateral micromanipulation, suction or injection, and biopsy device.[14]
- A micromanipulator should be placed on an antivibration table.

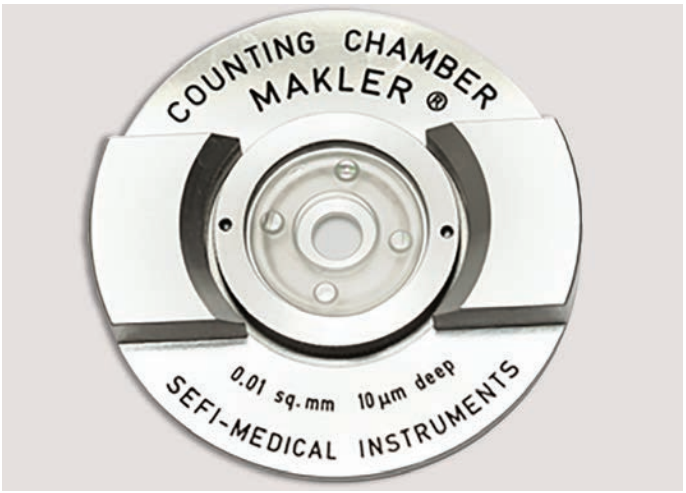


Fig. 9: Makler chamber.

Centrifuge

- Centrifuges are required for sperm preparation.
- Swing-out rotor centrifuges are preferred as they have a gentler effect on separated particles.
- The relative centrifugal field should not go beyond 800 g as this may cause accidental damage to the sperm.

Makler Chamber

- The *Makler counting chamber* is a simpletouse device for rapid and accurate sperm count, motility, and morphology evaluation from undiluted specimen **(Fig. 9)**.
- The chamber is composed of two parts:
  1. The *lower part has a metal base* and two handles. In the center of the base there is a flat disc made of optical flat glass on which the sample is placed.
  2. The *upper part is the cover glass* encircled with a metal ring. At the center of its lower surface there is a 1 mm^2 grid, subdivided into 100 squares, each one of 0.1 × 0.1 mm.
- When the cover glass is placed on the four tips, the space bounded in a row of 10 squares is exactly

onemillionth of mL. Therefore, the number of sperm heads in 10 squares indicates their concentration in million/mL.
- The depth of 10 microns eliminates blurring and allows sperm to move freely. The applied sample is observed in one focal plane.

Cryopreservation

- A separate room or an area in the laboratory, earmarked for cryostorage is essential.
- There should be enough space, and the growth of the clinic in future years should also be taken into consideration while ordering the cryogenic equipment also known as cryocans.
- Cryocans should always be placed on solid floor, which is resistant to liquid nitrogen; each tank should be easily accessible.
- The room should be safely and efficiently ventilated.
- There should be one storage can, to store liquid nitrogen. The liquid nitrogen can be dispensed into dewars using a pump. Appropriate protective gear like gown, mask, and goggles should always be worn when handling liquid nitrogen.
- Cryocans are available in different makes and capacities, appropriate ones should be procured keeping in mind the clinics load of cases **(Fig. 10)**.

Intracytoplasmic Morphologically Selected Sperm Injection

- Intracytoplasmic morphologically selected sperm injection is a variation of ICSI using higher magnification of 6600× **(Fig. 11)**.
- IMSI is used to study the sperm head in detail and look for abnormal head, vacuolation, and acrosome abnormalities.
- IMSI is configured of an inverted microscope with Nomarski optics, with video zoom and digital imaging system.

Laser

- The laser system is made up of a laser objective, which generates and releases the required energy in the form of laser shots allowing the zona pellucida to be dissolved.
- It comprises a software, which provides to the operator a precisely control of the laser energy output, pulse duration, and the hole size.
- Laser is used for assisted hatching, zona thinning, and for biopsy of embryo.

Embryoscope

- The embryoscope is an incubator that maintains the necessary physiological conditions required by a living embryo while they are in the IVF laboratory (**Figs. 12A and B**).
- It has an incorporated timelapse system that has a camera that continuously captures images and records them as a video of the embryonic development.
- This system allows the embryologist to monitor embryo cell divisions while the embryos are still in the incubator and we can carry out a study of the development of the embryos.

Electronic Witnessing System

- Electronic Witnessing System (EWS) is a modern day tool in the ART Laboratory.
- It acts as a double witnessing system for Embryologists.
- It provides complete electronic traceability and minimizes potential mix ups.
- An EWS uses radio frequency identification tags (RFID) for tracking and recording patients' information and the biological samples during the ART procedures.
- The EWS monitors each and every instance wherein the gametes or embryos are shifted from one dish to the next and ensures that only one patient can be worked on at one time. Monitoring is constant, so an identity check can never be overlooked.

Fig. 10: Cryocans.

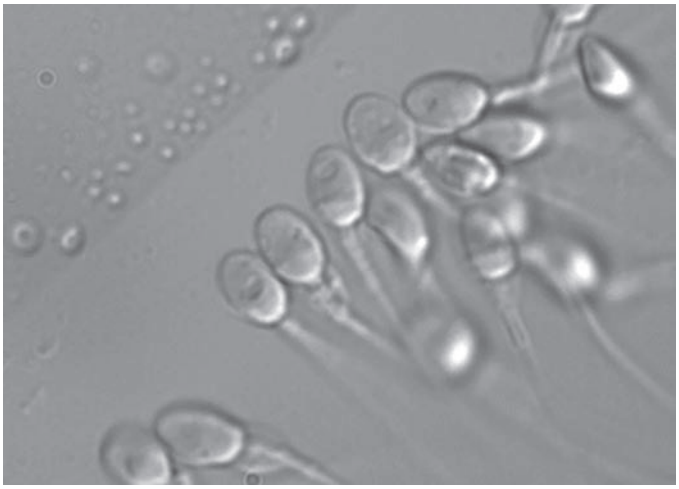

Fig. 11: Intracytoplasmic morphologically selected sperm injection.

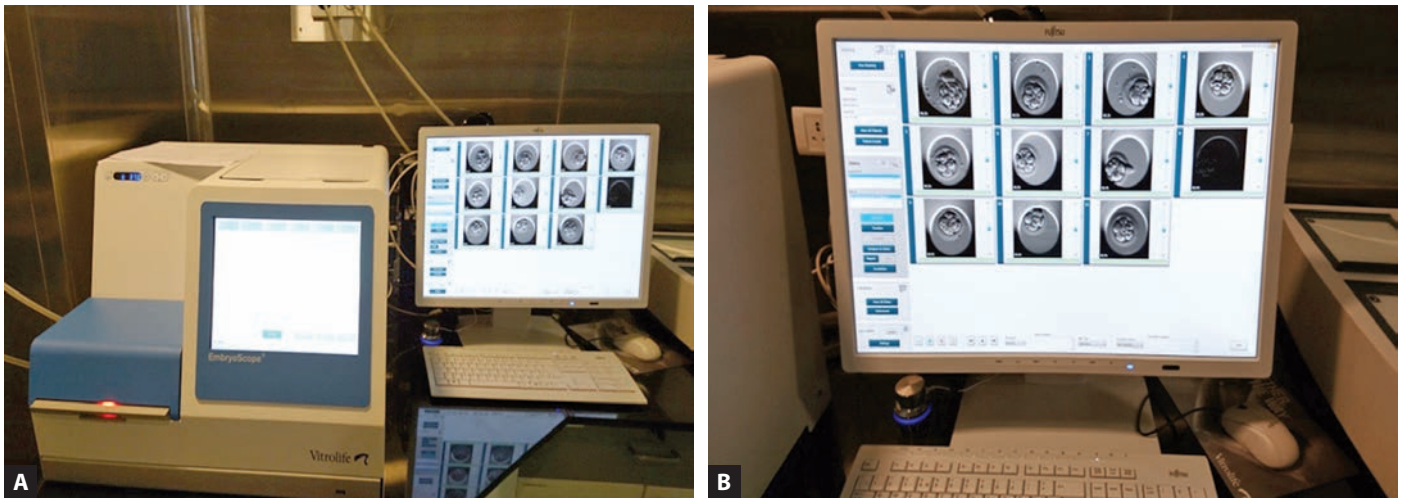

Figs. 12A and B: Embryoscope.

KEY NOTES

Careful Planning of the design, facilities, equipment, and layout is required for dedicated, focused, and uninterrupted concentration while working in an ART laboratory. Also equally important are the personnel who are trained and professional and can carry out the required procedures with proficiency. This maintains high pregnancy rates despite multifactorial variables. Thus, it is important to provide the IVF laboratory with the "best" technology available to produce top quality embryos, develop best methods to select best embryos, and develop optimized cryopreservation procedure.

CHAPTER 122

Quality Control in IVF Laboratory

Sanjay Shukla

INTRODUCTION

Last four decades have witnessed substantial growth in the field of assisted reproduction techniques (ART). Despite all the improvements in the field, ART success rate still remains relatively limited.

The organizational structure of an ART center is complex and multidisciplinary. It comprises medicos, laboratory staff, nursing and paramedics, management office, accounts department, and other support staff. Deficiency or poor performance of any element of this complex structure affects the overall performance of the entire organization and in turn emasculates the efforts to achieve high levels of success.

The Cairo consensus guidelines on IVF culture conditions reiterate the fact that everything in the IVF laboratory influences the outcome.[1] Thus, everything including infrastructure, designing, equipment, culture media, disposables and consumables, laboratory personnel and other staff, processes and procedures, needs to be "perfect" for proper functioning of the laboratory.[1]

In today's time, most of the in vitro fertilization (IVF) laboratories world over are equipped with excellent quality instruments designed to serve specific needs of human clinical embryology, however, only few IVF labs are able to produce consistently better results than the others.[2]

The clinical embryology laboratory's work goes beyond the role of other clinical or diagnostic laboratories and this needs to be understood that procuring good quality equipment or designing modular laboratories or using fancy gadgets only cannot translate into high success rates but the implementation of a total quality management (TQM) is needed to ensure consistency and reproducibility of results.[3,4]

WHAT IS QUALITY?

In different areas, quality can be defined differently. However, in generalized term it means "the degree of excellence". In medicine, it can be defined as the *duty of care* and is often considered as equivalent to the *best practice*.[5]

It is the responsibility of IVF laboratory to not only comply to the regulatory standards but also to provide quality services to the patients in a safe, effective and satisfying manner.[6]

Professional societies such as European Society of Human Reproduction and Embryology (ESHRE), Association of Clinical Embryologists (ACE) and American Society for Reproductive Medicine (ASRM) have prepared guidelines to standardize the functioning of infertility clinics.[7-14] Similarly, Indian Council of Medical Research (ICMR) has also come up with a National Guidelines for Accreditation, Supervision and Regulation of ART Clinics in India.[15] Indian Society of Assisted Reproduction (ISAR) conducted a consensus meeting (2021) of experts and compiled a set of recommendations to standardize the ethical and safe practices of assisted reproductive technology in the country.[16]

In some countries, ART centers and IVF laboratories are regulated by law. Recently, India has also passed and implemented the long awaited Assisted Reproductive Technology (Regulation) Act and Surrogacy (Regulation) Act.[17,18] The enforcing government machinery like State Boards and Appropriate Authorities are yet to be formed in all the states of the country. The rules and regulations have also been released through subsequent Gazette notifications. However, these guidelines describe only the minimum requirement and recommendations for IVF clinics.[15] Quality control program is left to the discretion and understanding of the individual laboratories.

QUALITY MANAGEMENT

In author's opinion, quality management (QM) is quality assurance (QA) by quality control (QC) and quality improvement (QI). This means, ensuring consistent "quality" by controlling each and every process, equipment, personnel and materials used in an IVF laboratory in a definite manner without deviations and then implementing strategies to improve further.[19]

This chapter is focused at the QC in human clinical embryology laboratory.

QUALITY CONTROL

Quality control program in an IVF laboratory required to keep a check on the quality and performance of all the products, equipment, processes and the people working at different levels in the laboratory.[20,21] Measures to control the quality of air and environment of the laboratory are of paramount importance.[22,23]

A special attention is needed on the selection of equipment/devices used for QC measures. All the devices used for this purpose must be certified, calibrated and suitable for the measurement. Not only that, the person performing these QC checks must be properly trained and must possess adequate technical knowledge of the process. The QC activities performed by any person must also be reviewed periodically by appropriate authorities.[13]

This comprehensive QC program is necessary to ensure that every component of laboratory is functioning properly.

The QC program of a successful IVF laboratory must include the following points described here.[24]

Standard Operating Protocols

Every IVF laboratory requires detailed, well documented, well defined and user-friendly standard operating protocols (SOPs). SOPs must include stepwise details of the scientific or technical procedures, monitoring techniques with methodology of the equipment used, laboratory cleaning and maintenance, etc. The frequency of all the monitoring measures must be decided by the workload of the laboratory. Every laboratory should establish and define the acceptable "range" of measures of activities and performance of all its constituents and these must clearly be mentioned in the SOPs. SOPs must also include corrective measures or actions required in case of any deviation from these predefined "ranges."[7,8,25]

A system to religiously follow the SOPs must be inculcated in every staff member and they must understand the importance of the type of work being carried out in the laboratory. The QC records should be available to the review committee. Proactive review of the QC record may help supervisors to identify possible problems or risks to take preventive measures.[5,26]

Quality Control of Laboratory Environment

Although, it is a part of laboratory designing, IVF laboratory environment deserves a special mention here as it is the first thing to start a QC program.

Modern day IVF laboratories are designed as per ISO 8 or ISO 7 cleanroom standards.[27] The air delivered in the laboratories is high efficiency particulate air (HEPA) or ultra-low penetration air (ULPA) filtered to reduce the particulate matter. This air is circulated in such a fashion that a constant positive air pressure is maintained inside the laboratory to minimize the entry of outside air. Further, volatile organic compounds (VOCs) and chemical toxicants have serious negative effect on fertilization and embryo development. Therefore, suitable VOC filters are recommended in addition to HEPA or ULPA filters.[23]

Air quality can be monitored by particle counters and microbial testing. Regular maintenance and changing of air filters should be done. It must be kept in mind that in the absence of regular maintenance, the air filtration system may itself become a source of contamination and could even be more detrimental.[9,22,23]

Volatile organic compounds can also be monitored and various VOC monitors are available commercially. The limitation of most of the VOC monitors is that they can detect only few toxicants and that too in the range of parts per million (ppm) only.[9,23]

The personnel working in the laboratory are a major source of particulate and microbial contamination. Therefore, the traffic inside laboratory should be restricted to minimum. The staff must enter the laboratory after donning proper clothing, cap and masks.[9,22,23]

Use of toxic disinfectants and cleaning agents must be avoided and safer alternatives must be used for cleaning and disinfection.

The ambience of IVF laboratory is usually kept cold and dry. Higher temperature and humidity favor microbial growth. Also, important equipment such as warmers and incubators function well when the ambient temperature remains around 7°C less than the set values. Thus, recommended temperature for an IVF laboratory is below 25°C and relative humidity (RH) between 35% and 50%. RH <35% not only causes discomfort to the people working in the laboratory but also promotes static electricity.[27,28]

The location of the incubators, workstations and laminar air flow (LAF) hoods should never be in front of or under the direct air drag from AC or heating, ventilation and air-conditioning (HVAC) inlets to avoid temperature fluctuations.

Room thermometers and hygrometers should be installed to monitor ambient temperature and RH and the record of the readings must be maintained.

Quality Control of Equipment

Temperature of equipment, such as incubators, heated stages of microscopes, test tube warmers, LAF hoods, dry baths and water baths should be monitored daily. Refrigerators used to keep media should also be monitored on a daily basis.

This monitoring must be independent of the inbuilt display of the equipment itself and must be done by a certified and calibrated thermometer. In case of any disparity in the readings of the equipment and calibrated

thermometer, authorized service engineer should be called to get the calibration done and display of the equipment set accordingly.[27-29]

There are a variety of thermometers or probes available commercially to serve this purpose. To monitor the inside temperature of large incubators, test tube warmers, dry bath or water bath and even refrigerators, a thermometer can be placed in an oil filled test tube. Specially designed probes attached to electronic devices can be used to monitor the temperature of heated surface of LAF and benchtop incubators.[27-29]

Gas supply and RH in the incubators need to be monitored daily too. Media manufacturers recommend specific CO_2 concentration to achieve the desired pH in that particular medium. Also, same CO_2 concentration at different sea levels gives different pH to the same medium. Therefore, more and more laboratories are now preferring to monitor pH of the medium equilibrated in the incubator. Like temperature, gas concentration in the incubators and pH in the medium can be measured by various devices. Proper humidity is essential to avoid evaporation of media and consequent osmolality changes.[27-29]

Laboratories which are using triple gas mixture must ask the supplier to provide certificate of the desired concentration of mixed gases for every cylinder. Inline gas filters adsorb and filter many impurities from the gas supplied to incubators hence, recommended. Such filters must be replaced timely with new filters as recommended by the manufacturers.[28-30]

Incubators must be cleaned, sterilized and water must be changed as per the laboratory's policy and workload. This needs to be understood that the gas censors in the traditional box type incubators do have an expiry. Over the time these may need to change.

Other equipment such as micromanipulators, microscopes, media and gamete handling pipettes, LAF, etc., should be cleaned and serviced regularly as recommended by manufacturer. Regular maintenance of equipment is required for proper functioning.

Gas levels in the supply cylinders must be monitored and recorded daily. Backup gas supplies should be available on site. Similarly, liquid nitrogen (LN_2) levels in the cryotanks must be monitored and recorded regularly. A log of LN_2 top-ups and refills must be maintained.

It is recommended to install external audible alarms for incubators as well as for cryotanks. These alarms must be tested and mock drills for adverse events must be carried out regularly to ensure that system is working properly.[5,25]

Quality Control of Culture Media

Culture media preparation demands very stringent quality control and precision. In present days' human IVF, most of the laboratories use commercially available culture media to avoid variations and technical problems that may arise in preparing comparatively smaller volumes in-house.

Laboratories using these media should control the way they store, handle and use the media. In countries such as India, where the temperature is high throughout the year in most parts of the country, transportation of culture media poses a great challenge. Perfect cold chain must be maintained throughout the transit and once the media have reached, these must be delivered to the laboratory without delay.[27-29,31,32]

Manufacturers' instructions must be followed for proper usage and the expired media bottles must be discarded immediately. Every batch of new medium must be observed for any visible contamination, change of color, turbidity and bottle leakage. Before using in a clinical case, every new batch must also be checked for pH after equilibration in the incubators.[27-29]

Buffers that contain HEPES or MOPS are designed to work outside the incubators hence, do not need CO_2 equilibration. Keeping them in CO_2 incubators may cause pH change and could be detrimental for gametes and embryos.

Culture dishes should be prepared quickly to avoid osmolality changes. It is especially important when droplets or microdroplets are being prepared. Oil overlaying is recommended. Peroxidation of oil could cause serious harm to eggs and embryos. Therefore, oil bottles must not be kept for long and once opened should be consumed as quickly as possible.[23,29]

Quality Control of Consumables or Disposables

Plastic ware and other consumables which come in contact with the gametes and embryos in IVF laboratory need to be off-gassed before use. Many of the plastic wares are sterilized by ethylene oxide (ETO).[33,34] The manufacturers keep them in special ventilated areas for off-gassing as a standard protocol before they are released for customer use. Still, it is recommended to let the residual toxic gas flush away by keeping them in a well aerated area in IVF facility before they are brought to the laboratory for clinical use.

The plastics themselves are a source of VOCs therefore the material should be selected which are nontoxic and intended for use in an IVF laboratory.[27]

Many large laboratories perform their own QC tests such as Mouse Embryo Assays (MEA), limulus amebocyte lysate test (LAL) and Sperm Survival or Sperm Motility Assay to test the suitability of contact material as well as culture media before use.[35] Small laboratories can at least do simple sperm motility test of any new batch against the previously tested and used regular consumables.[8,25,36,37]

Quality Control of Laboratory Personnel

Proficiency testing of all laboratory personnel should be done regularly. Those who perform poorly, must be given

an opportunity to go through a refresher training and learning to improve upon their performance. Those who perform well should also be encouraged to attend seminars/trainings/conferences to keep themselves updated with the newer technological advancements in the field. Strict actions may also be taken against someone who repeatedly fails to improve.[25]

Sufficient staffing is the key to reduce workload related errors and helps better performance.[25,32]

Quality Control to Avoid Mix-ups and Errors in the Laboratory

The IVF laboratories have a great responsibility to avoid mix-ups of the sample and gametes in view of serious legal, social, and financial consequences associated with ART procedures. Utmost attention is required to perform IVF laboratory procedures.[5,8,38-40]

Proper labeling of each and every sample, container or culture dishes or tubes with patients name and unique IDs must be done and double checked throughout the procedures. A witnessing system is a *must* in every laboratory for every step a gamete or biological sample is being handled. The operator and the witness must sign all the papers and records of the procedures done by them. Further, many laboratories are now adapting electronic witnessing systems to minimize human errors.[5,39-41]

A culture of error and incidents reporting must be developed in the laboratories. It is the responsibility of the directors and supervisor to build a trust among the staff members so that any incident or error is religiously reported and recorded. The root cause analysis (RCA) helps the laboratories minimize the likelihood of recurrence of such incidents in future. Also, an emergency plan should also be prepared in case of emergencies, natural disasters such as floods, earthquakes, storms, etc. To deal with all such situations a team of experts should be made that includes not only laboratory supervisors or directors and senior members but also clinicians, engineers, fire experts and even legal consultants who have expertise and experience of troubleshooting and capable of taking appropriate actions.[5]

A hierarchy of authority and responsibilities must be clearly defined in the structural organization to address any issues in the ART center.[25]

Adequate power back-up system should also be installed and regular validation of functioning must be done.

Key Performance Indicators for Quality Control

Vienna consensus meeting of renowned scientists from ESHRE and Alpha has produced a comprehensive document for key performance indicators (KPI) for IVF laboratory setups. These KPIs should be considered as the true reflection of the quality of an IVF laboratory.[38]

Alpha scientists also prepared another consensus document defining KPIs for cryopreservation of oocytes and embryos. This document describes minimum performance levels, basic competency and benchmark values for 14 KPIs.[42]

Based on the recommendations of various guidelines and consensus documents, every laboratory should set its own set of KPIs and regular evaluation of the laboratory performance of KPIs should be done and all the efforts should be done to improve and meet the set benchmarks.[38,42-43]

DISASTER MANAGEMENT

In vitro fertilization laboratory is a high complexity laboratory, involving handling of human gametes and embryos and performing sensitive procedures. Thus, in the event of a disaster, these laboratories are prone to suffer not only the disruption of services but also serious harm and damage; sometimes irreparable.[44] Disasters can be natural or man-made. Some natural disasters are common round the globe while some others could be location and area specific.[5,44]

Therefore, it is pragmatic to include disaster and risk management in the quality control program. A proactive approach to disaster and risk management is to prepare a risk-register.[5,44-46] Every laboratory should enlist potential risks or disasters that can be anticipated or that usually occur or that already have happened. This register in turn helps in developing emergency plans to deal with different types of extreme situations.[44]

The ongoing COVID-19 pandemic has taught us the importance of emergency planning and preparedness.[47,48] Several guidelines and directives were issued by different professional bodies to help fellow practitioners to safeguard their patients and the staff.[48-51] Safer approaches and procedures for sanitization and decontamination of the IVF laboratories were proposed and adopted.[47-51]

CONCLUSION

Quality control or quality management is a continuous process. Initially, it may appear cumbersome, once implemented properly, it becomes a habit. Self-motivation to apply the QC measures is the key to success. Laboratories that succeed to implement QC system are the ones that achieve consistent and dependable results.[2]

Since, the QC guidelines or standards or not uniform and not so well defined, following ISO 9001 2000 standards and getting accredited has been in practice by many ART centers. Recent version of ISO standards—ISO 15189 2002 is a more advanced version and may be adapted and followed by IVF laboratories.[52-54]

Moreover, government regulations, media coverage and public concern has led to recognize the need of implementing a TQM as the field of reproductive medicine has developed remarkably over few years. Most often, only IVF laboratory

is considered to have QC in place however, it is just a part of complex structure of whole ART program and desired results can only be achieved when the organization integrates a TQM system.

CHAPTER 123

Embryo Culture Systems

Goral Gandhi

INTRODUCTION

Human embryos are metabolically dynamic and their nutritional requirements change from day-to-day and from stage-to-stage. The embryos are grown in culture systems that mimic in vivo conditions. In vitro culture of human embryos was first successfully carried out by Dr John Rock in 1944.[1] Recent advances have resulted in the development of more physiological and effective culture media capable of maintaining the viability of the developing embryo. Suboptimal culture conditions may lead to impaired embryo development and a decrease in resultant implantation and pregnancy rates.[2] Therefore, improved embryo culture systems will enhance the overall success rates of assisted reproductive technologies (ART). The main objective of any in vitro fertilization (IVF) program is to generate viable embryo that is capable of efficaciously implanting in the uterus and giving rise to a healthy baby. Nowadays, embryologists have the option of selecting different culture media. The day of the embryo transfer also varies from day 2 till day 5 or day 6. The culture system includes culture media, culture oil, type of culture, disposables, and the air quality.

This chapter aims to discuss the various constituents of the culture system. At the end of the chapter, the readers should be able to decide on a culture system that facilitates optimal embryo development.

CULTURE MEDIA

In the early days of ART, the main energy sources in the culture media were glucose, lactate, and pyruvate. The buffered salt solution was supplemented with these compounds. Later on, the culture media were supplemented with serum albumin as the source of amino acids.[3]

Albumin is an important protein constituent for embryo development. Fatty acids play a major role in early embryo metabolism required for membrane synthesis. They are mainly bound to albumin but some albumins are heavily contaminated with lipid peroxides which are highly embryo toxic. Recombinant human serum albumin (HSA) is available as equivalent medium support since 2002.

In 1985, Quinn, et al., developed a media named human tubal fluid (HTF). The HTF resembled the composition of the fluids in human fallopian tubes.[4,5] HTF consisted of a salt solution supplemented with whole serum or serum albumin. This media was widely used to grow embryos till the day 3 stage.[6]

It is important to understand the physiology and metabolic needs of any cell type in order to culture it successfully in the laboratory. A number of physiological changes occur in the human embryo during the preimplantation period as it undergoes successive stages of development.

Several individual components go into making a majority of the embryo culture media. Till the 8-cell stage, the embryo development is still under maternal control and the developing embryos have pyruvate lactate preference for its energy requirements. After the 8-cell stage, the embryos move toward a glucose-based metabolism once the embryonic genome has been activated which then supports their growth up to the blastocyst stage.

The ART media needs to provide hydration ions, nutrients, and also waste products dilutants.

Water

Water is the basic foundation for culture media. The water used for culture media has to be highly purified and of high quality. From past many years, there has been progression in processing of water to be used for culture media preparation. In 1963, Brinster used deionized water whereas Whitten used distilled water in 1971 from deionized tap. Later, water processed through a Millipore Reverse Osmosis unit was used.[7,8]

Energy Requirements

The levels of glucose, lactate, and pyruvate vary between the oviduct, uterus as well as within the cycle.[9] The

preimplantation embryo is thus subjected to a diverse gradient of carbohydrates during the course of its development. Literature suggests that lactate is required for the embryo development after the 2-cell stage and glucose is required after the 8-cell stage.[10] The media used for early stages of development thus consist of pyruvate. After the 8-cell stage, the glucose intake is increased.[11] However, in a phosphate buffer medium which does not have amino acids, high levels of glucose lead to embryo arrest at the 8-cell stage. The addition of amino acids, Ethylene Diamine Tetraacetic Acid (EDTA) and vitamins to the culture medium minimizes the harmful effects of glucose. This explains the delicate balance of interactions amongst the media constituents. This also emphasizes the disastrous effects of using simple salt solutions as culture media. The key is the inclusion of pyruvate and exclusion of glucose at the early developmental stages. This will prevent developmental block at the 8-cell stage. This will also aid in the production of more trophectoderm cells.[12,13]

Amino Acids

Amino acids are without doubt the most important constituents of culture media. The studies evaluating the composition of fallopian tube fluid shave revealed that they contain high levels of some amino acids such as taurine and glutamine. This led to the belief that these amino acids must be playing a significant role in embryo development.[14-16] As the embryo progresses in development, its requirement of amino acids seems to be changing.

The nonessential amino acids (NEAA) and glutamine are present in high concentration in the oviduct fluid during the cleavage stage. NEAA are used for protein metabolism and pyruvate and lactate are used as energy sources by the cleavage stage embryos. The inner cell mass (ICM) needs essential amino acids for development.[17] A variety of advantages of amino acids are observed in the embryo development.

Chelators—Ethylenediamine Tetraacetic Acid

The beneficial effects of the divalent cation EDTA were first reported by Ambruzak, et al., over 20 years ago.[18] The positive effect of EDTA is limited to the cleavage stage embryos. EDTA is shown to reduce the ICM of human embryos past the cleavage stage and also negatively affect the fetal development.[19-22] A reason for this biphasic effect of EDTA is the inhibitory role that it plays in the glycolysis pathway by inhibiting cytosolic kinases during the cleavage stage of the embryos. However, in contrast to the cleavage stage embryos, the ICM uses glycolysis as its main energy producing pathway and the presence of EDTA has an adverse effect on the ICM growth and the subsequent fetal development.

Macromolecules

The IVF culture media used to be supplemented by human serum, even though in vivo, the embryo is not exposed to serum.[19,23] However, some harmful effects on embryo development have been attributed to the addition of serum. These harmful effects include morphological changes, early blastulation and disturbances in energy metabolism.[24,25] There were many drawbacks associated with the use of serum. Since all batches of serum would vary in composition, there was no standardization of the culture medium.[26] Due to these disadvantages associated with whole serum, the media was supplemented with HSA instead of whole serum.[27,28] Albumin has a lot of benefits on embryo development and is abundantly found in the reproductive tract of the female.[27] Albumin also helps in in vitro handling of the gametes. It avoids the embryos from sticking to the bottom of the culture dishes due to its effect on the surface tension.[29,30] Hyaluronan is another molecule that is found in the tract as well as used increasingly in the culture media.[31] Hyaluronan is said to increase implantation as well as aid in the survival of embryos after cryopreservation.[32-34]

Antibiotics

The presence of numerous components in the embryo culture medium makes it susceptible to bacterial contamination. Use of antibiotics in the culture medium prevents this. Penicillin (B-lactam; 100 U/mL), gentamycin (aminoglycoside; 50 μg/mL), and streptomycin (aminoglycoside; 100 μg/mL) are commonly used antibiotics in culture media.[35,36]

Protein Supplement

In early days, 10% heat inactivated patient serum or fetal cord blood serum was used to supplement the media but it was becoming difficult with increase in number of cycles. To overcome this burden of logistics of collecting and preparing maternal serum the use of pooled donor sera was started but this resulted in an episode of hepatitis B cross contamination.

Twenty-four women conceived following IVF treatment but suffered acute hepatitis B infection, five pregnancies aborted spontaneously, and remaining 19 led to birth of 24 children but the episode confirmed that the use of poorly screened human serum in IVF is unacceptable.[37]

Working without albumin has been attempted but protein or similar macromolecule (polyvinyl alcohol or hyaluronate) is required for IVF for many reasons.[37,38]

- *Sperm capacitation:* Albumin acts as sterol acceptor molecule in media.
- *Handling:* Prevents embryos and sperm from sticking to pipettes, dishes, or tubes.
- Proteins act as peptide and lipid carriers.

Recombinant HSA is used in the medium as a source from 2002. Human serum contains approximately 4.5% albumin

(45 mg/mL). An addition of 10% HSA provides albumin of 4.5% concentration.[39]

MEDIA SYSTEMS

An ideal culture system simulates in vivo microenvironment for human gametes. Defining and designing an ideal culture system is a herculean task because the detailed composition of in vivo environment of the gametes is not clear. Selection of proper culture system is one of the key factors, which can influence the development of embryos in vitro. Other factors influencing are CO_2-O_2 level and number of incubator chamber.

Sequential Culture Media System

Back to nature is the principle for the sequential media systems. In this system, the media constituents vary as per the developmental stage of the embryos, based on the natural environment of the reproductive tract.[40,41] The embryo has the ability to control its ionic gradients and can self-regulate its internal environment. The preimplantation period of the embryo can be categorized into two phases with respect to the embryo physiology: pre-and postcompaction.[41] Classification of the preimplantation period is essential while considering alterations to media formulations. It is also important to consider activation period of the embryonic genome.[41]

There has been a remarkable rise in usage of sequential culture media wherein for initial 3 days one medium is used and for next 2 days another medium is used which supports morula, compaction, and blastocyst development.[42] The glucose and other energy substrate levels are modified in the latter media along with altering concentration of amino acids, chelators, etc.[10,17,19] Embryos at the early stage needs pyruvate and lactate in higher concentrations and glucose at lower levels. This ratio reverses at the blastocyst stage, with higher glucose requirement.[11] Since the composition of oviduct fluid varies from uterine, two different medium are used so as to imitate in vivo conditions of embryo. This also facilitates elimination of harmful by-products, such as ammonia, and to ensure adequate supply of substrates replenishing of media is involved in the method **(Table 1)**.[43]

Monoculture Media System

The principle of monoculture media system is to let the embryo decide its needs during development and differentiation.[44] This culture medium has a mixture of all required components.[10] In this media system, the entire components essential for the embryo development is provided. This system hence does not need the media to be replenished daily. Therefore, during the development of embryo till blastocyst a single formulation is used. The embryo will utilize the required components, whose concentrations are optimum and will adapt to the medium.[10,40,44,45] The response of embryos to different permutation and concentration of constituents can also be analyzed. The best media in monoculture media system is the one with combination of components with defined concentrations providing a maximum response.[10]

Coculture System

The system of adding different cell types to the culture medium is called coculture system.[46] The oviduct is the natural site of early embryo development. Coculture mimics the oviduct environment in vivo which provides developmental support to the embryos.[47]

Embryo coculture endeavors to perk up the cleavage and blastulation rate, reduced fragmentation, with good implantation rates.[48-50] Maternal serum or protein substitutes are often used to supplement the media.[47] Coculture helps in cases of poor quality embryo with low implantation rate and in cases where in spite of obtaining good quality embryos, implantation failure occurs.[51,52] Oviductal cells in coculture have shown to provide a better support because of their varied ability to produce embryotrophic factors.[53,54] In coculture apart from oviductal cells, endometrial cells, granulose cells, and vero cells can also be used.[55] In practice, presently only homologous endometrial cell coculture is used.[56]

Open and Closed System

Overlay of oil protects media droplets and has been an important part of human IVF culture since 1960s. Closed system consists of microdroplets of culture media which is then covered with liquid paraffin oil so as to maintain the

TABLE 1: Media systems: culture, monoculture, and sequential culture systems.

Culture systems	*Monoculture systems*	*Sequential culture systems*	
Days	Day 1–Day 6	Day 1–Day 3	Day 4–Day 6
NEAA	✓	✓	✓
EAA	✓	✓	✓
Glucose	✓	Reduced	Elevated
Pyruvate	✓	✓	✓
Lactate	✓	✓	✓
EDTA	✓	✓	✓

(EAA: essential amino acid; EDTA: ethylene-diamine-tetra-acetic acid; NEAA: nonessential amino acids)

osmolarity, pH, and temperature of the media.[57] The open system consists of culture media in sterile multiwell plates without the oil overlay. The main difference between both types of systems is the volumes of media required. Larger volumes (0.5–2 mL/dish) are needed in the open system and the closed system, involves comparatively smaller volumes of the media (25–100 µL/drop).

There is a risk of rapid fluctuations in temperature and pH with the open systems. The closed system with its microdroplet culture has a better fertilization rate mainly due to the homogenous distribution of sperms in the culture medium.[58]

CULTURE CONDITIONS

Several culture conditions are reviewed here, each of them directly affecting the media performance.

Osmolality

The osmolality of human fallopian tube fluid is >360 mOsmol.[59] The osmolality of the culture media is kept around 300 mOsmol. Osmolality higher than this is harmful for the embryo development.[36] Amino acids added to the culture media become organic osmolytes. They protect the embryos against hypertonicity as well as aid in the growth and development of embryos.[36,60,61]

pH

If pH is permitted to drift outside of an optimized working range of 7.2–7.4, this may place "stress" on gametes or embryos. The pH of the media is affected by its constituents.[62] Cleavage stage embryos are cultured at a slightly lower pH whereas the advanced stage blastocysts are cultured at a slightly higher pH.[63,64] It is advisable to keep the CO_2 concentration between 5 and 6% as this will help to maintain the optimal pH of the bicarbonate buffer media.[65]

While using CO_2/bicarbonate, it is important not to expose the culture dish in the external environment to prevent changes in the pH. When the gametes need manipulation outside the incubator, as while performing intracytoplasmic sperm injection (ICSI), media buffered with 20 mM HEPES or MOPS can be used together with 5 mM bicarbonate.[66] An overlay of oil also prevents increase in pH due to loss of CO_2.

Temperature

Exposure of embryos and oocytes to low temperatures is detrimental to their microtubules thus risking aneuploidy in resulting embryos.[67] High temperatures (39°C) can also disrupt the microtubule organization. Exposure to suboptimal temperatures also affects transmembrane transport and metabolism and slows down the embryo development. It is essential to maintain the temperature at 37°C.[67]

Light

The effect of exposure of visible light on the growth of embryos in vitro has been studied. In human IVF, low light setting is preferred. Exposure of the embryos to light should be kept at a minimum.[68]

MEDIA STORAGE AND EQUILIBRATION

Culture media mimics the natural environment of the female reproductive tract. Most of the components of commercially available media are labile and hence have restricted shelf life. Media is thus prone to deterioration during storage.[69] Storage and handling of culture media is thus very crucial to successful in vitro embryo development.

The most labile components in a culture media known are amino acids and vitamins. Vitamins are light sensitive and are preferably stored in dark bottles so as to minimize exposure to light. Amino acids are comparatively stable in solution at 4°C. However, they break down and release ammonium when kept at 37°C. Ammonium is known to have deleterious effect on the embryo development.[70] Hence, it is of utmost importance not to incubate media for long before use.

During the entire culture period, all media need to be equilibrated for temperature and pH for minimum 4–6 hours prior to use. It is a common practice to incubate the media at 37°C for an overnight period.[69] The composition of the media must be taken into consideration as incubation in certain types of media has been found to initiate a depletion of glutathione (GSH) content of oocyte.

The equilibration time to acquire optimum temperature and pH should be asserted by validation.

The temperature and pH fluctuation causes many problems such as precipitation of $CaCO_3$, which makes media alkaline. Pyruvate present in media tends to become acidic and converts to pyruvic acid which will polymerize and decompose. The glutamine decomposition produces ammonium ions (NH^+) at 37°C it decomposes at 10%/day whereas when stored at 4°C it takes 9 days for the same.

Oil Equilibration

An overlay of equilibrated oil confers specific advantages to enhance culture conditions. Oil forms a physical barrier between the culture medium droplets and the external environment carrying air borne particles or pathogens. It also helps in maintaining the pH, temperature and osmolality of the medium by preventing evaporation of the media.[58,71]

INCUBATORS

The incubators are special chambers used for the growth of the developing embryos. Incubators are designed to maintain a controlled temperature, humidity, osmolality, pH level as well as gas content as per the requirement of

the growing embryos. The embryos spend most of their in vitro time inside the stable atmosphere of the incubator. This makes the incubator undoubtedly one of the most important equipment in any IVF laboratory.

Human embryos are generally cultured at 37°C with a 5–7% Cor concentration. The oxygen concentration is either reduced or not reduced. Many different types of incubators are now available in the market for specific use for IVF. These include water jacket incubators, drawer incubators, benchtop incubators, and the latest time-lapse incubators.[72] The main differences in these incubators are the ways in which temperature, pH, gas content, and humidity are maintained. There are many studies comparing different types of incubators, however, most studies have concluded that the type of incubators does not have any effect on the embryo development or the success rates.[73-75] The atmosphere inside the incubator has to be maintained perfectly and a robust quality control program needs to be in place to ensure optimal incubator performance. The number of incubators in a laboratory needs to be decided based on daily and annual number of cycles. A lot of planning needs to go regarding allotment of dishes to incubators, so that there is minimum opening of incubator doors.

AIR PURIFICATION UNIT

The quality of air in the laboratory is of utmost importance when it comes to embryo culture. Ambient air in an IVF laboratory may consist of various components such as volatile organic compounds (VOCs), perfumes, deodorants, microbes as well as odors coming from the external environment. All these components have a negative effect on the in vitro development of the embryos.[73,76,77] VOCs are shown to have a negative impact on embryos in a way that they attach directly to the deoxyribonucleic acid (DNA) and terminate growth of embryos during embryonic development.[78] Episodes of air pollution in an IVF laboratory has been shown to cause fragmentation of the human sperm DNA.[79,80] Embryo culture and subsequent ART success rates are thus compromised in a poor air quality environment.

It is, thus, of great importance to set up proper air cleaning systems. Removal of these airborne pathogens, however, requires an advanced air handling system/air-handling unit (AHU). The air purification unit must be affordable, effective, quiet and should have the ability to filter VOCs, hydrocarbon pollutants, chemical air contaminants, and other chemically active compounds.[81,82] Creating a stable environment for embryo culture ensures embryo viability which in turn supports favorable pregnancy outcome. Some of the filters used in a number of air handling units are activated carbon filters and high efficiency particulate air (HEPA) filter. Outside air that enters the unit can be filtered using activated carbon filters which have the ability to remove hydrocarbon pollutants. HEPA filters, on the other hand, can filter out particulate pollutants as small as 0.3 μm.

QUALITY CONTROL

Establishing a successful IVF laboratory essentially requires the incorporation of an appropriate quality control system.[83] Quality control procedures in an IVF laboratory mainly involve fine tuning of the existing protocols, so as to achieve optimum embryo development and desirable pregnancy rates.[84] Quality control should not only be limited to the culture media used, but also the gases and all the other supplies used in a regular IVF procedure. Temperature, pH, and osmolality are some of the important physical conditions that require regular monitoring and documentation as part of the quality control protocols.

EPIGENETIC CHANGES

The time period of a few weeks before conception till fertilization, cleavage, and preimplantation embryonic development has greatly increased possibilities of epigenetic changes.[85,86] There are many studies showing evidence of this.

It has also been shown that adult diseases have their origins in the conditions around the early stages of development.[87,88] Animal studies have also supported this association between preimplantation development and diseases in adults.[89] Just as in vivo, in vitro culture can also induce epigenetic changes.[85,90] Millions of babies born through IVF worldwide have shown that there not many adverse effects of IVF, however, we must bear in mind that the first baby born through IVF, Louise Brown is still only 43 in the year 2022. Any possible causes of alarm in later years of adulthood are yet to be explored.

CONCLUSION

There are many parameters that should be kept in mind in order to maintain the optimal conditions for both gamete and embryo development in an IVF laboratory. In vitro, cells and embryos are exposed to different stress situations that must be minimized. Therefore, a routine control at different levels needs to be performed, so that the environment in the laboratory is adapted to resemble the reproductive tract and the intrauterine conditions.

A detailed attention must be paid to not only the selection of culture media but the designing of the entire of culture system. Creation of viable embryos is dependent as much on the environment of the IVF laboratory as on the constituents of the culture media. Finally, we must remember that no culture system in the world can be as good as the mother's womb. We should also pay attention to the emerging evidence of epigenetic changes during the periconception and preimplantation period. It is our duty as

reproductive scientists to take care of the human eggs and embryos to the best of our ability, to create embryos with highest implantation potential that turn into human beings with a healthy life.

MULTIPLE CHOICE QUESTIONS

1. The combination of which amino acid and EDTA gives rise to optimum blastocysts?
   a. Glycine b. Lysine
   c. Glutamine d. Taurine
2. What is the function of EDTA in embryo culture media?
   a. Vitamins
   b. Hyaluronan
   c. Promotes production of reactive oxygen species
   d. Suppresses the production of reactive oxygen species
3. Which one of the following statements is false?
   a. Exposure of embryos and oocytes to low temperatures is detrimental to their microtubules thus risking aneuploidy in resulting embryos.
   b. Amino acids in embryo culture media are comparatively stable in solution at 25°C, but they release ammonium at 37°C.
   c. The blastocysts are cultured at a higher pH than the cleavage stage embryos.
   d. The osmolality of human fallopian tube fluid is more than 360 mOsmol.
4. At what stage of development does the EMP cycle of the embryo gets fully functional?
   a. Blastocyst stage b. 4-cell stage
   c. 8-cell stage d. 16-cell stage
5. Serum has the following reaction on culture of embryos:
   a. Perturbation in ultrastructure
   b. Changes in energy metabolism
   c. Premature blastulation
   d. All of the above
6. Embryo culture media was first developed to grow _____ embryos.
   a. Rabbit b. Mouse
   c. Hamster d. Bovine
7. What is the major source of energy for cleavage stage embryos?
   a. Glucose b. Pyruvate
   c. Lactate d. Sucrose
8. Which antibiotic inhibits peptidoglycan synthesis?
   a. Gentamycin b. Penicillin
   c. Streptomycin d. All of the above
9. What should be osmotic pressure of embryo culture media?
   a. 250–300 mOsmol
   b. 350–400 mOsmol
   c. 200–250 mOsmol
   d. 300–350 mOsmol
10. In coculture system which cells have the ability to produce embryotrophic factors?
    a. Vero cells b. Granulosa cells
    c. Endometrial cells d. Oviductal cells

CHAPTER 124

Micromanipulators

Mir Jaffar, Syed Waseem Andrabi, Veena Gangaraju, Mohammed Ashraf C

INTRODUCTION

The use of micromanipulator for the manipulation of cells by biologists and physiologists dates back more than a century. It was GI Kite who reported first microinjection of sperm into the oocyte of starfish in 1914.[1] A series of experiments was carried on different species demonstrating major species differences. Ryuzo Yanagimachi demonstrated the development of pronuclei from the hamster oocyte nuclei after microinjection into homologous eggs, and a similar result was observed after injecting freeze-dried human spermatozoa into the hamster egg.[2] These experiments indicated that the membrane fusion of the gametes during natural fertilization can be bypassed during the activation of mammalian oocytes without compromising the normal development. The experiments led a foundation stone to a new technique in clinical embryology. Later many experiments were carried out by cell biologists with subsequent improvements in the technology and methods. Earlier experiments were carried out with the primary intention to record the early events in the oocyte after injecting the sperm.

It was the birth of Louise Brown in 1978 that changed the mind of reproductive biologists to implement the microinjection techniques in the medical field for infertile human couples. This was a milestone to overcome the female infertility with the primary cause of their infertility as tubal block. But later the focus shifted toward infertile men. On the other hand, surgical sperm retrieval techniques came into practice, which gave a new ray of hope to the men to father their own child who could not do so earlier either because of the absence, low count or morphologically abnormal sperms in their ejaculate **(Table 1)**.

The first technique implemented in the clinical field was partial zona dissection (PZD) by Jacques Cohen and colleagues. In this micromechanical technique, a breach is created by a sharp glass micropipette and subsequently the oocyte is placed into a suspension of spermatozoa, assuming the uninterrupted entry of sperm through the slit created by the micromanipulation technique to yield fertilization. Very soon subzonal sperm injection (SUZI) was experimented in which several spermatozoa are injected into the perivitelline space to bypass the vestments of zona pellucida. The practice of SUZI was soon followed by the introduction of intracytoplasmic sperm injection (ICSI) in which a single spermatozoon is injected directly into the ooplasm. ICSI[8] opened new vent for very poor male factor infertility. In conjugation with other methods like percutaneous epididymal sperm aspiration (PESA) and testicular sperm aspiration (TESA), ICSI became "the technique" for azoospermia. Assisted hatching (AH) for embryos with thick zona, blastomere biopsy for preimplantation genetic diagnosis (PGD), cytoplasmic transfer to overcome the inherent defect in oocyte, were the other methods to improve the success rate of human assisted conception.

MICROMANIPULATOR

A micromanipulator is a device which is used to physically manipulate the microscopic structures under a high magnification, where a level of precision of movement is necessary which cannot be achieved by the unaided human hand. Micromanipulator in assisted reproduction is meant for microscopic handling of human gametes such as holding,

TABLE 1: Landmarks of micromanipulation in assisted reproductive techniques.

Technique	*Reference*

Preimplantation genetic diagnosis (PGD)[7]	Handyside et al. (1990)
Intracytoplasmic sperm injection (ICSI)[8]	Palermo et al. (1992)

injection, drilling, and aspiration of oocyte, sperm or embryo with very precised movements under microscope.

Features Desirable in a Micromanipulator

- *Single control:* Single control is typically attained by operating the single joystick, which gives the operator the flexibility to travel in X-, Y-, and Z-axis without changing the hand from the control unit.
- *Variable sensitivity of control:* It is extremely useful to be able to vary the sensitivity of control with different magnification objectives. If it cannot be done, it may be found that work under low powers is too slow, as it may take a long time to traverse the field typically during alignment of microtools prior to the procedure and too fast and jerky when working under high power magnification, especially during the actual manipulation of the gametes.
- *Freedom from play/backlash:* It is essential that the microtool holder (receiver unit) should respond to the control unit without any delay, and that there should not be any further movement or creep on sudden removal of the hand from the control unit.
- *Freedom from vibration:* The dampening of vibration to the maximum possible limit is essential during microinjection. It can be achieved by (1) massive construction; (2) clamping the micromanipulator and microscope to a common heavy weight metallic base plate; (3) remote control; and (4) flexible tubing connection between the control unit and drive unit (microtool holding unit).
- *Rapid centration:* This function is highly desirable and convenient for the operator like in Eppendorf the prefixed operating placement of the microtool can be brought back with one click and in IntegraTi [Research instruments (RI)] the "home function" delivers the function after aligning the microtool in the space under the spacer object.
- *Three-dimensional movements:* The instrument should offer three-dimensional movements and the movement should take place in the same direction as the hand, so that there should be no apparent reversal of the movement under the microscope giving the operator better control.

Different types of manipulators have been developed by different manufacturing companies from time to time with subsequent improvements with each model. Although the commercial models are different but the basic principle is same among all: Scale down of movement from "macroscale to microscale" with the highest possible precision and convenience, which avoids the possible damage to the oocyte. This can be achieved by mechanically, hydraulically, and electronically depending on the manufacturing company. But the combination of any of the two gives more convenience to the operator. The commercially available micromanipulators used in assisted reproductive techniques (ARTs) include:

- Research instruments (IntegraTi, UK): Mechanical
- Narishige (Japan): Hydraulic and electronic
- Eppendorf (Germany): Electronic
- S-Corporation (Japan): Hydraulic.

Micromanipulation of gametes was initially performed with mechanical manipulators followed by hydraulic micromanipulator with single axis device and they were in use for a long time, which were later upgraded by three-axis hydraulic and electronic micromanipulators after careful evaluation of different possibilities (Narishige, Japan). The combination of both hydraulic and electrical incorporated in one instrument turned to be more promising.

Micromanipulation Systems

Broadly, a micromanipulator system comprises a "controller unit" containing one or more manual controls, and a "drive unit" (receiver unit) containing the microtool holder, which is observed under high magnification optical lens of microscope. Since the cells to be manipulated can be observed only if magnified several times, which is possible only under the microscope. Unaided human hands cannot manipulate the microscopic cells with the extreme precision so a micromanipulator is needed to attain such a manipulation control to handle such delicate cells like oocytes. Micromanipulators of any choice can be built on any inverted microscope, generally with 4×, 10×, 20×, and 40× objectives. Two types of contrast systems are employed in the microscope: (1) Hoffman modulation contrast optics to visualize the cells on plastic petri dishes and (2) Nomarski optics uses polarized light and can be used to visualize the cells on glass petri dishes (PolScope). Inverted microscopes are available from different companies like Nikon, Olympus, Leica and Zeiss. Apart from inverted microscope and micromanipulator, the micromanipulation system also needs microtools to manipulate the gametes. Two types of microtools are used in ICSI procedure:

1. Holding pipettes to manipulate and stabilize the oocyte with round and fire-polished aperture
   - Outer diameter: 0.080–0.150 mm
   - Inner diameter: 0.018–0.025 mm
2. Injecting pipette with sharp beveled tip to immobilize, aspirate and inject the oocyte with sperm with minimal damage
   - Outer diameter: 0.0068–0.0078 mm
   - Inner diameter: 0.0048–0.0056 mm.

Generally, both the microtools are bent to an angle of approximately 30° at the distal end to facilitate smooth movements on the dish. Different diameters and shapes of the pipettes are used for different procedures like PGD, PZD, AH, etc.

Narishige Micromanipulator

Most commonly used micromanipulator in the field of embryology is by Narishige brand (Narishige Company Limited, Tokyo, Japan) **(Fig. 1)**.

Narishige comes with both hydraulic as well as motorized micromanipulators installed in one instrument itself. Motorized is used for coarse adjustments and the hydraulic for fine adjustments and manipulations, which is most important function of any micromanipulator for successful results. Like any other micromanipulator, this manipulator also exists of two main parts, namely the control unit and the drive unit.

The control unit consists of a heavy weight metal plate on which is mounted the control unit system, which can be locked and unlocked to hold and release the parts from the metallic plate by turning the magnetic control knobs. The parts of the control unit used for manipulation are the hanging joystick, which can work in both X-axis as well as Y-axis travel. The joystick has a distal rotating knob, which controls Z-axis travel. All the knobs are kept at neutral before starting the alignment or when not in use to maintain the precision and life of the instrument. On the whole the hanging joystick controls all the required moments but with very limited freedom and speed, so this set of control system is used for final fine movements like when actually manipulating the gametes. Normally, the right-hand dominant embryologists prefer the injecting pipette control unit on the right-hand side and the holding on the left-hand side for their convenience. This hydraulic unit also has three rotating knobs on the upper side, which controls movements in only two axis (X and Y). This unit is connected to the drive unit mounted on the microscope by three flexible oil contained tubings. The rotation of any knob or any movement of the joystick creates a pressure in the oil containing tubings, which is translated in the form of micromovement in the drive unit.

The second control unit of Narishige is motorized with an upright joystick mounted on either the separate metallic plate or on the same as on hydraulic. It controls movements in X-, Y-, and Z-axis with different speeds as desired. It can be slanted either toward laterally on both sides or forward and backward to translate the same direction movements in the drive unit. It has two press buttons (blue and red) on the top to control Z-axis movements. The speed of the movements can be made fast by pressing a front press button on the same joystick or by turning the speed knob placed just in front of the joystick mounted on the metallic base plate. Normally, this unit is used for coarse adjustments and a backup for the hydraulic unit especially the hanging joystick to regain it in the middle before starting the actual procedure of ICSI or even during the procedure when the joystick loses the freedom.

The second part of the Narishige manipulator is the drive unit mounted on the coarse manipulator and connected with the control unit by three flexible, noncompressible and inelastic tubings filled with light mineral oil. The tool holder can be fixed in the universal joint that is mounted in the drive unit. The movement of the control unit causes the compression in the oil contained in the tubes, which is transferred to the small pistons fixed in the universal joint and causes the movement in the microtool holder to move according to the movement of the control unit. The movement in the drive unit is in proportion to the amplitude and speed executed on the joystick or other control knobs. This direct and proportional transfer of movement from control unit to the drive unit gives a feeling of direct control, which gives confidence to the operator.

The Narishige TAKANOME MTK-1 four-axis hanging joystick oil hydraulic micromanipulator system is a new generation micromanipulator **(Fig. 2)**. With a large retraction range of 50 mm, the MTK-1 fulfills multiple functions

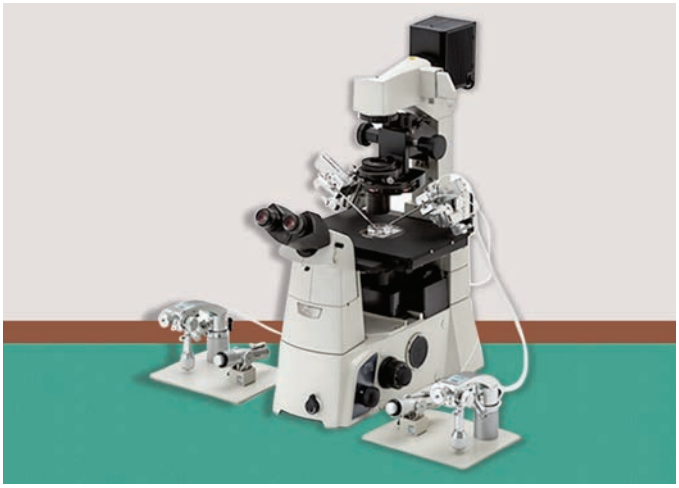

Fig. 1: Narishige micromanipulator unit incorporated to Nikon microscope.

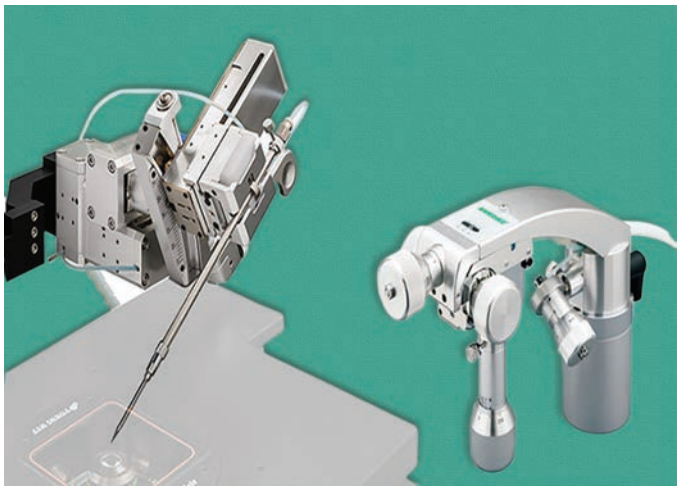

Fig. 2: Four-axis hanging joystick oil hydraulic micromanipulator (MTK-1).

in a single unit, eliminating the need for a separate coarse manipulator **(Fig. 3)**. Additionally, this upgraded version includes an innovative design that allows the user to change the pipette angle while keeping the needle tip in the center of the field of view, making angle adjustment a very easy **(Figs. 4A and B)**. One can easily switch the pipette from its "home" position to its "working" position, resulting in a significant reduction in the probability of pipette breakage and save the time by not having to reposition the injection holder each time you change pipettes **(Figs. 5A and B)**.

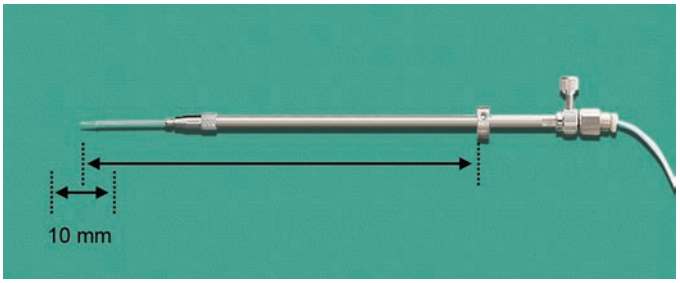

Fig. 3: Easy attachment of a pipette.

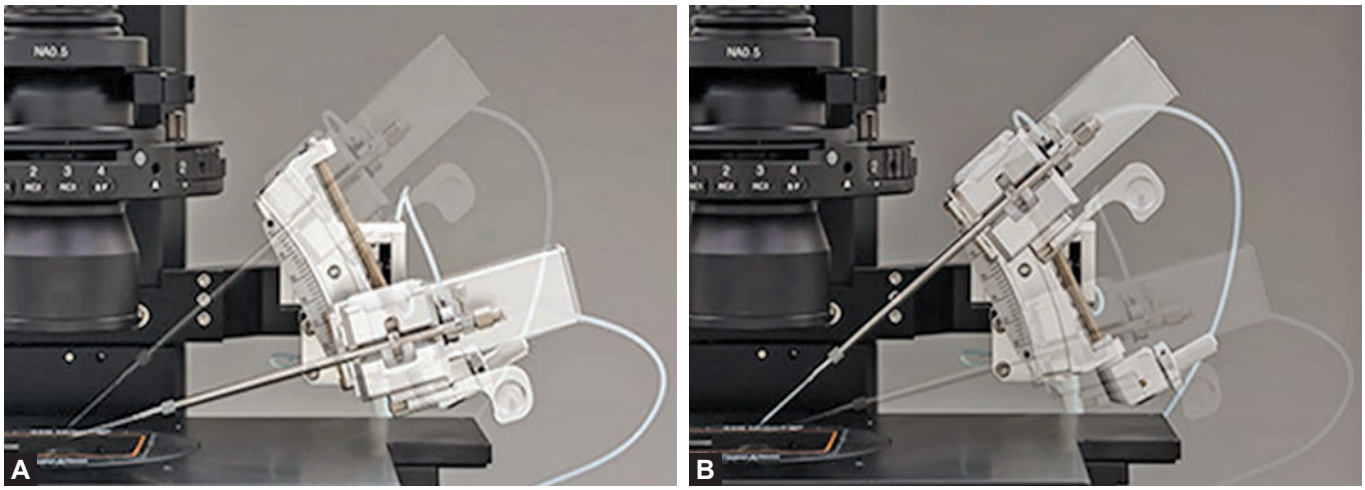
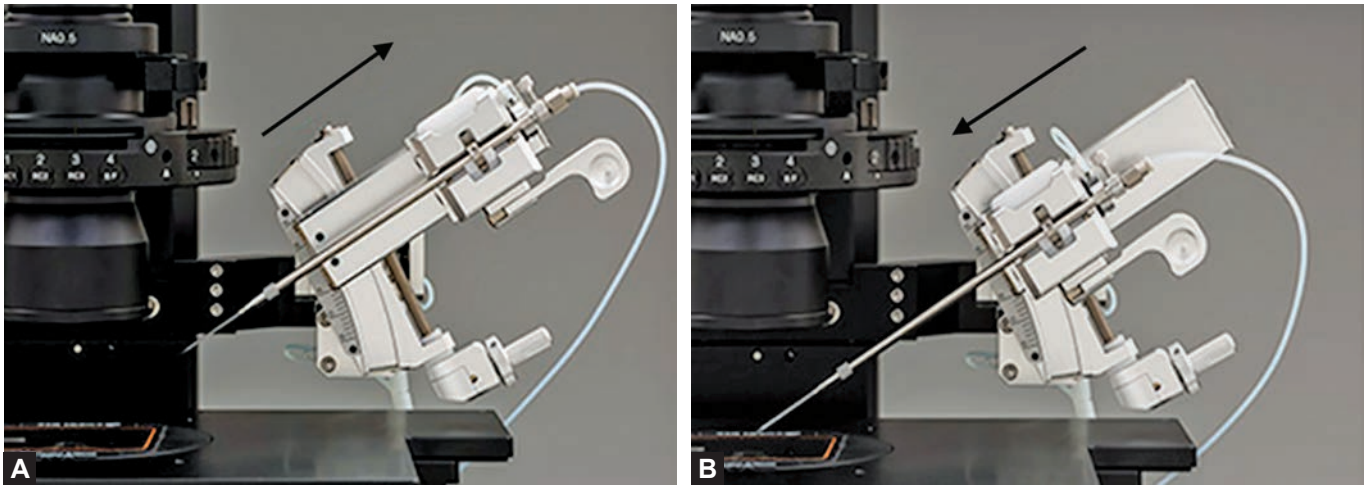
Alignment of Microtools

It is always advisable to check the proper functioning of the micromanipulator well in advance of any ICSI procedure to ensure that the machine is in good working condition. Proper alignment of the microtool before starting the injection procedure is crucial for successful ICSI.

First of all, all the alignments of the drive unit as well as control units are brought to the neutral position. The drive unit has scale marked on the universal joint. All the three scales on the universal joint are brought to zero with the help of motorized joystick, preferably by keeping the speed knob to the highest or front speed button pressed to gain the neutral position very quickly. Make sure while doing this the hydraulic control system is already placed in neutral position to enjoy the maximum freedom of movement during the actual procedure. If the rotating knobs over the joystick are kept to any extremes then movement of joystick will not cause respective movement to the microtools. Check all the tubings for any traction which may hamper the smoothness of the movement. This setting is same on both the sides.



Figs. 4A and B: Pipette angle adjustment centered at the tip to stay in view. (A) 15°; (B) 40°.



Figs. 5A and B: Simple and reliable motion from home to working position.

Once all the scales are set to the neutral position, the oil syringe (IM-11-2, Narishige) is checked for proper oil loading without any air bubbles, neither in the syringe nor in the tubings, connecting the syringe to the respective tool holder. If enough oil is not loaded in the syringe, then one must load prewarmed (37°C) light mineral oil in it. Narishige has two options of oil loading, one is either directly at the tip of the syringe with a BD syringe connected to a three-way valve which can be rotated to open the desired channel marked by an arrow and sign "OFF" on the valve. The other way to load the oil is by dipping the tip of the tool holder inside a round bottom tube containing oil with the "pipette tightening screw" loose.

After loading with oil and getting the oil syringe as well as control unit of the holding pipette to the neutral position (middle), microtools are fitted into the microtool holder preferably with the injecting one on the right-hand side and the holding one on the left-hand side or as desired. Make sure to discard few drops of oil before fitting the micropipette (injecting or holding) into their respective holders to avoid any air bubble formation inside the pipette, which may seriously hamper the sensitivity of the injecting pipette while aspiration of sperm and injection of the oocyte with the spermatozoa. Gently push the pipettes past the sealing rings inside the tool holder. No attempt should be made to take pipette "in and out" rather it should be done with one go to avoid the formation of air bubbles. Set the microscope to 20x or 40x objective, the tip of which serves as the pointer close to the warm stage, so that pipettes can be aligned just over the tip of the objective with direct visualization. Mark an ICSI dish with a marker or scratch with a hypodermic needle and focus under the lowest objective by using both coarse and fine adjustments available on both the sides of the microscope. Next place the microtool holder back in the universal joint and tighten the respective screw after placing the tip of the pipette very close to the tip of the inverted objective visible over the transparent heating plate stage. Rotate the pipette by holding the distal screw on the pipette holder in such a way that the tip is pointed upward. Get both holding as well as injecting pipette tips very close to each other right over the tip of the objective used as a pointer. Now turn the objective to 4× and focus under the microscope first the holding pipette because it is easier to focus compared to the injecting pipette because of its bigger diameter. While focusing the pipette the hydraulic adjustments are kept at neutral position constantly until the actual injecting procedure starts. Pipette alignment is done with motorized adjustments first then later fine adjustments can be assisted with the help of hydraulic control unit. Once both the pipettes are properly aligned the marked empty dish used for the alignment is replaced with the ICSI dish proper loaded with the gametes by gently lifting the whole microscope. Injecting microtool is slowly lowered in polyvinylpyrrolidone (PVP) through mineral oil to allow priming of mictotool with PVP for better control. To check the proper angle of the injecting pipette, an attempt to immobilize a spermatozoa, is done with not more than two attempts, till a proper angle is found which yields easy immobilization of sperms. Once both the pipettes can be visualized and moved without any dragging sensation, that must be considered the proper angle. Immobilization, loading of sperm and injection of oocyte is done under higher magnification (20× or 40×) preferably with the help of hydraulic joystick.

Research Instruments (Integra 3)

Micromanipulator RI (TDU500, Cornwall, UK) has been manufacturing the mechanical micromanipulators since 1964. In the early 1990s, following the successful application of ICSI to the human gametes, RI modified their manipulators with number of user-friendly features and precisely controlled heated plates with two touch screen displays for temperature control (TDU500, IntegraTi). The current version of the Integra is known as Integra 3. A special objective of 4x spacer allowes the micropipette to be adjusted 16 mm above the petri dish to avoid the advertent pipette breakage during the alignment of the pipettes. After focusing in the mid-air (16 mm above the dish), the pipette could be dropped down without any chance of breaking it and this function was referred as a "home function".

Another feature added was tool holder angle adjustment indicators for more accurate alignment for a range of micropipettes with various degrees of bend between the tip and the shank. It allows the user to make very fine adjustments to the angle of the micropipette without the tip ever moving out of focus, ensuring that the micropipette is slightly "toe-down" during sperm immobilization and horizontal during injection. For PGD, RI has developed a unique double tool holder, which offers independent movement of both micropipettes **(Fig. 6)**.

Later they introduced three heated plates over the working stage, middle, left and right, each having independent control. In integra 3 an extra heating blower is given which blows the warm air at the bottom of the dish through the aperture in the middle of the glass heating stage. Apart from this, a fourth extra channel is also given, which can be used to connect an external heating plate or if any of the three channels does not function then the fourth one can be connected as a backup option. All four heating plates can be controlled independently with the settings set on the touch-screen display.

Like Narishige, RI also has a control unit and a drive unit. In control unit, it has two levers, one protruding upright over the stage on both sides and one hanging joystick underneath the stage exactly opposite to the upper one. The

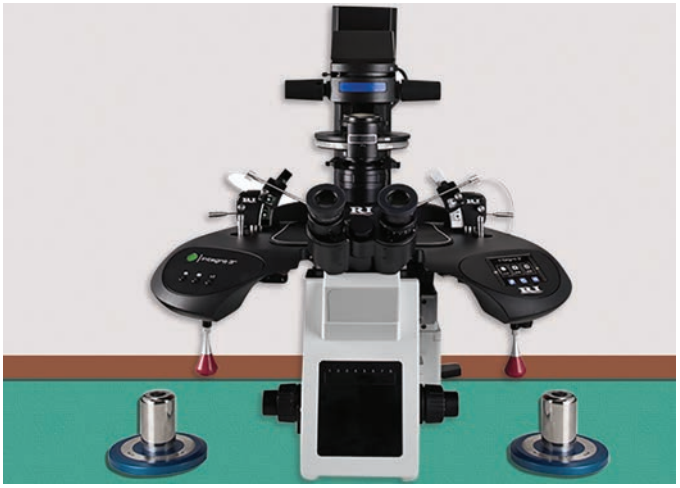


Fig. 6: Integra 3 micromanipulator incorporated to Nikon microscope showing the PL30 tool holder and touch screen display.

upper protruding one is for coarse adjustments, which gives freedom in only X- and Y-axis. While the lower hanging lever (joystick) is for fine movements and gives freedom in X-, Y-, and Z-axis.

The drive unit (tool holder) is very simple with marvelous functions. It has a special lever on the outer side of the tool holders to focus the pipette in the mid-air by lifting it up and once focused can be dropped down exactly over the surface of the petri dish. Also the tool holder has a single screw for angle adjustment to set the pipette to the desired angle or as per the angle of the pipette provided with different angles.

Alignment of Microtools

Alignment of microtools in IntegraTi is very simple with minimal chances of breaking the pipette. Like in any other micromanipulator, oil syringe and its tubings should be checked for proper oil filling without any air bubbles. In this equipment, oil loading can be done only through PL30 microtool holder unlike Narishige where one can directly load the oil in the syringe. Once oil filling is done, make sure both the control levers are kept in the neutral position with the desired angle already preset. Both the levers can be seen in the neutral position except the fine control rotating knob on the hanging lever for Z-axis movement. In order to avoid running out of travel mid-procedure, it is recommended to set its travel of movement at the midpoint, which can be done by turning the knob to either of the extreme till it stops and then mark on the knob to count the total number of turnings. Typically, this knob can turn 24 (±2) rounds, so it is easy to calculate to turn back the knob to the middle (12 turns) to ensure its neutral position. In the latest version (Integra 3), the turning status can be seen on the display given.

Discard few droplets of oil from the syringe in an upright position, without wiping it fit the microtool (pipette) in the tool holder till one senses the hard end feel with one go, unlike Narishige where the operator has to go few millimeters beyond after feeling the pipette passing through the rubber ring. Repeated in and out will create air bubbles in the pipette and affect the sensitivity of the aspiration. The holding micropipette usually come with air controlled so does not need oil filling. Fix the micropipettes to their respective tool holders. Once the micropipettes are fitted, clip them back into their respective holders. Using the 4x objective lens the ICSI dish is focused like in any other microscope. Once the mark or scratch on the inner side of the dish is focused, turn the objective to 4x spacer. With outer levers still raised, the micropipettes are brought closer to each other by turning the knobs placed over the tool holder till the tip of the microtools illuminates.

The micropipettes have to be fitted, aligned and equilibrated before starting the ICSI procedure. Since the holding pipette is much bigger than the injection pipette, it can be used as a guide for positioning and equilibrating. Align the injecting pipette close to the holding pipette by directly visualizing the microtools. After focusing both the microtools, now it is safe to bring down the tool holders to the dish by using the home function. Now ICSI dish can be placed by just lifting and dropping the tool holder with the help of respective lever on the tool holder (home function). Briefly touch the tips of both pipettes in oil, and then in medium (ideally PVP), which gives better control because of its high viscosity, so that the ends fill by capillary action. The alignment in the horizontal plane has to be done with great care. Both the pipettes should be aligned flat on the bottom of the dish.

Microinjectors

Screw-actuated Syringe

The screw-actuated syringe (SAS) is for air-assisted microinjection and aspiration incorporated on a heavy circular base, which provides a good stability to the unit. It provides sensitive control with an extremely low dead-air volume of 10 mL capacity. When required they can generate high aspiration and pressure. Positive and negative pressure is created by turning the metal colored actuator screw control incorporated on top of the syringe. On top of the syringe, a release button is provided to overcome the equilibration problems by pressing the release button once the microinjection needle is taken underneath the medium for rapid equilibration. These are the only air syringes suitable for air injection of the sperm, eliminating the need for oil. The syringe is connected to the PAR21 microtool holder by hard yet flexible polythene tubing. For those who prefer to use an oil microinjector, RI provides the option with micrometer-actuated sealed oil syringe (SOS) mounted upon a heavy metallic base **(Fig. 7)**.

Fig. 7: Examples of air and oil syringes of research instruments (RI) micromanipulator.

Fig. 8: Eppendorf micromanipulator unit incorporated to Nikon microscope showing motor module unit, control board and oil syringes.

Stage Heating

The Integra 3 incorporated with three independently controlled heated surfaces that are accurately calibrated to within 0.05°C of the set point. It also provides one extra heating channel for external device adjacent to the manipulator like stereo dissecting microscope if required. The combination of the warm inserted stage and the warm blower provides the most accurate heated system available to maintain the temperature of additional petri dishes.

Mechanical Stage

The Integra 3 is supplied as standard with dynamic voltage scaling (DVS) variable reduction mechanical stage incorporated with stainless steel stage plate. The DVS offers both X and Y positioning from a single hanging lever just underneath the stage on the right-hand side, enabling quick and precise positioning of the cells. Each turn of the stage control moves the stainless steel stage plate 28 mm in either the X or Y plane, with total 40 mm travel.

Eppendorf Micromanipulator

The company was founded by two German scientists in Hamburg-Eppendorf University Hospital after World War II. To repair the broken instruments, a workshop was conducted under the supervision of both the scientists. The team of doctors and scientists who participated succeeded in repairing many devices and also invented the new ones out of these damaged instruments.

The Eppendorf micromanipulator **(Fig. 8)** is also motorized/electronic one like Narishige but the advantage of the Eppendorf micromanipulator is that movement of the joystick is sensed by the microprocessor and certain preferred positions can be saved in its inbuilt memory, so that they can be recalled at any time as desired. This particular function of Eppendorf makes it outstanding compared to the other commercial micromanipulators.

The Eppendorf micromanipulator is composed of mainly motor module unit and control board.

Motor Module Unit

The motor module unit can be fixed on any microscope but typically it is fixed on both sides of the microscope, especially for micromanipulation of gametes, so that they can be fitted with commercially available microtools close to the operating petri dishes. The whole motor unit can be rotated in and out of the stage to create the space for the replacement of petri dishes or while fixing the microtools without losing the exact original place. It consists of two main parts attached to each other through a straight guide fixed with a screw and a wire. One part of it plays Y- and Z-axis movements (Y/Z module) and the other part plays only X-axis movements (X module).

Control Board

It consists of two control boards placed on either side of the microscope on the table away from the microscope **(Fig. 9)**. Both the control boards are connected to the motor module unit by flexible electrical wires. The control board contains following features:

- An upright joystick protruding in the middle of the board, which contains a button on the top of the joystick. It enables the user to move in all the planes (X, Y, and Z) in a desired speed according to the preset speed settings. The joystick can also be disabled by pressing and holding the top button on the joystick, which gives the operator the freedom of replacing the joystick to the desired position without any movement in the microtools. One of the main advantages of the manipulator is that it can save certain positions and limit certain movements,

Fig. 9: Control board of Eppendorf micromanipulator.

which might break the micropipette. Once a working alignment is attained, it can be saved, so that after every procedure it can be regained back by pressing the home button with just one click. This feature is found only in Eppendorf micromanipulator.

- A multifunctional keypad, which can be used for different functions to feed the microprocessor to save particular alignment and adjust or limit the speed.
- A light-emitting diode (LED) display on the upper side, which displays the axis coordinated and the options chosen.

CONCLUSION

New developments in microscopy and the need of manipulating the cells have brought a renewal of interest in methods of micromanipulation. While human hand can be very deft and may be capable of surprisingly well controlled movements but when it comes to handling microtools or living cells under high magnification, a micromanipulator is an incredible invention, which provides the solution beyond certain unaided human limits. The micromanipulators work in such a limited environment that a minor tremor or muscle contraction could be devastating for manipulating the living cells. However, we must not forget that the first baby born through ICSI procedure was in 1992, which is still immature to conclude its long-term consequences because of lack of data. Since ICSI is also routinely being performed for normozoospermic male couples, when conventional in vitro fertilization (IVF) yields similar outcomes, it should be restricted only for the couples with severe male factor infertility.

CHAPTER 125

Troubleshooting in the In Vitro Fertilization Laboratory: Challenging Case Scenarios

Varsha Samson Roy, Sangita Sharma

INTRODUCTION

The laboratory processes are understood to be well designed, protocols standardized for the respective laboratory, operator involvement well defined, and observation of even the smallest of details mandatory. With so much precision into how, what, when, and where, we do not expect the laboratory to face adverse scenarios frequently. Over the years, a lot of understanding, acceptance, and conformance to quality management has made assisted reproductive technologies (ARTs) more proficient.

The basic principle of quality management is based on the cycle of plan-do-check-act **(Fig. 1)**.

Before performing a procedure, the in vitro fertilization (IVF) laboratory needs to plan how to do it. A well-written standard operating procedure (SOP), written in a manner that is easily understood, easily accessible, and does not assume the operator to "know it", becomes mandatory. Proper documentation is the key to troubleshooting. Inadequate or improper documentation may not provide the required information to identify the probable factors contributing toward the adverse outcomes. Corrective measures can only be implemented once the causative factor is identified. Unfortunately, it may not be a single but multiple factors contributing, namely clinical, procedural, patient factors, operator, and culture conditions.

Hence, troubleshooting requires the involvement of both the clinician and the laboratory personnel.

The basic physiology behind the event should be well understood by the clinicians and embryologists. A deviation from what is normal can only be identified and addressed only with an adequate understanding of the normal.

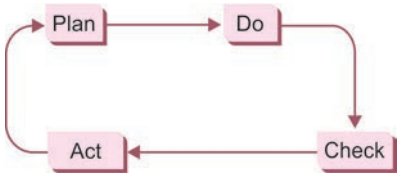

Fig. 1: Plan-do-check-act cycle.

As per the guidelines for good practices in IVF laboratory,[1] quality requirements cover the organization, management, personnel, equipment and materials, facilities/premises, documentation, records, and quality review.

Troubleshooting should target the following aspects on a broader scale as discussed here.

LABORATORY QUALITY MANAGEMENT PROGRAM

Quality management includes quality control (QC), quality assurance (QA), and quality improvement (QI). A total quality management (TQM) for the ART clinic includes not only quality management but also system management and risk management.

A validated, written, authorized, signed instruction for each process (SOP), addressing every small detail, is mandatory. There should not be any scope for assumption. The SOP should be regularly updated and the operators should be informed and trained on the changes before implementing.

Identification and traceability of the patient, their biological materials, and records are extremely crucial Corrective action to keep procedures under conformity and risk assessment analysis for all procedures should be done. A protocol for management of adverse events should also be in place.

Every laboratory should determine its own key performance indicators (KPIs) and the critical level. Data relevant to that should be collected and evaluated at regular intervals. For batch IVF, some part of the data [e.g., fertilization rate, cleavage rate, embryo utilization, blastulation rate, cryosurvival in frozen embryo transfer (FET) cycles] can be evaluated immediately after the ongoing cycle and before the resumption of the next batch.

Internal quality control (IQC) and external quality assurance (EQA) programs are highly recommended.

EQUIPMENT

Quality control of lab equipment involves (1) design qualification (DQ), (2) installation qualification (IQ), and (3) operational qualification (OQ). This also includes periodic equipment calibration, disinfection, service, and maintenance. A log book for maintenance/repair and breakdown of each equipment will help decide on the continuity or replacement of the equipment.

Critical equipment such as incubators, microscopes, manipulators, freezing machines, and computers should be on uninterruptible power supply (UPS) backup. All the essential equipment should be in appropriate numbers to the workload. This is most crucial for incubators to prevent frequent openings, which are detrimental to embryo development.

Consumables should be off-gassed prior to use to reduce the volatile organic compound (VOC) burden.

AIR QUALITY AND CULTURE CONDITIONS

Studies by Cohen[2,3] have shown that air quality impacts embryo quality. Improving the air quality improves the ART success by increasing the pregnancy rates and reducing miscarriage rates.[4]

Manipulation of gametes and embryos in vitro should be performed under controlled environment. Laboratory air should be subjected to high-efficiency particulate air (HEPA) filtration system and should be low on VOC.

The gametes and embryos should be manipulated and cultured under appropriate CO_2 concentration, temperature, and pH for the best outcomes.

Culturing embryos under low O_2 tension has shown to reduce the stress, improve blastulation rate in pregnancy, and implantation rate.[5,6]

Accepted ranges for parameters (e.g., temperatures, CO_2 concentration, pH) should be determined and recorded at regular intervals with calibrated instruments.

DISPOSABLES AND MEDIA

Media and consumables designed for use in human ART and of embryo culture grade should be used. Commercially available media and disposables are tested for quality, using stringent QC assays in compliance of the regulations. It is important to ensure that the cold chain for media is maintained from the manufacturing unit through the shipment to the doorstep of the laboratory. Package integrity and appropriate certificates complying to the QC tests should be available with the distributor and a copy of the same should be retained with the laboratory. The media and oil should be stored and used as per the manufacturer's instructions. Media, once uncapped, should be consumed at the earliest, prior to the expiry date.

Other factors such as culture droplet size, group or individual culture, and oil overlay are also known to influence the embryo development.

OPERATOR SKILLS

Operator skill and culture conditions are crucial to the IVF laboratories' performance. It is important to define the responsibilities and ensure that all personnel are qualified and competent to handle the particular procedure.

Operator performance should be accessed regularly to ensure competence, compliance, and consistency. These can be done by accessing the individual's KPIs and direct observation of procedural skills (DOPS). They should be provided assistance in improving and upgrading their skills.

In a study by Dessolle et al., the first 50 vitrification warming cycles of trainees were analyzed on the basis of embryo wastage and survival. The results suggested that after 35–45 procedures, the individuals achieved proficiency as per the set standard by the investigators.[7] Most of the procedures do have a learning curve and embryologists should handle procedures under supervision till they achieve proficiency in the particular procedure.

PROCEDURAL ASPECTS

Appropriate consents for the procedures to be performed should be obtained after adequate couple counseling and verified by both the clinical and the laboratory staff. A system should be in place to ensure patient identity and sample identification is done at appropriate steps and by appropriate people.

During the follicular scans done at the time of controlled ovarian stimulation (COS), a mention should be made about the ovarian accessibility, presence of endometriomas, hydrosalpinges, or other ovarian cysts.

The records of the patient, including the ultrasound images, should be seen by the clinician before commencing the procedure.

Oocyte retrieval is a very sensitive procedure. There should be standard SOPs for it, which should be followed by all the clinicians in the particular unit. A checklist should include the inquiry about the final oocyte maturation trigger. Consents should be checked not only by the staff nurse, but also by the clinician himself as troubleshooting can take place not only in the IVF laboratory or operation theater but also in a courtroom. The clinician should have undergone a structured training program, with a minimum of 20 (a minority may require up to 50) oocyte retrievals done under supervision to achieve the required proficiency.[8] During the follicular scans done at the time of COS, a mention should be made about the ovarian accessibility, presence of endometriomas, hydrosalpinges, or other ovarian cysts. The records of the patient, including the ultrasound images,

should be seen by the clinician before commencing the procedure. It is needless to emphasize the importance of confirming the patient identity and communicating it to the embryologist. Depth of anesthesia should be adequate to make the patient comfortable and to help in retrieving the maximum number of oocyte–cumulus complexes (OCCs). In case of arrival of a new lot (batch) of oocyte retrieval sets or embryo transfer catheters in the center, their expiry dates, QC assays, and packaging should be checked like any other consumables and media, and the lot number recorded separately. As the OCCs are highly sensitive to any sudden change in temperature and pH, the oocyte retrieval set, test tubes, and 3-(*N*-morpholino) propanesulfonic acid (MOPS)/4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) buffered media should all be prewarmed. The test tube warmers and holders should have a digital display of temperature, and its record should be maintained. An external thermometer should be used to check the accuracy of the temperature displayed. It is of utmost importance to hand over the OCCs to the embryologist as quickly as possible, while minimizing any change in the temperature. The efficacy of the procedure in terms of the number and quality of OCCs retrieved depends on the integrity of the circuit, negative suction pressure, laminar or turbulent flow of the follicular fluid, velocity of the flow, sharpness and thickness (gauge) of the aspiration needle, length of the tubing, experience of the clinician, depth of anesthesia,, and accessibility of the ovaries.

Simultaneous communication between the clinician and the embryologist is crucial to ensure proper retrieval of OCCs in the follicular fluid reaching the laboratory. After the procedure, the oocyte recovery rate should be documented in relation to the larger (>17 mm) follicles mentioned in the follicular scan reports. Any gross discrepancy should be mentioned and audited.

Every IVF laboratory should have an emergency backup plan. There should be uninterrupted power supply to the ultrasound machine and the suction apparatus for uninterrupted functioning during the procedure. An extra suction pump is ideal, but it might be a costlier issue. At least, facilities for manual aspiration of the follicles should be there, although the negative pressure generated this way is uncontrolled and sometimes might be detrimental to the OCCs.

PATIENT FACTORS

Complete evaluation of a couple before starting an ART cycle is very important. There should be a complete history taking and proper examination. All the previous records should be studied and relevant history/findings should be documented in a systematic manner. Every center should have a complete pro forma designed to document relevant history, examination, investigations, imaging reports, findings of endoscopic procedures if done earlier and any related treatment taken in past. Having such information helps in maintaining uniformity in the presence of more than one clinician in the unit. Moreover, the record-keeping becomes easier for any future reference. Such data can also be stored electronically for simpler handling.

Documentation of Previous In Vitro Fertilization Cycles

A detailed history of any treatment taken in the past for infertility is important, including IVF or intrauterine insemination (IUI) cycles. Effort should be made to gather information about the protocols used, types and doses of gonadotropins given, evidence of ovulation (IUI cycle), number of oocytes retrieved (IVF cycle), and endometrial thickness during insemination/embryo transfer. Any adverse events such as failure to retrieve oocytes or premature/postmature oocytes, poor or failed fertilization, low and poor quality of the embryos complications such as ovarian hyperstimulation syndrome (OHSS) should be documented. Other relevant information, such as stage of embryos transferred and cryopreservation details, should also be sought.

Apart from the ovarian response, it is equally important to check for the endometrial thickness and pattern achieved in past. Finally, the outcome of the previous cycles, namely, successful/unsuccessful cycle, biochemical pregnancy, blighted ovum, missed abortion, or an uneventful pregnancy, completes the list.

Each and every aspect is important and can give us a clue to avoid troubleshooting situations by taking prior precautions, making changes in the protocols or drugs used, getting any further investigations, or endoscopic procedures done if required, before the commencement of the next cycle.

This detailed evaluation and record-keeping also help us in prognostication of the further cycles.

Documentation of the Current In Vitro Fertilization Cycle

All investigations done, including the hormonal assays and transvaginal scans, should be documented in charts or pro formas made for this purpose. The protocol decided, type and dose of gonadotropins given and the ovarian response to it in terms of number of larger follicles and serum estradiol levels if done, should be mentioned, along with all the details of the oocytes retrieved and embryos formed, as mentioned earlier also (vide supra). Any coincidental finding during the COS such as an endometrial polyp or a hydrosalpinx should be noted separately. Any correction in a problematic situation in future cannot be done without a retrospection of the cycle details.

Certain patient factors are known to be associated with lower pregnancy rates and poorer outcomes of an ART cycle. The most important ones being:[9]

- Higher age of the patient
- Poor ovarian reserve
- Unexplained long-standing infertility
- Recurrent implantation failures in past
- Persistent suboptimal endometrium[10]
- Severe oligoasthenoteratozoospermia (OAT)[11]
- Obesity
- Smoking, alcohol, and caffeine consumption.

CLINICAL ASPECTS

Apart from the laboratory aspects and culture conditions, clinical aspects can be equally responsible for a problematic situation during an IVF cycle.[12]

Gonadotropins and gonadotropin-releasing hormone (GnRH) analogs have become an essential part of an IVF/ART program. Production and purification of gonadotropins have to undergo stringent QC assessment, thus ensuring a pure product of high quality. As these preparations are highly temperature sensitive, it is of utmost importance to ensure the maintenance of cold chain from the manufacturer to the IVF center via the distributors. It is equally important to sensitize the patients about the importance of cold chain while they carry the gonadotropin preparations from the center and keep it with them before finally injecting. A person should be made responsible for receiving, proper storage, and record-keeping of the gonadotropins and GnRH analogs. Every new batch which is received at the center should be documented, the batch number should be mentioned, expiry dates checked, and cold chain ensured.

There should be a dedicated staff nurse or a counselor who would make the patients understand the doses of the injectable, their reconstitution, administration, adjusting, and administering the doses with pens. Any misunderstanding of the doses or wrong administration can have significant effects on the final outcome.

Monitoring of the ovarian response by a transvaginal scan is very crucial and preferably should be done by the same person. Over or underestimation of the number and size of follicles before the final oocyte maturation trigger can lead to retrieval of premature or postmature oocytes.

The final oocyte maturation trigger [human chorionic gonadotropin (hCG) or GnRH agonist] is the most crucial in terms of adhering to the exact timing and proper administration. It is one of the single most important factors responsible for the oocyte yield with regard to quantity and maturity. The patient should be given clear written instructions about the dose, timing, date, and route of administration. On the day of oocyte retrieval, the checklist should include asking about the date and timing of the injection taken. Some centers routinely perform a urinary hCG testing with a urine pregnancy kit before oocyte collection, while others get serum β-hCG levels done on the next morning of the trigger, and still others rely on their embryologist mentioning about the presence or absence of the OCCs in the given initial tubes with follicular fluid after aspiration.

CHALLENGING SCENARIOS

Oocyte Retrieval

Prior to starting aspiration, the complete circuit of the aspiration pump connected to the tubing of the aspiration needle should be checked. This is done to ensure the integrity of the circuit and adequate buildup of the required pressure, which is around 90–120 mm Hg for conventional IVF cases. Oocyte retrieval is usually done using a 17-gauge single-lumen needle. Thinner needles with smaller diameters (20 gauge) significantly prolong the operating time but are associated with lesser postoperative pain without affecting the oocyte yield.[13] As the thinner needles are less stiff, they can bend and may cause technical difficulties, especially in deep-seated ovaries.[14] Flushing of the follicles with a double-lumen needle has been found to be associated with longer procedural time and need of more anesthetic agent without any significant difference in the oocytes retrieved, fertilization, or pregnancy rates when compared with direct aspiration with a single-lumen needle.[15]

Aspiration of culture media into the tubing should be done to rinse the tubing and needle prior to penetrating the follicles. This also helps in removing the dead space of the needle and the tubing and allows a uniform laminar flow as turbulent flow can damage the OCC.[14]

Failure to Aspirate a Follicle/Failure to Build up Adequate Negative Pressure

In case of failure to generate negative suction pressure, ensure the functioning of the suction pump, power supply to it, check the digital pressures displayed, confirm the needle is inside the follicle, any break/interruption in the circuit should be looked for, e.g., cracked tubes, loose caps of the tubes or kinks and bends in the tubing. Slight rotation of the needle might be helpful if the bevel of the needle tip is blocked by the adjacent follicular wall. Once all this has been ruled out, a blocked needle can be a possibility due to a blood clot or tissue blocking the tip or the lumen. The emergency button, present in some aspiration pumps, can be pressed, which generates sudden high negative pressures to dislodge any clot, or the needle can be withdrawn and flushed with media.

No Oocytes Obtained/Less than Anticipated Number Obtained

At times if the patient has been triggered earlier when the follicles are still smaller, the OCCs are immature with very

few layers of granulosa cells. This makes identification difficult, especially if the embryologist is not consciously "looking" for the OCCs. This is also the scenario in in vitro maturation (IVM) cycles wherein cell strainers or filters have to be used for faster OCC identification.[16]

Sometimes, in spite of normal ovarian response on ultrasound and normal follicular steroidogenesis, there is a complete failure to retrieve any OCC. This so-called "empty follicle syndrome (EFS)" can be false EFS or genuine EFS.[17] The reported incidence varies from 0.45 to 7% of the IVF cycles in different studies[18] and most of the cases are sporadic.[19] The false EFS is due to a fault in the administration of the final oocyte maturation trigger in terms of dose, time, date, or administration of the injection.[20] Good communication between embryologist and the clinician during oocyte retrieval is crucial. In case of failure to find any OCC in the initial few tubes with follicular fluid, the serum hCG levels or urinary hCG should be checked, although there is no consensus on the threshold of circulating hCG levels to define an adequate trigger. HCG values ranging from 5 to 160 IU/L after about 36 hours from the hCG administration have been reported as the concentration threshold by different groups.[21,22] Some authors have even reported checking hCG in the follicular fluid.[23] However, a positive test cannot exclude incomplete administration of the injection or any wrong timing of it. In case of a negative hCG test, the oocyte maturation trigger should be given and oocyte retrieval planned after 36 hours of it. There can be reduced in vivo biological activity of some batches of commercially available hCG, especially in cases of urinary products.[18] Thus, it is important to document any change in the batch entering the center. Other causes of false EFS can be incomplete aspiration of the follicles or defects in the aspiration circuit such as too low suction pressures, which might be missed during the procedure.

Nowadays, with increasing use of antagonist protocol for COS and GnRH agonist trigger to minimize the incidence of OHSS, testing for hCG holds no relevance in such cycles. In such cases with GnRH agonist trigger, serum luteinizing hormone (LH) and progesterone level testing have been proposed, but the exact thresholds are yet to be established. Some investigators have indicated an LH circulating level of 15 IU/L as the cutoff value.[24]

The true or the genuine EFS is failure to retrieve oocytes in spite of a correctly and timely administered trigger (hCG or GnRH agonist). This is associated with older age, prolonged infertility, poor ovarian reserve, and poor responsiveness to gonadotropins during ovarian stimulation (indicating dysfunctional folliculogenesis).[25]

The pathophysiology of genuine EFS is still poorly understood, but probably there is a role of specific genetic factors. These patients are predisposed to abnormal folliculogenesis and precocious atresia of the OCCs as seen by the increased expression of some proapoptotic genes and a significant reduction in transcripts whose products are responsible for normal follicular growth.[26] Cases have been reported where after a second bolus of hCG, adequate number of OCCs were retrieved after 24 hours (i.e., much later to the initial hCG trigger), indicating partial and slow response of the follicle to hCG, thus requiring an extended time for complete follicular maturation.[27,28] Meniru and Craft[27] suggested that there could be a delayed detachment of OCC from the follicular wall following hCG injection.

The molecular mechanism(s) underlying the slow or insufficient follicular response to LH/hCG receptor stimulus is not yet understood but could involve the receptor sensitivity itself or the efficiency of postreceptor signal transducing pathways.[29] Still, there are different kinds of patients who do not respond even to a second bolus of hCG, in whom mutations have been identified in the gene encoding for the LH/hCG receptor.[30]

Recurrence of EFS increases with age, 24% recurrence rate in 35–39 years age group and 57% for those over 40 years have been reported.[31]

Thus, the different strategies to prevent EFS in the subsequent IVF cycles are: Changing the batch of hCG[32,33] using recombinant hCG,[34] changing the protocol to antagonist with a GnRH agonist trigger,[35] administering a dual trigger with hCG and GnRH agonist[23] increasing the interval between the trigger and oocyte retrieval.[28]

Only Immature Oocytes Obtained

Retrieval of only immature oocytes can happen if the aspiration is done too early after the oocyte maturation trigger (<34 hours). This can be due to the wrong timing of the trigger, which is not reported to the center by the patient on the day of oocyte retrieval. Therefore, it is important to make the patient understand the importance of the correct timing of the trigger. Overestimation of the size of the follicles on ultrasound before the trigger can also be a reason. The pathophysiology of such a condition (all immature oocytes retrieved) is at times same as that of an EFS, both being different presentations of the same etiology. This is further explained by a few cases which were initially thought to be genuine EFS, but on more careful examination of the follicular fluid with strainers, few immature OCCs were found.[36] Prognosis in subsequent cycles depends on the underlying cause. If the trigger was correctly administered on the right time, then it could be due to genetic predisposition to partial and slow response to hCG. The immature oocytes should be followed and any signs of IVM should be considered as a good prognostic factor. Delayed aspiration (>36 hours) after the oocyte maturation trigger should be planned in the subsequent cycle.

Follicular Aspirates are too Bloody

Aspirating smaller diameter follicles as in cases of IVM usually end up with bloody aspirates. In these cases, the follicular walls are thick and penetrating them requires force and at times multiple punctures. Aspiration needles which are being reused cause difficulty in penetrating the ovarian tissue due to blunting of the tip on repeated washing. Hence, aspiration needles should not be reused. The embryologist should make the utmost attempts to get rid of any blood clot in the OCCs as they are known to be toxic to the gamete and can retard embryo development. If the blood clot with OCCs is used for IVF insemination, they can also increase the reactive oxygen species (ROS) production. Hence, cutting the part of the granulose cells that are embedded in the blood clot with an insulin needle should be attempted prior to inseminating or even culturing these OCCs further till denuding or inseminating.

Poor Oocyte Quality

Sometimes poor oocyte quality is seen, the reasons of which can be intrinsic or extrinsic. It can be found in women with higher age, poor ovarian reserve, long-standing unexplained infertility, polycystic ovarian syndrome, and endometriosis. Environmental changes and psychological stress are also reasons for poor quality oocytes due to the high ROS generated in ovaries.[37] A particular batch of urinary human menopausal gonadotropin (hMG) or hCG might have higher protein impurities or lower bioavailability, thus resulting in poor quality oocytes. Repeated problem in a few patients, especially during a batch IVF, should alert us toward a drug-related issue. Poor oocyte quality may indicate chromosomally abnormal oocytes, which may be associated with low fertilization rates, poor embryo grades, lower implantation and pregnancy rates, and higher miscarriage rates.[38]

Semen Quality

Unable to Produce Semen on Day of Oocyte Pickup

Unexpected ejaculation failures for the first time can occur on the day of retrieval due to stress and anxiety or "uninviting surroundings".[39] Ideally, all the patients going through the procedure of oocyte retrieval should have adequate frozen semen sample as backup. The number of samples to be frozen per individual depends on the semen quality and the number of oocytes expected. The first line of management should always be reassurance, irrespective of availability or nonavailability of a frozen backup. Counsel the patient and ask him to try another attempt after 30–60 minutes of break. In the meanwhile, the frozen sample (if available) can be thawed and kept ready. Prescription of sildenafil citrate 50 mg followed by an attempt to ejaculate 30–40 minutes later. Other methods of getting sperms in case of anejaculation are penile vibratory stimulation (PVS), prostate massage, and electroejaculation. Electroejaculation is usually reserved for spinal cord injury cases where even PVS fails as it requires general anesthesia, special equipment, and expertise. Surgical sperm retrieval can be the last resort.

In case of failure of all these methods, the patient should be offered oocyte vitrification. The results of vitrified oocytes are best when they are vitrified within 1–2 hours of retrieval; hence, timely decisions will optimize the outcomes even in challenging scenarios.

Semen Sample with Pus Cells/Debris/Infected

Chances of bacterial contaminations seem to be more in males who require female partner assistance for collection. In cases of contamination reported during the routine semen analysis, an andrologist's opinion and adequate antibiotic treatment to the sensitive organism should be considered. Pus cells are most common in patients with chronic prostatitis/urethritis. On the day of oocyte retrieval, semen samples with presence of debris/pus/contamination are best treated with gradient method of semen processing. Density gradient followed by wash and swim-up significantly reduced the risk of transmission in human immunodeficiency virus (HIV)-discordant couples regardless of viral suppression in the male partner.[40]

Fertilization Issues

Fertilization rates in the range of 70–80% are achieved by both conventional IVF insemination and/or intracytoplasmic sperm injection (ICSI). To combat fertilization failure, many laboratories subject the oocytes to ICSI without good evidence in its favor. Approximately 30% of the oocytes fail to fertilize with ICSI[41] and total fertilization failure (TFF) occurs in 2–3% of the cases.[42]

Poor or TFF can be anticipated in severe male factor infertility (severe OAT, immotile sperms, globozoospermia, nonviable sperms), poor oocyte quality, and low oocyte numbers (≤3 oocytes).

Some metaphase II (MII) oocytes although may appear meiotically mature in displaying extrusion of the first polar body, they may not have achieved the complete degree of cytoplasmic maturity. These oocytes may actually be lacking essential maternal factors required for subsequent fertilization, pro-nucleus (PN) formation, and embryo development. Thus, visualization of the oocytes does not give us the complete picture of oocyte maturity.

In aberrant phospholipase C zeta (PLCζ) expression, abnormal chromatin, centrosome dysfunction, and lack of sperm aster formation affect the ability of the sperm to contribute successfully toward normal fertilization.

To understand fertilization failure, the sperm–oocyte interactions are crucial especially in IVF. To understand the causes of fertilization failure in IVF and ICSI, the

process of fertilization can be divided into pre-sperm interaction (cumulus cell interaction, sperm–oocyte binding and penetration, and sperm oocyte fusion) and post-sperm penetration events (oocyte activation, sperm decondensation, and PN formation). The pre-sperm penetration events are bypassed by ICSI.

In poor or TFF with IVF, the factors contributing could be semen parameters (count, motility, and morphology), contaminated sample, sperm processing method, and final insemination count. Thick zona pellucida and immature oocyte can contribute toward these adverse outcomes. Finally, the inseminating technique—too low sperm count and more oocytes, suboptimal culture conditions, frequent openings of the incubator doors, and contamination of the culture media or oil.

Intracytoplasmic sperm injection requires single sperm, which is injected directly into the ooplasm. Hence, the pre-sperm penetration events, the sperm count, and zona abnormalities are least contributory to the failure. However, procedural aspects such as too gentle injection, which prevent oocyte activation, poor sperm selection, too harsh technique of injection leading to oocyte degeneration especially in a compromised oocyte, and expulsion of the injected sperm can adversely affect the fertilization. There is a learning curve associated with micromanipulation, which will vary in individuals and a beginner should be supervised and evaluated for the same before assigning him independent case handling. Prolonged exposure of the oocyte, temperature of the heated plate during denuding and microinjection, and the culture conditions, which also include the laboratory air quality, can affect the outcome.

Artificial oocyte activation can be beneficial in patients with history of TFF or low fertilization (<30%) in the previous cycle.[43] Different methods have been proposed and used to increase calcium oscillations and thereby increasing intracellular calcium ion concentration, which sets in a cascade of events, leading to better fertilization rates:

- Treatment with calcium ionophores, e.g., ionomycin or calcimycin A23187[44]
- Treatment with strontium chloride[45]
- Mechanical methods such as vigorous aspiration of cytoplasm and a different position of the pipette tip when ejecting sperm in the oocyte[46]
- Injection of human recombinant PLCζ into oocytes[47]
- Electric and piezoelectric stimulation of oocytes.[48]

A recent systematic review and meta-analysis indicated that using calcium ionophore to activate oocytes was beneficial for couples with poor fertilization rates following ICSI.[49] Although, the limitation of this systematic review is that there were only 5 randomized controlled trials (RCTs) and the rest 17 studies were observational studies.

Abnormal fertilization (multiple PN) in IVF could be due to high insemination count. The inability of the oocyte to release the second polar body can also cause abnormal fertilization both in IVF and ICSI. The oocyte deficiencies are more common in women of advanced maternal age, poor oocyte quality, postmature oocytes, and giant oocytes.

Embryo Quality

Poor Embryo Quality/Increased Fragmentation

Embryo quality is a strong determining factor for the success rates of IVF programs. Fragmentations of variable degrees are observed in about 75% of human embryos produced in vitro[50] and have also been observed in in vivo embryos,[2] though in vitro culture conditions affect embryo quality. In vitro culture conditions that can affect embryo quality are inadequate media and oil equilibration and media pH, frequent incubator openings, and poor laboratory air quality with increased VOC. Similarly, the gas in the incubator should be filtered by attaching an inline filter. Oocytes fertilized by IVF insemination may be exposed to high ROS due to the exposure to dead sperm and cumulus cells, especially if long duration of insemination is followed. Hence, these zygotes should be transferred to a fresh culture dish. Oil overlay prevents rapid and drastic change in pH and temperature and hence preferred over open cultures, especially if using microdroplet culture. To prevent change in media pH and temperature, overexposure of the embryos should be prevented. During dish preparation, embryo monitoring and transferring, the embryologist needs to be conscious of the time factor. Maternal oocyte cytoplasmic factors also play a critical role in early embryo development. These maternal factors include cell-death regulatory elements, stress-response proteins, and mitochondrial content. It may originate from multiple cellular defects altering the cytoskeletal organization.[51] In the group of patients who exhibit embryo fragmentation in repeated IVF attempts, it has been postulated that deficiencies in some maternal factors, such as stress-response factors, might have a role.[52] Embryo fragmentation is also known to be increased in chromosomally abnormal embryos.[53]

Thus, in order to overcome the stress imposed by sub optimal culture conditions, embryos have to be able to synthesize essential compounds not provided by the medium and adapt to conditions imposed by the artificial environment.[54]

Fragmentation rate has been associated with chromosomal abnormalities. Chromosome abnormalities increase from 50–60% in nonfragmented embryos to 70–90% in embryos with >35% fragmentation.[55,56]

Embryo viability is severely compromised when fragmentation exceeds 50%.[57] The early miscarriage rate is also significantly increased when fragmentation is >20% of the volume in 4-cell embryos.[58]

The live birth rate (LBR) increases when high-quality embryos are obtained.[57] Extended cultures until blastocyst stage poses its own limitations due to high risk of developmental arrest partly due to inherent poor embryo status but also the suboptimal culture conditions.

Slow Cleavage Rate and Embryo Arrest

Delayed embryo development and/or embryo arrest could be related to the poor sperm or oocyte quality. It is known that the impact of the male gamete on the embryo development is evident after day 3 and results in poor blastulation. Though not all but aneuploidy embryos also exhibit poor blastocyst formation rate and undergo embryo arrest during extended culture. Suboptimal culture conditions and contamination of the cultures can be detrimental to early embryo development.

Troubleshooting in Cryopreservation

The most common issues related to embryo cryopreservation are poor embryo survival post warming and poor pregnancy rates in FET cycles.

Prefreezing embryo selection plays an extremely important role in the outcome of the freezing program. This is irrespective of the method used for freezing. Freezing poor quality embryos or oocytes does not improve or alter its potential to implant.

Today most of the clinics use the vitrification method. In this procedure, the crucial factors determining success are rapid cooling rates (15,000–30,000°C/min). To achieve this, higher concentrations of cryoprotectants are used. Thus, timing of exposure to these cryoprotectants, equilibration of the freeze and warming media, and temperature at which they are used become crucial. The manufacturer's instructions have to be followed for optimum results. Selection of the correct device for vitrification is important since it also determines the loading volume. Vitrification is also called "the minimal volume" method. The loading volume is crucial to obtain high rates of cooling. Thus, lesser the volume loaded higher the cooling rate and better the embryo survival. The loading volume should be <1 µL. This procedure too has a learning curve, and the skill and timing of the operator affects the outcome. For oocyte vitrification, the denuded oocytes should be frozen within 1–2 hours of retrieval and they should be injected 1 hour post warming for fertilization.

The factors affecting vitrification are:

- Type and concentration of cryoprotectant agent
- Temperature of vitrification solution at exposure
- Length and time of exposure to the final cryoprotective additive (CPA) before plunging into liquid nitrogen (LN_2)
- Loading volume on the device
- Device used
- Technical proficiency of the embryologists
- Quality of the cells to be vitrified
- Device used for vitrification
- Risk of recrystallization during warming.

The American Society for Reproductive Medicine (ASRM) has published the practical recommendations to optimize patient outcomes with oocyte and embryo vitrification. KPIs of rapid-cooling vitrification success are also defined for the TQM program of vitrification.[59]

Outcome

Poor Pregnancy Rate in Spite of Good Embryos Transferred

Repeated implantation failure (RIF) can be due to multiple reasons. Apart from the embryonic factors, which have been discussed separately, other factors contributing could be anatomic, endometrial, thrombophilia, immunological factors, and male factor. There can be other reasons such as presence of hydrosalpinges, the correction of which (salpingectomy) would significantly improve the implantation rates.[33,60] Each factor has to be looked into carefully before any further IVF cycle. A hysteroscopy is highly recommended in RIF. Intrauterine lesions such as small endometrial polyps or flimsy adhesions, which can be missed on an ultrasound, can be directly visualized and corrected during hysteroscopy.[61] Moreover, even if no abnormality is detected during hysteroscopy, pregnancy rates are still found to improve after the procedure in the subsequent IVF cycles.[62] An element of fibrosis or decreased endometrial vascularity due to previous curettages and/or infections can also be responsible for suboptimal endometrium leading to RIF. In such cases, different therapies have been reported with conflicting results, e.g., aspirin, vitamin E, pentoxifylline, sildenafil, granulocyte colony-stimulating factor (G-CSF), endometrial scratch, high-dose estrogen, and recently stem cell therapy in form of platelet-rich plasma.[63-66]

Contribution of the sperm is also to be kept in mind. For RIF, deoxyribonucleic acid (DNA) fragmentation index (DFI) of the semen should be checked. This can be high even with normal semen parameters. In case of high DFI, intracytoplasmic morphologically selected sperm injection (IMSI) or surgical sperm retrieval can be considered.[67-69]

There is no definitive proven management for thrombophilia or immunological factors which might improve the implantation rates, but many are being used, namely, low molecular weight heparin (LMWH), aspirin, intravenous immunoglobulin (IVIg), etc.

Naturally displaced window of implantation (WOI) has been found to have a role in RIF in some patients, for which endometrial receptivity array (ERA) is recommended and a personalized embryo transfer can improve the reproductive

outcome in the subsequent cycles.[70] Further evidence is however required before its role in improving implantation rates can be established beyond doubt.[71] Blastocyst culture[72,73] and laser-assisted hatching[33] have shown improvement in pregnancy rates in RIF. Preimplantation genetic testing of embryos for aneuploidies (PGT-A) by array comparative genomic hybridization (array CGH) earlier and now by next-generation sequencing (NGS) at blastocyst stage has also shown improvement in clinical pregnancy rates in couples with RIF.[74,75] Although PGT-A increases the LBR per embryo transfer, it decreases the time taken to get pregnant, but it comes with a cost of many embryo transfers being cancelled in the absence of a euploid blastocyst. Dealing with the blastocysts having mosaicism is another challenge, and yet another disadvantage is the higher cost of the cycle with PGT-A.[76] These findings need to be further validated by well-designed RCT.

Apart from the viability of the embryo and the endometrial receptivity, the pregnancy and implantation rates are also influenced by a third variable, the embryo transfer procedure technique. The clinician should be well-trained in the procedure; there should be clear SOPs. Patients with particular anatomic defects such as presence of a false passage, acute anteversion/retroversion of the uterus, and cervical stenosis, have to be dealt with very carefully with good skill and expertise in order to improve the pregnancy rates. A systematic review of literature was done and guidelines were published regarding how to perform embryo transfer, based on whether the interventions demonstrated a benefit or not in improving the pregnancy rates.[77]

High Biochemical Pregnancy Rate

Biochemical/chemical pregnancy is defined as one where in spite of a "positive" β-hCG test, the pregnancy fails to progress to the point of ultrasound confirmation.[78]

Biochemical pregnancies are considered to be very common in natural spontaneous conceptions, being as high as about 40–50%. But nearly half of these biochemical pregnancies are usually not detected as in most of the instances, the woman does not even miss her periods.[79]

In patients undergoing an ART cycle, due to time-bound testing of the β-hCG levels in serum and the availability of ultrasensitive pregnancy tests, many biochemical pregnancies are discovered, which would have otherwise gone undetected. Recently, a comparison of biochemical pregnancy rates was reported between women who underwent IVF and fertile controls who conceived spontaneously.[80] Both fresh and frozen transfers were included and were found to have comparable biochemical pregnancy rates (13.8 vs. 14.4%, p = 0.82). In spite of the use of gonadotropins for COS in fresh cycles and the use of estradiol and progesterone in the FET cycles, which are all thought to alter the gene expression of endometrium, surprisingly the biochemical pregnancy rates were significantly lower in ART cycles when compared to fertile controls with natural conceptions (13.8 vs. 18%, p = 0.01). Selection of better embryos for transfer in IVF cycles was probably thought to be one of the reasons.

This further shows that the detection of chemical pregnancies might be apparently higher in ART cycles, but actually, the spontaneous conceptions also have a high pro portion of such pregnancies, which go unrecognized.

Different reasons for biochemical pregnancies have been proposed, including aneuploidy embryos, suboptimal culture conditions, and suboptimal endometrium.[78] Some have found a higher incidence in older women, while others have failed to see any such correlation with age.[81,82]

However, a biochemical pregnancy means that at least an embryo reached blastocyst stage and is finally implanted in the endometrium.

Thus, pregnancy rates in subsequent IVF cycles are better in women who have had a biochemical pregnancy as compared to those who had a negative pregnancy test.[51] In case of high biochemical pregnancy rates in an IVF laboratory, both the embryo and the endometrium need a reevaluation. Everything which might affect the embryo should be looked into, namely, batch of gonadotropins, media, consumables, air quality, and other aspects of the IVF laboratory. Three-dimensional (3D) scans, Doppler for subendometrial blood flows, and hysteroscopy are used for the endometrial evaluation.

KEY POINTS

- Every batch, every laboratory, every patient, and every professional involved is a variable. To add to these, the culture conditions and air quality, which in spite of stringent controls, can always be challenging.
- Every ART clinic will go through ups and downs in their success rates though most of the times with the implementation or introduction of new variables. However, it is not always that we would be able to identify the causative factor.
- A proper documentation, adherence to QC measures, and follow through of the SOPs can prevent most of these challenges.
- Troubleshooting is a team effort which should be undertaken with the clinical, nursing, biomedical, and the laboratory personnel on board.

CHAPTER 126

Quality Management in Assisted Reproductive Technology Clinics

Gautham T Pranesh

PRINCIPLES OF QUALITY MANAGEMENT

Quality in healthcare systems refers to the ability of being able to achieve conformance consistently to the requirements of patients and healthcare providers are the users of the services. "Total quality management" provides a management philosophy and process for development of systems that improve the quality of work across all areas. This encompasses a view that healthcare organizations are composed of a set of interlinked repetitive processes that aim at achieving optimal outcomes for patients. The quality management systems provide a framework to support the identification of issues or problems within processes and empower employees to resolve them to ensure consistent and sustainable delivery of optimal outcomes. Establishing such systems within an organization requires a commitment to quality by the management and resources including manpower, time, and money which contribute to the costs quality. The costs of quality conformance also may lead to advantages such as cost reduction and competitive advantages for organizations by reducing wastage, improving efficiency, and adding value to customers. Examples of the potential costs and benefits of quality are provided in **Table 1**.

DEVELOPING A QUALITY MANAGEMENT SYSTEM IN ASSISTED REPRODUCTIVE TECHNOLOGY CLINIC

In the last five decades after the first successful in vitro fertilization (IVF), understanding of assisted reproductive techniques has improved increasing success rates and outcomes. As a result, the body of scientific evidence has established best practice guidelines and standards. Organizations may adopt one or more of standards for development of a quality management system. A quality management system is a framework of business processes within an organization focused on providing reliable, efficient, and consistent services to customers and ensuring compliance to regulations. Such systems include several elements such as organizational goals, objectives, policies, procedures, and documents to monitor the effectiveness of implementation, structured in a hierarchical manner **(Fig. 1)**. Standard definitions of elements within quality management systems are provided in **Table 2**.

Organizations must strategically select appropriate quality standards and regulations that may be applicable in their operational environment. Establishing an effective quality management system requires organizations to align policies, processes, and practices to meet the requirements of these quality standards and regulations to achieve desirable outcomes. Policy directives are expressed from the top management in the form of a quality policy which is documented and communicated across the organization. Individual clinical and nonclinical departments within an organization such as embryology, andrology, nursing, clinical, operations, billing, etc., establish written standard operating procedures (SOPs) for key business and technical processes. SOPs are written documents which provide step by step instructions to help individuals to carry out tasks

TABLE 1: Concept of cost of quality.

Quality costs	*Type of costs*	*Examples*
Costs of prevention	Conformance costs	Cost of equipment maintenance, infrastructure for quality systems, calibration, and maintenance
Costs of appraisal	Conformance costs	Cost of establishing periodic checks and an audit process
Costs of internal failure	Costs of nonconformance	Cost of rework and wastage of media, reagents, etc.
Costs of external failure	Costs of nonconformance	Cost of patient complaint resolution, patient dissatisfaction with services, and litigation risk

Fig. 1: Structure of quality management systems in an organization.

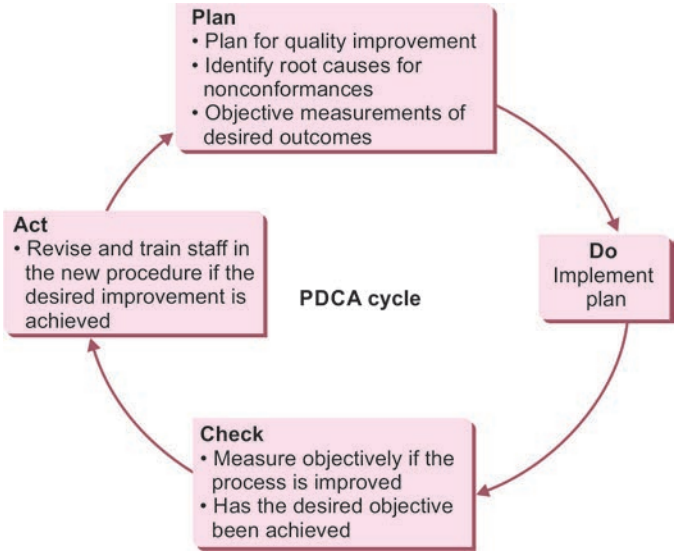

Fig. 2: Plan-do-check-act (PDCA) cycle for continuous quality improvement.

TABLE 2: Standard definitions in quality management systems.

Terms	*Definition*
Accreditation	A procedure by which an authoritative body gives formal recognition that an organization is competent to carry out specific tasks (ISO 15189:2012)
Nonconformity	Nonfulfillment of a requirement in the quality management system (ISO 9000:2005)
Quality	Degree to which a set of inherent characteristics fulfill requirements (ISO 9000:2005)
Quality management system (QMS)	Management system to direct and control an organization with regard to quality (ISO 9000:2005)
Quality policy	Overall intentions and direction of a laboratory related to quality as formally expressed by the laboratory management (ISO 9000:2005)
Quality indicator	Measure of a degree to which a set of characteristics fulfill requirements
Validation	Confirmation, through the provision of objective evidence, that the requirements for a specific intended use or application has been fulfilled (ISO 9000:2005)
Verification	Confirmation, through the provision of objective evidence, that specified requirements have been fulfilled

in a consistent and correct manner. Implementation of SOPs is ensured through appropriate data records that are created during the tasks, which may be reviewed or audited periodically.

Standard operating procedures must be comprehensive and prepared by individuals who are proficient in the tasks being performed. Training and compliance to such written procedures is critical to ensure consistency in the tasks performed, standardization across operators, regulatory compliance, clarity in communication, reduction in errors, and help to retain the knowledge created within an organization.

MAINTAINING ONGOING COMPLIANCE TO A QUALITY MANAGEMENT SYSTEM

Once a quality management system is established in an organization, maintaining compliance, and ensuring continual improvements are the next objective. Assessment of compliance and ongoing modifications for quality management systems based on evidence is a continuous process. Typical methods used to evaluate compliance include periodic review of records, review of documentation of procedures, records and nonconformances, and audits by internal or external groups. Reviews of processes can be performed by supervisors using an ask-observe-review model. This involves asking staff questions to evaluate their understanding on procedures and policies, observing staff when they are performing tasks and review of records, and documents to evaluate availability of standardized procedures and compliance to the same.

Continual improvements in the quality management system are initiated using repetitive iterations of the plan-do-check-act cycle **(Fig. 2)**. The management can appoint a "project team" with a mandate to review internal processes and identify areas for improvement. The team is empowered to use a structured methodology for review of processes within the organization. The methodology employed must:

- Carefully define conformance desired within a process.
- Accurately describe the nonconformances observed.
- Establish the baseline measures for process performance and conformance.
- Identify the root cause for nonconformances within the process.
- Establish an effective plan for correction and prevention of such nonconformance.
- Verify that the established plan provides desired conformance on implementation.

- Standardize the solution for routine implementation of the improved process.
- Establish metrics to ensure ongoing control and effective monitoring of the process.

Key performance indicators or quality indicators must be established to objectively measure outcomes of critical processes. Measures such as oocyte retrieval rate, fertilization rate, lysis rate, cleavage rate, freeze-thaw survival rates, blastocyst conversion rate, clinical pregnancy rate, and live-birth rates are examples of such indicators in an assisted reproductive technology (ART) setting. Benchmarks for such indicators may be set by the laboratory management and are usually derived based on acceptable consensus across clinical settings. Clinics and laboratories must periodically review quality indicators and initiate root cause analysis of problems, corrective, and preventive actions when required.

ACCREDITATION, CERTIFICATION, AND LICENSING REQUIREMENTS FOR ASSISTED REPRODUCTIVE TECHNOLOGY CLINICS

Several countries have developed frameworks to regulate assisted reproductive techniques **(Table 3)**. Quality systems may be aligned by the process of accreditation or certification to one or more of these standards.

The process of certification involves an assessment by a third party to verify that the processes for an operational quality management system are adequate within an organization. Laboratories participating in accreditation programs the quality management systems evaluated, by third party accreditation providers to ensure that the system delivers the intended quality of results.

Organizations operating in regulated environments must comply with the local and national laws. Compliance to regulatory requirements may be enforced through licensing procedures **(Table 4)**.

KEY ELEMENTS OF A QUALITY MANAGEMENT SYSTEM

Accreditation programs oriented toward ART clinics are focused toward laboratory quality. Such programs broadly mandate standard requirements in areas such as systems for management, qualifications, experience and proficiency requirements for staff, technical requirements for embryology and andrology laboratory processes, validation and maintenance of laboratory equipment, systems for management of IT systems, and requirements for safety. International quality standards such as ISO further breakdown these requirements into numbered sections **(Box 1)**.

TABLE 3: Quality standards and accreditation standards.

Standards	***Scope of quality management***
ISO 9001:2008	• General guideline on quality management • Focus primarily on best practices in general management systems, equipment selection and maintenance, and personnel management
ISO 17025:2005	Guideline specific to testing and calibration laboratories—Developed on the basis on ISO 9001 standards; focus on general management and technical management in laboratories. Covers aspects of validation, quality control, and quality assurance
ISO 15189:2012	Guideline specific to medical testing laboratories—Developed on the base of ISO 17025 standards; focus on clinical need and outcomes in addition to general and technical management guidelines
Joint Commission International (JCI)	Standards specific for healthcare organizations—JCI is an organization that develops healthcare standards with a focus on patient safety and quality. The organization is based out of USA with a reach in over 90 countries
Clinical and Laboratory Standards Institute (CLSI)	Nonprofit organization which develops standards and guidelines focused toward laboratory quality
GMP/GLP	These guidelines provide minimum requirements that a pharmaceutical or a food product manufacturer must meet to assure that the products are of high quality and do not pose any risk to the consumer or public
College of American Pathologists (CAP)	• IVF laboratories must comply with the requirements of the Clinical Laboratories Improvement Act (CLIA) of 1988 • Standards and accreditation program specific to embryology, andrology, and tissue cryopreservation. The program is developed jointly with the American Society for Reproductive Medicine (ASRM). The accreditation complies with the CLIA requirements.

(GLP: good laboratory practice; GMP: good manufacturing practice; IVF: in vitro fertilization)

TABLE 4: List of region-wise standards globally for quality management in assisted reproductive technology.

Regions	***Local and regional regulations and licensing requirements***
Asia and Middle East	• *India:* ICMR guidelines, registration is not mandated by the government http://icmr.nic.in/art/art_clinics.htm • *UAE:* IVF centers are governed and licensed by the health authority • *Japan:* Japanese Gynecology Society guidelines for IVF • *Singapore:* Licensing mandated by the Ministry of Health • *China:* Guidelines by Ministry of Health for providing approvals to IVF clinics in the respective province
North America	• College of American Pathologists (CAP) in association with American Society for Reproductive Medicine (ASRM) provides an accreditation program for fertility centers in the US http://www.cap.org/web/home/lab/accreditation/reproductive-accreditation-program?_afrLoop=101173589932947#!%40%40%3F_afrLoop%3D101173589932947%26_adf.ctrl-state%3D3oyhhwjha_17 • The Society for Assisted Reproductive Technologies (SARTs) covers over 90% of the IVF clinics in the United States. SART is involved in publishing outcomes, quality assurance, participation in patient advocacy and interaction with regulators, and establishment of best practice guidelines http://www.sart.org/patients/what-is-sart/
South America	The Red Latinoamericana de Reproducción Asistida (RED—Latin American Network of Assisted Reproduction) is a scientific and educational institution, which brings together >90% of the centers engaged in assisted reproduction techniques in Latin America http://redlara.com/aa_ingles/default.asp
Europe	• IVF laboratories are governed by European Union Tissues and Cells Directive (EUTCD), a legal framework published as a document under the European Union's Public Health Program. The document focuses on patient safety with an objective of preventing transmission of infectious diseases and prevention of inadvertent exchange of gametes or embryos • The European Society of Human Reproduction and Embryology (ESHRE) has provided a position statement and guideline on the EUTCD. "ESHRE guidelines for good practice in IVF laboratories" is complementary to the EUTCD bringing a focus on best practices to improve clinical outcomes • Human Fertilization and Embryology Authority (HEFA) licensing authority in UK
Australia	IVF clinics are licensed by Reproductive Technology Accreditation Committee (RTAC)

(ICMR: Indian Council of Medical Research; IVF: in vitro fertilization)

BOX 1: Section titles for management and technical requirements as per ISO 15189:2012 international standard.

Management requirements:
- Organization and management responsibility
- Quality management system
- Document control
- Service agreements
- Examination by referral laboratories
- External services and supplies
- Advisory services
- Resolution of complaints
- Identification and control of nonconformities
- Corrective action
- Preventive action
- Continual improvement
- Control of records
- Evaluation and audits
- Management review

Technical requirements:
- Personnel
- Accommodation and environmental conditions
- Laboratory equipment, reagents, and consumables
- Pre-examination process
- Examination process
- Ensuring quality of examination results
- Postexamination process
- Reporting of results
- Release of results
- Laboratory information management

GUIDELINES FOR GOOD PRACTICE IN IN VITRO FERTILIZATION LABORATORIES

The European Society of Human Reproduction and Embryology (ESHRE) guideline group in 2015 published the revised guidelines for good practice in IVF laboratories, a comprehensive document based on current clinical evidence and practice. These recommendations, although not intended as a quality standard, provide a framework to establish quality requirements in ART clinics. The guideline provides suggestions to aid quality and clinical decisions across 11 areas summarized here in **Table 5**.

Assisted Reproductive Technology Act, 2021 and Its Implication on Quality Management Systems

In India the regulatory framework for assisted reproductive techniques was published in the Assisted Reproductive Technologies Act, 2021. The act prescribes a regulatory framework where clinics and banks offering services in the realm of assisted reproductive techniques need to demonstrate a minimum standard of compliance to the requirements of the act. This has an implication on quality management system wherein clinics must ensure written policies, SOPs, and records to establish the manner

TABLE 5: Guideline provides suggestions to aid quality and clinical decisions.

Key areas for quality management	***Summarized recommendations***
1. Staffing and direction	• The guideline suggests that two qualified embryologists are available for every 150 procedures including retrievals and transfers must be provided • Laboratory director for embryology must have appropriately recognized qualifications (MSc, MD, or PhD), expertise and experience (a minimum of 6 years) in the field of embryology. It is preferable that the laboratory director has completed a certification in embryology in addition to the earlier requirements • Roles and responsibilities of laboratory director, laboratory supervisor, and clinical embryologists are specified in the document • The human resources planning within an organization must enable performance of tasks in a timely manner, adequate backup for staff, ensure patient safety, and provide quality service
2. Quality management	• The clinical embryologist is responsible for implementation of the quality management system in the laboratory. The components of such a quality management system include: – Availability of a comprehensive set of written, validated, and authorized standard operating procedures and evidence of training on the same – Processes ensuring traceability of measuring equipment's to standards – Processes ensuring unique identity of all patients and traceability of their reproductive cells and tissues – Processes to confirm the quality of reagents and consumables before use in the clinic – Processes to ensure appropriate maintenance of equipment including periodic servicing and calibration – Processes to identify, correct, and prevent nonconformities – Processes to collect, record, and review key performance indicators (quality metrics) – Processes to audit, review, and ensure continual compliance and improvement in quality management systems – Analysis of risks and plans for risk mitigation – Periodic review of technical competence, compliance to the management system, and consistency through evaluation, proficiency testing, and training – Processes for internal quality control in critical processes and participation in external quality assurance programs – Processes for statistical evaluation and review of clinical performance on a periodic basis – Processes for periodic review of the quality management system (annual review is recommended)
3. Laboratory safety	*Laboratory design and air quality:* • ART laboratory must be situated adjacent to the operating room performing the oocyte retrieval and transfer procedures • Materials used within the laboratory must be appropriate for clean room use, minimize release of volatile organic compounds, and not embryo toxic • Access to the ART laboratory must be restricted to authorized personnel only • Facilities for changing and hand wash must be available for use before entry into the ART laboratory • The laboratory must have a clean access for personnel and material entry • Incompatible activities such as handling or storage of toxic reagents, cleaners, and sterilization materials must be separate from the laboratory • The laboratory air quality must be subjected to high efficiency particulate air (HEPA) and VOC control • The laboratory must maintain a positive air pressure when compared to the surrounding environment to prevent contamination • Tissue and cell processing procedures must be done in a good manufacturing practice (GMP) grade D environment at a minimum (grade A environment ideal) • The laboratory must have sufficient environmental lighting and air conditioning with controlled humidity and temperature *Laboratory equipment:* • Gas cylinders must be placed outside the laboratory premises with automatic changeover systems and adequate backup. The use of inline HEPA and VOC filters where possible is recommended • Equipment must be validated for performance and to ensure its fitness at the time of installation Performance of an equipment must be verified by calibrated instruments wherever applicable. Records of calibration, maintenance, and repair must be maintained within the laboratory • The laboratory must define acceptable ranges for all measured parameters (e.g., temperature, humidity, etc.). Records of actual measurements must be evaluated against defined ranges. Corrective actions must be initiated if the values are found to be out of range • Critical equipment such as cryostorage tanks and incubators must be continuously monitored for failure and equipped with alarm systems • Power failure alarm systems and backup power must be available for all critical equipment

Contd...

Contd...

Key areas for quality management	***Summarized recommendations***
	• The laboratory must have adequate and appropriate equipment to manage the number of procedures within a clinic • Equipment must be kept clean and operational. Malfunctioning equipment must be labeled as "out of use". Instruction and troubleshooting manuals must be available for all critical equipment *Cryopreservation facilities and materials:* • Cryopreservation facilities must be located close to the ART laboratory. The facility must have adequate ventilation with low oxygen alarms for safety • The laboratory must have processes for continuously monitoring cryostorage units. Alarm systems to detect low levels of liquid nitrogen or temperature failures must be incorporated • The laboratory must have a documented process and train staff in handling of liquid nitrogen. Personal protection devices (PPDs) such as glasses, apron, and cryogloves must be used when handling liquid nitrogen *Infectious agents:* • Staff must be vaccinated against hepatitis B. Staff must be trained in use of personal protective devices and handling biological samples • Patients must be screened for infectious diseases as per local regulations • The laboratory must have processes for handling biomedical waste, decontamination, and response to needlestick injuries • Screening results for infectious diseases must be obtained in advance whenever biological materials are imported into a laboratory from another clinic *Protective measures:* • The laboratory must treat all biological material as potentially infectious. The staff must be trained in universal precautions and adopt safe practices within the laboratory
4. Identification of patients and traceability of their reproductive cells	The clinic and laboratory must have processes to insure accurate identification of patients and their reproductive cells. Such processes must include: • Generation of a unique identification code for each patient • Generation of a unique code for each treatment cycle • Clear and permanent labeling of all devices containing biological material • Direct identification of the patient and verification of the unique identifier at all critical steps. A minimum of two identifiers (example: name and date of birth) must be used to generate a unique identifier • A policy to ensure that biological material from different patients is not processed in the same area at the same time to avoid misidentification and sample mix up • Organization of incubators and cryostorage systems to ensure easy access and identification of biological materials • A witness system with double checks to maintain the chain of custody during critical steps involving movement of biological materials • A system for unique coding and identification of nonpartner gametes • A system for verification of identity and conformity of samples, records, and storage devices imported or shipped out of a clinic The clinic must maintain the following records to ensure compliance with earlier processes: • Date and time of each manipulation and movement with the identity of operators and witnesses • Training records as evidence of mandatory training of staff on traceability procedures
5. Consumables	• The laboratory must use media and consumables that are fit for purpose and embryo culture grade. The laboratory must have a process to verify packing integrity, appropriate delivery conditions, and records of quality control testing for each batch of media or consumable used • Reagents, media, and consumables must be used before expiry. The size of packaging must be appropriately selected to minimize contamination. Single use disposable consumables must be used wherever possible • Media and consumables must be stored under appropriate conditions as indicated by the manufacturer • The laboratory must have an appropriate inventory management system including details of batch number, date of entry, and expiry date for stock management • The laboratory must perform a risk assessment to ensure that all consumables and media are easily identified to avoid misuse
6. Handling of biological material	The clinic and the laboratory must have processes for biological materials ensuring: • Safe handling under laminar flow hoods using aseptic precautions • Maintenance of appropriate temperature, pH, and osmolality during culture and handling • Minimal exposure to light, radiation, or toxic substances • Appropriate preparation of buffered media • Maintenance of chain of custody and traceability to the source of origin at all times

Contd...

Contd...

Key areas for quality management	***Summarized recommendations***
7. Oocyte retrieval	The clinic and the laboratory must have processes to: • Mandatorily check identity of a patient before oocyte retrieval • Prevent prolonged exposure to follicular fluid and minimize the time between oocyte retrieval and culture. • Maintain oocytes at 37°C using prewarmed media • Check follicular aspirates for oocytes using a stereomicroscope with 8–60X magnification and a heated stage The clinic and the laboratory must have records which: • Document the time of retrieval, the operator, and the number of oocytes retrieved
8. Sperm preparation	The clinic and laboratory must have standard procedures to ensure proper sperm preparation. This includes documented processes for: • Providing instructions to patients for collection of semen samples • Obtaining a backup sample in anticipation of possible difficulties in sperm collection on the day of oocyte retrieval • Correct labeling and correct identification of sample containers and patients • Analysis and preparation of semen samples • Semen preparation in case of patients diagnosed with blood borne viruses • Alternative sperm retrieval procedures when patients are found to be azoospermic The laboratory or clinic would need to maintain the following records in a manner that is traceable to the patient: • Records for sperm collection must include the type of container used, time and place of collection, time between collection, analysis and preparation, use of medications, fever during previous months and completeness, and volume of ejaculate collection • Records for sperm preparation including sample origin, preparation method, pre and postsperm preparation parameters, and dilution, if applicable
9. Insemination of oocytes	The clinic and laboratory must have appropriately documented procedures for insemination of oocytes by conventional IVF or ICSI The laboratory must have established processes for the following in cases of conventional IVF or ICSI: • Use of appropriate sperm concentration for IVF procedure • Use of appropriate immobilization and sperm selection techniques in case if ICSI • Selection of sperm preparation medium and methods which is compatible with the oocyte culture system • Verification of patient identity and traceability of the oocytes and sperms before the procedure • Validated procedure for conventional IVF and ICSI The laboratory must maintain records traceable to patients including data on the time of insemination, the operator, and concentration of progressively motile sperm for conventional IVF. Details of the injection start times and end time must be noted in the case of ICSI
10. Scoring for fertilization	The clinic and laboratory must have procedures to verify the presence of pronuclei and polar bodies 16–18 hours postinsemination. The clinic must document its procedures to discard more than or equal to three PN or less than or equal to one PN oocytes
11. Embryo culture and transfer	The clinic and laboratory must have documents and implement processes for: • Maintaining chain of custody and verification of identity during the process of culture and transfer • The use of a standardized culture system including media and culture conditions • Extended culture for blastocysts • Standardized embryo scoring for cleavage stage embryos and blastocyst • Selection for embryos for transfer • Management of supernumerary embryos The clinic and laboratory must maintain records for: • Embryo quality assessment including the name of the operators, date and time of assessment, and the embryo morphological characteristics • Transfer procedure including the date and time of embryo transfer, name of the operator, name of the practitioner performing the transfer, number of embryos transferred, developmental stage and quality of the embryos at the time of transfer, the type of catheter used, fate of supernumerary embryos, and details of the procedure such as retained embryos or blood in the catheter
12. Cryopreservation	The clinic and laboratory must have processes for cryopreservation of gametes, embryos, and tissues. Such procedures include: • Instructions for selection of cryopreservation approaches according to the type of biological materials • Measures to minimize the risk of transmission of infective diseases • Instructions for clear and permanent labeling of cryodevices

Contd...

Contd...

Key areas for quality management	***Summarized recommendations***
	• Methods for periodic evaluation of inventory in the cryobank with cross references to storage records • Methods for establishing patient identity before storage and retrieval • Systems to store and handle cryopreserved biological material under safe and appropriate environmental conditions The clinic and laboratory must maintain the following records traceable to patients when storing or handling cryopreserved samples: • Records for cryopreservation including labeling of devices, cryopreservation method, date and time of cryopreservation, operator, details of embryo quality and stage of development, number of oocytes or embryos per device, number of devices per patient, and location of stored samples to ensure traceability • Records for thawing including details of the thawing method, date of thawing, operator, and post-thaw quality of biological sample
13. Emergency plan	The clinic and laboratory must have a tested emergency plan to serve as mitigation in even of exceptional failures of infrastructure or service facilities. Such procedures include: • Communication measures in event of emergency procedures • Systems to ensure redundancy in case of failure of electricity, gas supply, or depletion of liquid nitrogen • Identification of appropriate backup for all critical equipment such as incubators, storage tanks, etc • Measures to backup and store critical medical records identifying ownership and traceability of stored biological material • Regular review and training procedures on the emergency plan • Appropriate arrangements with third party facilities for emergency transfer of gametes or embryos

(ART: assisted reproductive technology; ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization; VOC: volatile organic compound)

TABLE 6: Internal audit checklist of quality requirements.

Checklist requirement (ask questions, observe practices, read policies, procedures, and records)	***Reference***	***Clause/ section***
Does the clinic, bank provide facilities and maintain equipment and standards including specialized manpower, physical infrastructure and diagnostic facilities as required by the ART act, 2021	The Assisted Reproductive Technology (Regulation) Act, 2021	15-(4)
Has the clinic applied and obtained a valid registration as per the requirements of the above mentioned act?	The Assisted Reproductive Technology (Regulation) Act, 2021	15-(3)
Has the clinic or bank displayed the registration certificate at a conspicuous place within the facility?	The Assisted Reproductive Technology (Regulation) Act, 2021	16-(7)
Does the displayed certificate contain the details of validity of such a registration?	The Assisted Reproductive Technology (Regulation) Act, 2021	16-(7)
Does the clinic and bank have a documented process/procedure to ensure that couple, women and donors are eligible to avail assisted reproductive technology procedures as per the requirements of the act?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(a)
Does the clinic have a process/procedure to ensure that donors have been medically tested for the diseases mentioned in the ART act?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(b)
Does the clinic have a process/procedure for counselling patients?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(c)
Does the process of counselling include documented records as evidence of counselling on: • Implications and the chances of success in ART • Advantages and disadvantages of the prescribed procedure • Cost of the procedure • Medical side effects • Risks involved including the risk of multiple pregnancies • Rights of the unborn child	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(c)
Does the clinic have policies and procedures in place to ensure confidentiality of information pertaining to treatment of couples, women, and donors?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(d)

Contd...

Contd...

Checklist requirement (ask questions, observe practices, read policies, procedures, and records)	***Reference***	***Clause/ section***
Does the clinic have procedures to make the records available for specific requirements specified in the ART act: • National registry • In a medical emergency • On request of the commissioning couple • By order of a court of competent jurisdiction	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(d)
Does the clinic have a grievance cell and a procedure to make a complaint before the grievance cell?	The Assisted Reproductive Technology (Regulation) Act, 2021	12-(f)
Does the clinic have a policy and procedure to provide a discharge certificate to the commissioning couple or women stating the details of the Assisted Reproductive Technology procedure performed?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(h)
Is there evidence of such discharge certificates routinely being provided to commissioning couples or women?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(h)
Does the clinic maintain records on: • Enrollment of commissioning couples, women and donors • Procedures being undertaken in couples, women and donors • Outcomes of procedures • Complications, if any	The Assisted Reproductive Technology (Regulation) Act, 2021	12-(j)
Does the clinic have a process/procedure to provide the details in the aforementioned records to the National Registry periodically as prescribed?	The Assisted Reproductive Technology (Regulation) Act, 2021	21-(j)
Does the clinic have a policy and procedure of obtaining a written informed consent from all parties seeking assisted reproductive procedures?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-1-(a)
Is there evidence of records indicating the use of a correct and current version of the informed consent?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-1-(a)
Is there evidence of records indicating completeness of documentation and details on informed consents?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-1-(a)
Does the clinic have policies and procedures to verify that the donor is insured by the commissioning couple or women before initiating any assisted reproductive procedure?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-1-(b)
Does the clinic have policies and procedures governing the cryopreservation of human gametes or embryos in event of death or incapacity of any of the parties?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-(2)
Does the clinic have policies restricting the use of human reproductive material only in any manner other than those permitted by the ART act?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-(3)
Does the clinic have a policy or procedure on the process to follow when any party in a commissioning couple or women withdraws consent before transfer of human gametes or embryos into the uterus?	The Assisted Reproductive Technology (Regulation) Act, 2021	22-(4)
Does the clinic maintain ongoing records of all donor oocytes, sperm or embryos, used or unused?	The Assisted Reproductive Technology (Regulation) Act, 2021	23-(a)
Does the clinic maintain ongoing records of the manner and technique of use of donor oocytes, sperm or embryos?	The assisted reproductive technology (regulation) act, 2021	23-(a)
Does the clinic maintain ongoing records of progress of the commissioning couple or women?	The Assisted Reproductive Technology (Regulation) Act, 2021	23-(b)
Does the clinic maintain ongoing records on: • Number of donor sperm or oocytes samples • Number of donors screened • Number of donor samples maintained • Number of donor samples supplied to commissioning couples	The Assisted Reproductive Technology (Regulation) Act, 2021	23-(b)
Does the clinic have policies, procedures and infrastructure to maintain the aforementioned records for a minimum period of 10 years?	The Assisted Reproductive Technology (Regulation) Act, 2021	23-(c)
Does the clinic have specific policies governing the maintenance of records in the event of any criminal or other proceedings against the clinic?	The Assisted Reproductive Technology (Regulation) Act, 2021	23-(c)

Contd...

Contd...

Checklist requirement (ask questions, observe practices, read policies, procedures, and records)	***Reference***	***Clause/ section***
Does the clinic have policies for handling, maintenance and transfer of records in event of closure to ensure retention for 10 years?	The Assisted Reproductive Technology (Regulation) Act, 2021	23-(d)
Does the clinic have policies and procedures on oocyte retrieval procedures?	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(a)
Does the clinic have policies and procedures to ensure that no more than three oocytes or embryos are placed in the uterus during a treatment cycle?	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(b)
Does the clinic have policies/procedures prohibiting the transfer of gametes derived from more than one man or woman during a single treatment cycle?	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(c)
Does the clinic have policies/procedures prohibiting the mixing of semen from two individuals for procedures specified under the ART act?	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(d)
Does the clinic have policies/procedures prohibiting splitting of embryos for twinning to increase the number of available embryos?	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(e)
Does the clinic have policies/procedures for posthumous collection of gametes?	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(f)
Does the clinic have policies/procedures prohibiting the use of oocytes derived from a fetus in any process of in-vitro fertilization	The Assisted Reproductive Technology (Regulation) Act, 2021	24-(g)
Does the clinic have written policies and procedures for the use of pre-implantation genetic testing	The Assisted Reproductive Technology (Regulation) Act, 2021	25(1)
Does the clinic have policies/procedures prohibiting sex determination or providing a child of a predetermined sex in any manner contravening the requirements of the PCPNDT act, 1994?	The Assisted Reproductive Technology (Regulation) Act, 2021	26
Does the clinic have adequate process/procedures and records for storage, identification, security and handling of gametes?	The Assisted Reproductive Technology (Regulation) Act, 2021	28-(1)
Does the clinic have adequate process/procedures and records for storage, identification, security and handling of embryos?	The Assisted Reproductive Technology (Regulation) Act, 2021	28-(1)
Does the clinic have policies, procedures and records for storage of gametes and embryos for not >10 years?	The Assisted Reproductive Technology (Regulation) Act, 2021	28-(2)
Does the clinic have policies, procedures and records for storage of gametes and embryos for a duration of longer than 10 years with permission of the national board in patients with specific medical requirements?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13-(b)
Does the clinic have policies, procedures and records for disposal of gametes and embryos as per the ART act?	The Assisted Reproductive Technology (Regulation) Act, 2021	28-(2)
Does the clinic have a policy prohibiting sale, transfer or use of gametes, zygotes or embryos any part thereof or information related thereto to any party other than the commissioning couple within or outside India?	The Assisted Reproductive Technology (Regulation) Act, 2021	29
Does the clinic have a policy, procedure and process for the transfer of own gametes or embryos for personal use with the permission of the National Board?	The Assisted Reproductive Technology (Regulation) Act, 2021	29
Does the clinic have a policy prohibiting the transfer of human gametes or embryos to any country outside India for research?	The Assisted Reproductive Technology (Regulation) Act, 2021	30-(1)
Are the staffs recruited in the clinic as per the requirements of "The Assisted Reproductive Technology Act (Regulation) Rules"?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	4
Does the clinic have the minimum required infrastructure and equipment as per the "The Assisted Reproductive Technology Act (Regulation) Rules"	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	5
Does the clinic have policies, procedures and records that ensure that all unused gametes or embryos shall be preserved by the ART clinic for use on the same recipient?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13a
Does the clinic have policies, procedures and records that prohibit the use of unused gametes or embryos assigned to recipient to any other couple or woman?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13a
Does the clinic have adequate policies and procedures to prevent ovarian hyperstimulation in women undergoing controlled ovarian stimulation?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13c

Checklist requirement (ask questions, observe practices, read policies, procedures, and records)	*Reference*	*Clause/ section*
Is the consent form to be signed by a couple or woman in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f) (i) Form 6?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f)(i)
Is the format for making complaints to the grievance cell in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 11 Form 5?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	11
Is the format for consent for IUI with husbands semen/sperm in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(ii) Form 7?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f)(ii)
Is the format for consent for freezing of gametes/sperm/oocytes in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(v) Form 10?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f)(v)
Is the format for consent for freezing of gametes/Sperm/oocytes and parental consent in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(vi) Form 11?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f)(vi)
Is the format for consent for Intrauterine Insemination with donor semen in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(iii) Form 8?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f)(iii)
Is the format for consent for freezing of embryos in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(iv) Form 9?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f)(iv)
Is the format for consent for oocyte retrieval in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(vii) Form 12?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f) (vii)
Is the format for consent for the donor of oocytes in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(f)(viii) Form 12?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(f) (viii)
Is the format for consent form for donor of sperm in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(2)(ii) Form 15?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(2)(ii)
Is the format for record of use of donor gametes in the format specified by "The Assisted Reproductive Technology Act (Regulation) Rules" rule 13(2)(i) Form 14?	The Assisted Reproductive Technology (Regulation) Act, Rules, June 7 2022	13(2)(i)

in which they comply to the requirements of the act. Clinics in the coming days may be audited where the records associated with such a quality management process in conjunction with records of training and compliance to such procedures would be required to ensure regulatory compliance. An internal audit checklist of quality requirements to ensure compliance to the act is provided in **Table 6**.

CONCLUSION

Quality management systems in assisted reproduction clinics help to offer better value, consistency, improve outcomes, maintain regulatory compliance, and enhance efficiency. Organizations must establish their quality management systems based on their size, service objectives and goals.

KEY POINTS

- Quality management systems aim at standardizing interlinked repetitive processes in healthcare to optimize outcomes.
- Quality management systems are prepared to comply with standards and regulations and are composed of organizational policies, standard operating procedures, and records from top-down.
- Continuous quality management involves continuous monitoring of key performance indicators, non-conformities and risks with appropriate corrective and preventive actions for mitigation.
- Quality management systems may help clinics to maintain ongoing compliance with local or national regulations such as the Assisted Reproductive Technology Act, 2021 in India.

CHAPTER 127

Oocyte Cumulus Complex Evaluation

Kamini A Rao, Divyashree PS

INTRODUCTION

Assessment of oocyte maturity will be difficult immediately after retrieval as it is surrounded by cumulus complex. Although it is not of much importance in intracytoplasmic sperm injection (ICSI), as the oocyte will be evaluated after denudation, evaluation of oocyte cumulus complex (OCC) for the oocyte maturity is important in conventional in vitro fertilization (IVF).

There are conflicting reports regarding correlation of OCC morphology and fertilization and pregnancy rates.[1-4]

Presently we know that evaluation of OCC is not enough to grade oocyte maturity, but we also have to accept that these supporting cells play a vital role in the development of the oocyte. Therefore, in those circumstances where direct evaluation of oocyte is not possible, OCC evaluation is a useful tool in selecting a mature oocyte.

According to Lin and collegues,[3] there are five groups of OCCs based on the morphology of oocyte cytoplasm, cumulus mass, corona cells, and membrane granulosa cells.

Figures 1 to 5 show the oocyte—corona cumulus evaluation.

MATURE OOCYTE CORONA CUMULUS (FIG. 1)

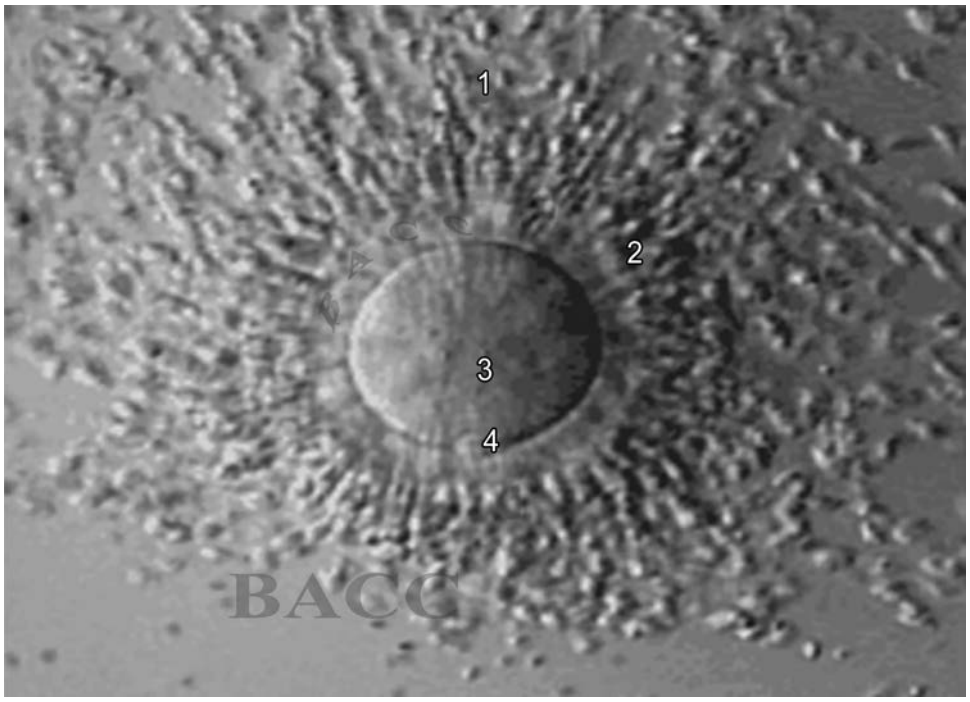

Fig. 1: (1) Expanded cumulus; (2) radiant corona; (3) clear cytoplasm; (4) first polar body.

APPROXIMATELY MATURE OOCYTE CORONA CUMULUS (FIG. 2)

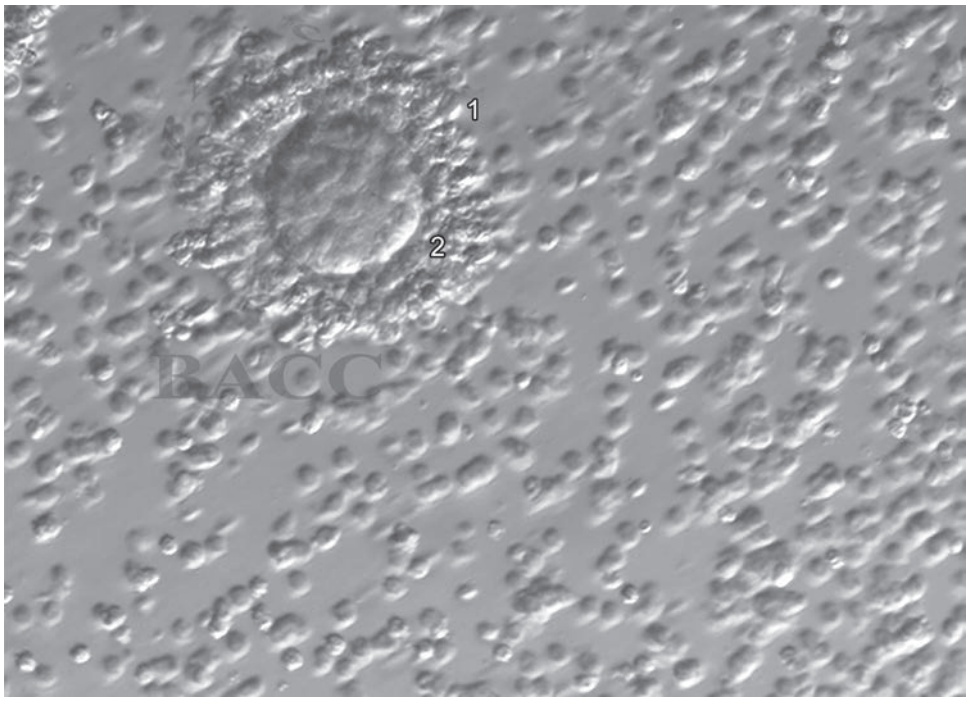

Fig. 2: (1) Expanded cumulus; (2) slightly compact corona.

IMMATURE OOCYTE CORONA CUMULUS (FIG. 3)

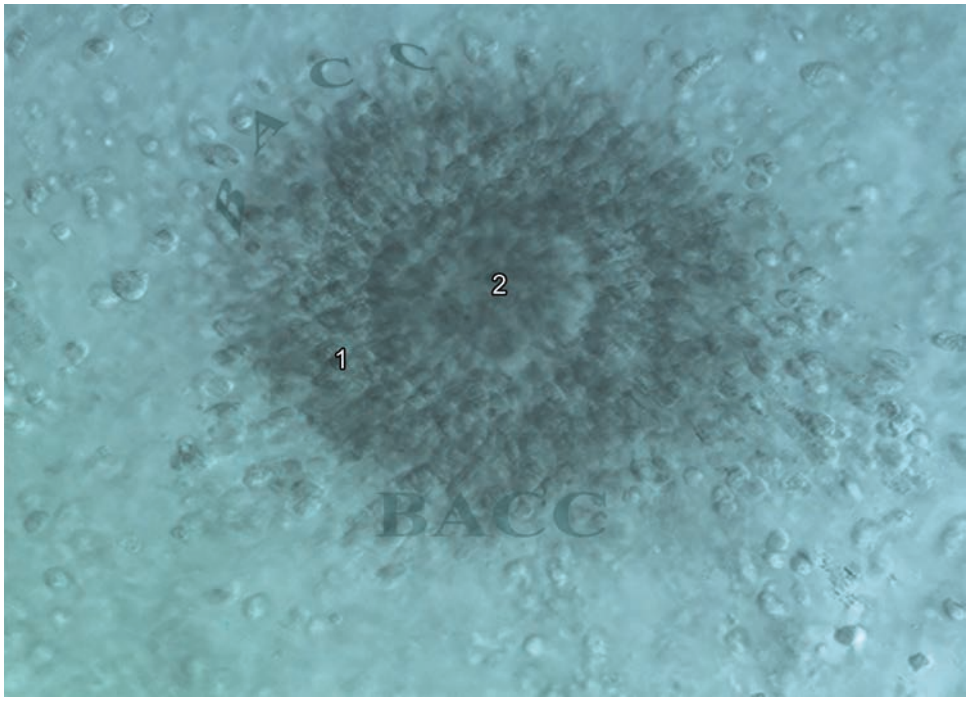

Fig. 3: (1) Adherent compact layer of corona; (2) ooplasm with germinal vesicle (Note: First polar body is not visible).

POSTMATURE OOCYTE CORONA CUMULUS (FIG. 4)

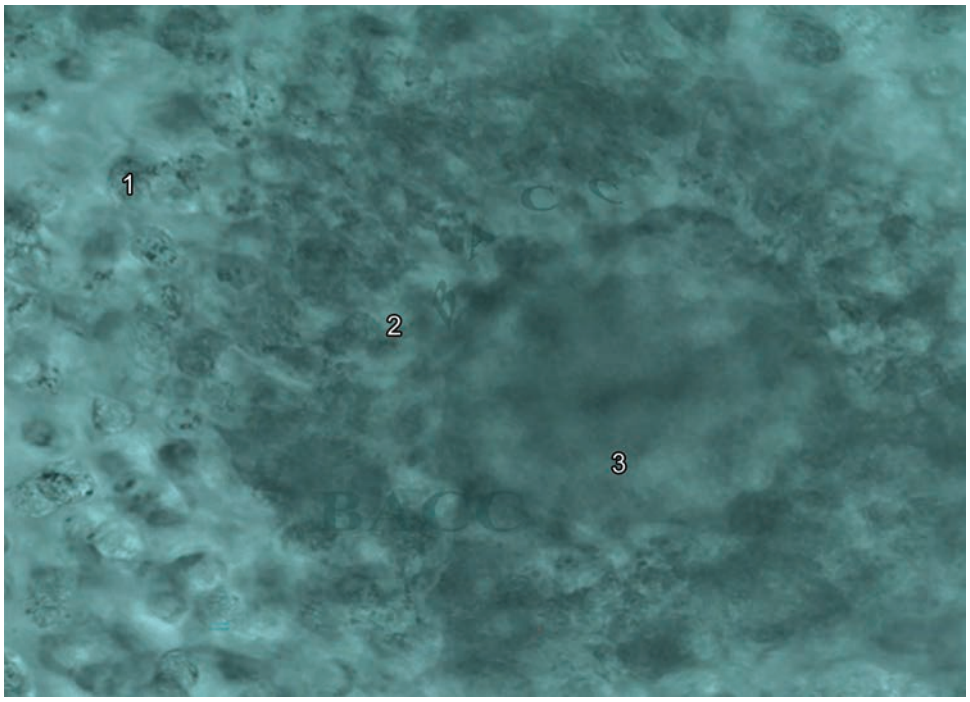

Fig. 4: (1) Expanded cumulus with clumps; (2) irregular, incomplete corona; (3) dark and granular cytoplasm.

ATRETIC OOCYTE CORONA CUMULUS (FIG. 5)

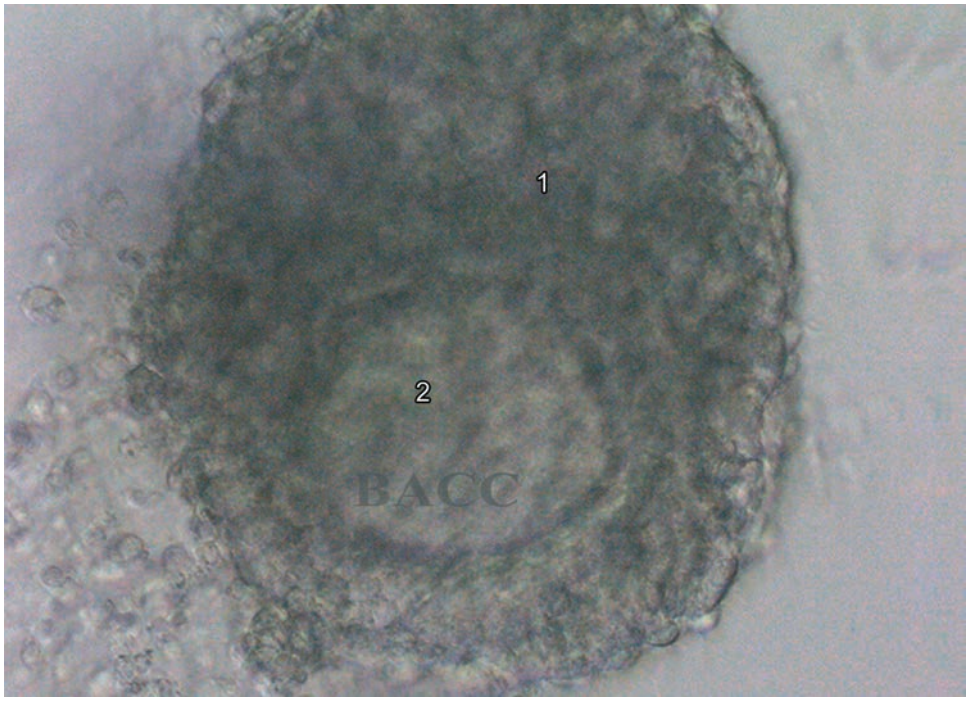

Fig. 5: (1) Clumped and very irregular corona; (2) dark and mishappen cytoplasm.

CHAPTER 128

Oocyte Nuclear Maturity Evaluation

Divyashree PS, Kamini A Rao, Anu Kottur

INTRODUCTION

The goal in assisted reproductive technologies is not only to obtain, but also to identify, the best quality oocyte. This is because the health of embryo, fetuses, neonates and adults is unquestionably rooted in a healthy oocyte. Indeed, we first need to know how to differentiate between the mature and immature oocytes and also to identify different oocyte abnormalities, so that we can reliably produce it.

Denudation is a prerequisite for intracytoplasmic sperm injection (ICSI), as only denuded oocytes can be successfully manipulated by the holding pipette. This ancillary effect of ICSI allows us to focus on oocyte nuclear maturity and also its morphological abnormalities.

Currently, oocyte nuclear maturity is assessed by the presence of an extruded first polar body (IPB) in the perivitelline space (PVS) and by the absence of germinal vesicle (GV).

Germinal vesicle: The chromatin in the meiotically arrested oocytes is encapsulated by a nuclear structure known as the germinal vesicle.

First polar body: As a part of reductional division, oocytes undergo disproportionate cytokinesis and extrusion of half of their genetic material within the IPB.

During controlled ovarian hyperstimulation cycles, approximately 85% of the oocytes are metaphase II (MII), 10% are GV and 5% are metaphase I (MI)[1] **(Figs. 1 to 4)**.

*Metaphase II oocyte **(Fig. 1)**:* Otherwise called mature oocyte or egg should have following characteristics:[2,3]

- Round, clear zona pellucida
- Small PVS containing a single unfragmented IPB
- Cytoplasm that is pale and moderately granular and with no inclusions.

Germinal vesicle oocyte: Germinal vesicle is present in the ooplasm.

Metaphase I oocyte: No visible GV in the ooplasm and no IPB in the PVS.

METAPHASE II (FIG. 1)

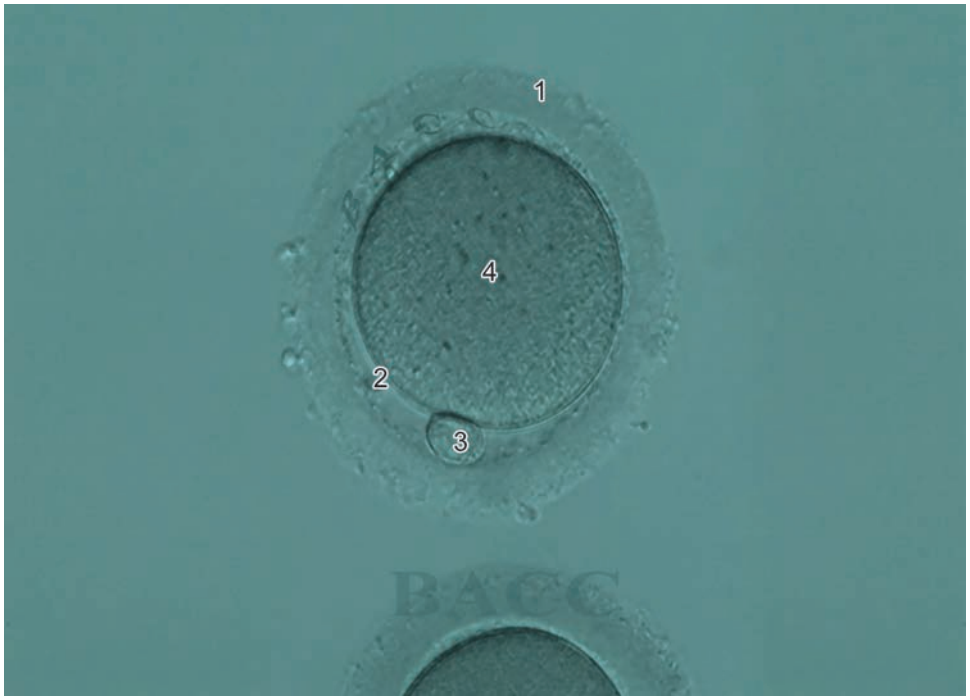

Fig. 1: (1) Round, clear zona pellucida; (2) small perivitelline space; (3) single unfragmented first polar body; (4) pale, moderately granular ooplasm.

METAPHASE I (FIG. 2)

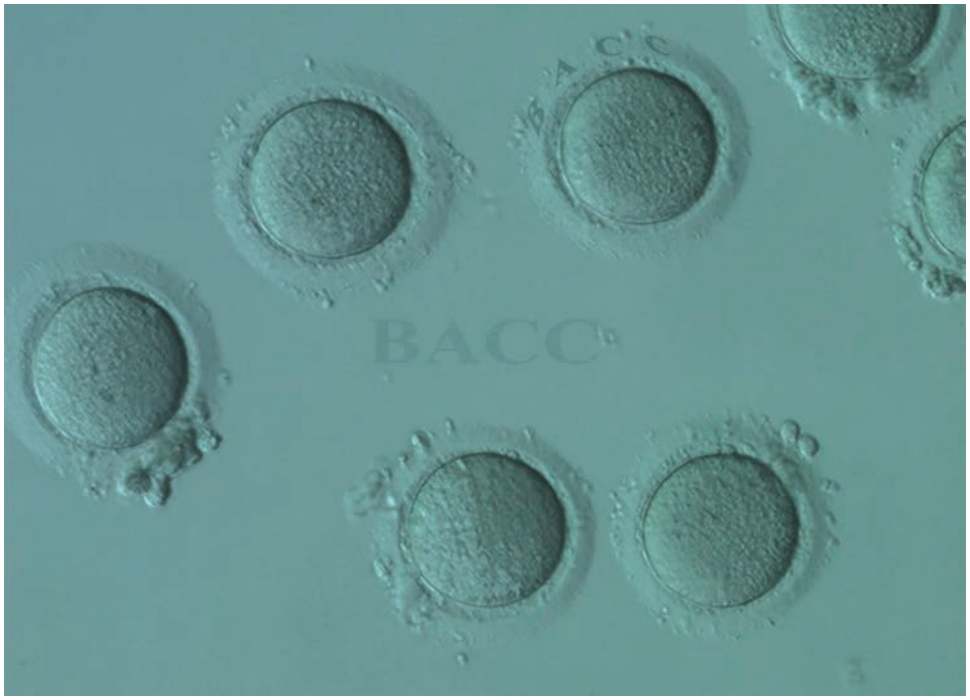

Fig. 2: Metaphase I oocytes. (*Note:* No germinal vesicle in the ooplasm; no visible first polar body).

GERMINAL VESICLE OOCYTE (40×) (FIG. 3A)

CHAPTER 129

Oocyte Dysmorphisms

Divyashree PS, Bezar Ghan VV, Kamini A Rao, Mohammed Ashraf C

INTRODUCTION

In the previous chapter, description regarding an "ideal" oocyte has been given. However, all the ideal characteristics may not be found in all the oocytes retrieved during controlled ovarian hyperstimulation (COH), this is true even in donor in vitro fertilization (IVF) cycles.

Following denudation, specific anomalies or dysmorphisms of the oocytes may be detected by examination with light microscopy. These anomalies or dysmorphisms have been observed in a high proportion (63%) of metaphase II (MII) oocytes obtained after retrieval.[1,2]

Oocyte abnormalities can be broadly categorized as shown in the **Flowchart 1**.

GRANULAR CYTOPLASM

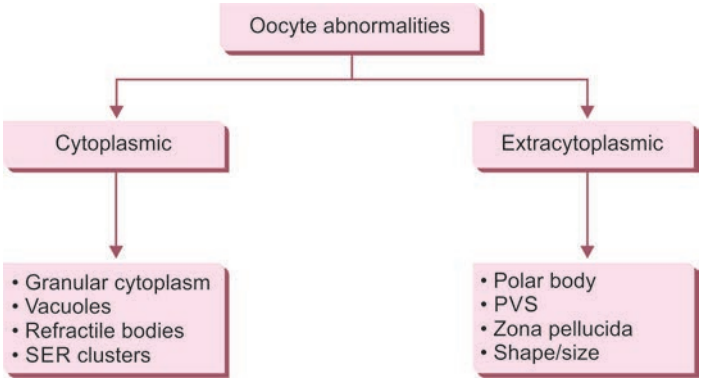
Granularity can be observed within the cytoplasm and it may be either homogeneously or centrally placed **(Figs. 1 and 2)**.

Severity of granularity is based on its depth and diameter (>50%—severe) **(Fig. 3)**.[3]

VACUOLES

Vacuoles are membrane-bound cytoplasmic inclusions filled with fluid virtually identical with perivitelline fluid. Vacuoles vary in size as well as in number **(Figs. 4A to C)**. They can be present in the oocyte on the collection day (day 0) or may be artificially created by intracytoplasmic sperm injection (ICSI) (day 1) or may be seen in embryos

Flowchart 1: Category of oocyte abnormalities.



(PVS: perivitelline space; SER: smooth endoplasmic reticulum)

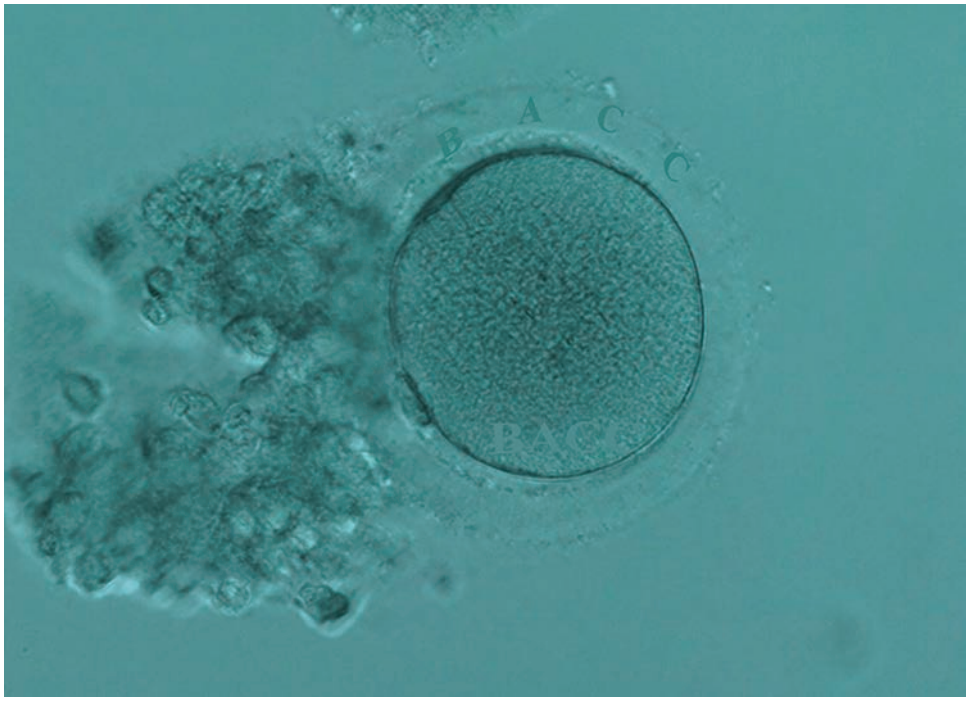


Fig. 1: Oocyte having homogeneous granular cytoplasm.

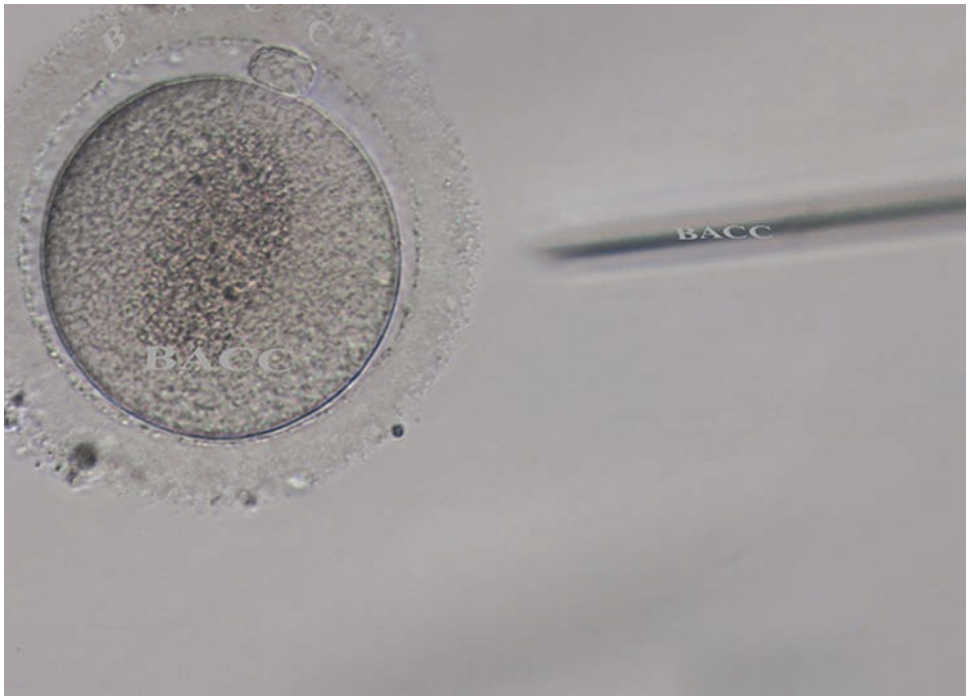

Fig. 2: Oocyte with centrally placed granularity.

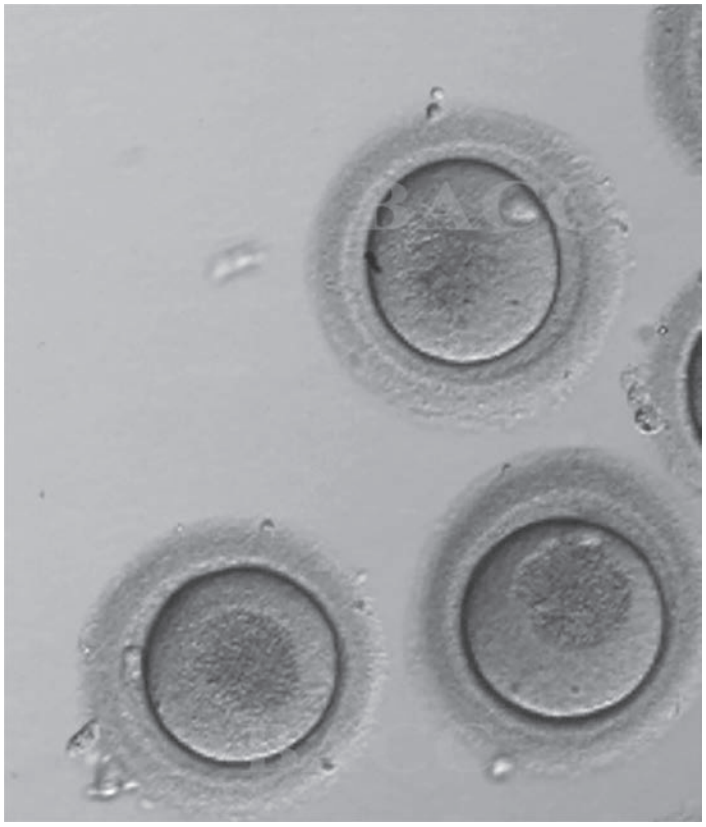

Fig. 3: MII oocytes showing a very large centrally located granular area occupying the majority of the cytoplasm. This granularity is typical of organelle clustering.

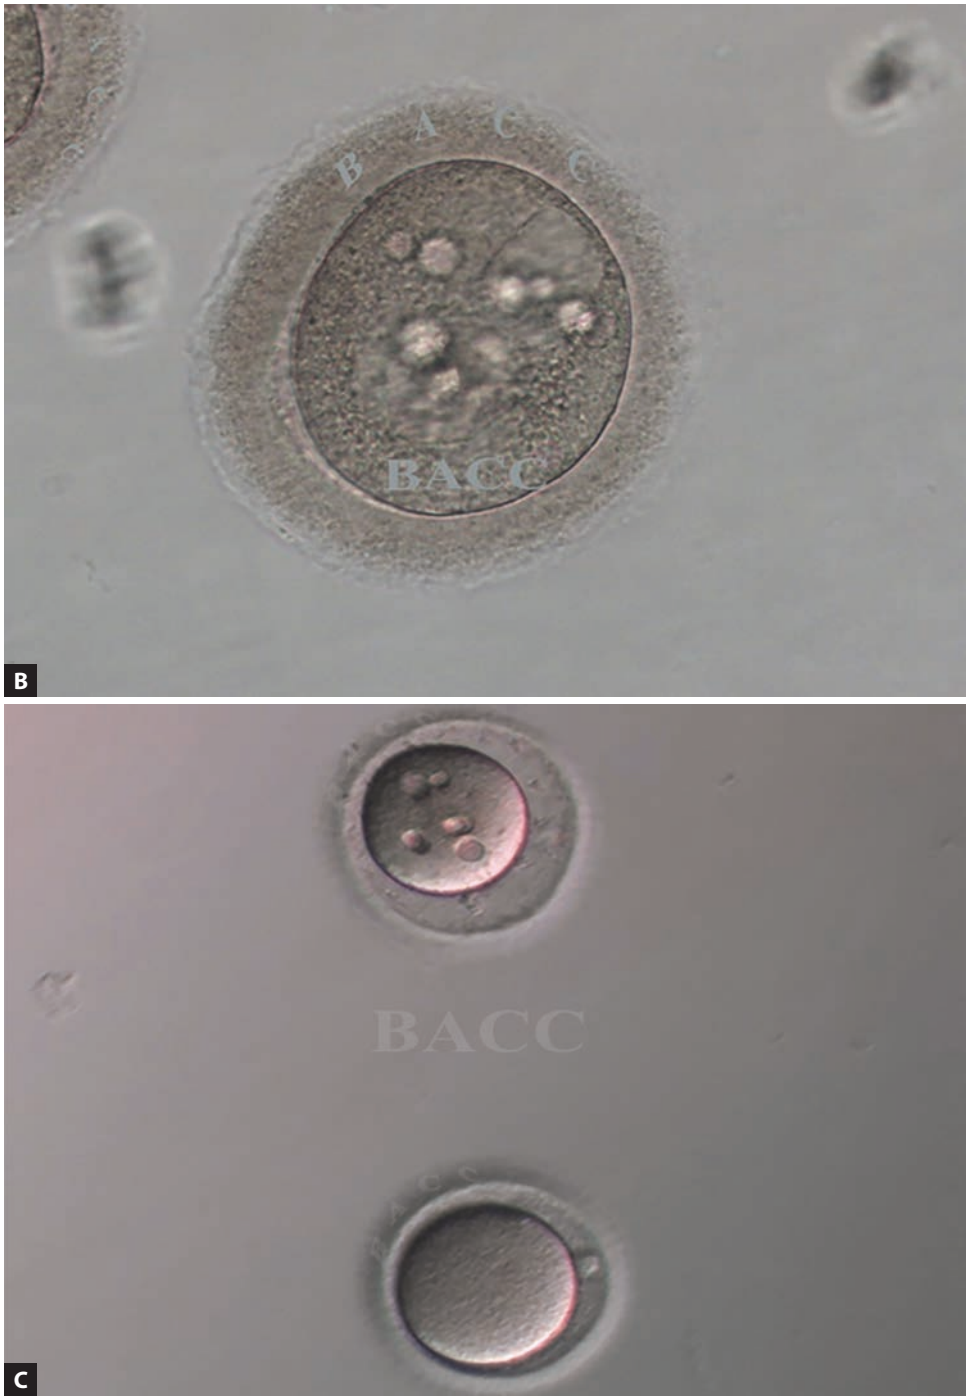
Fig. 4A: Single large vacuole in metaphase II oocyte.



Figs. 4B and C: Multiple vacuoles.

associated with developmental arrest. The later the vacuole arouse, the poorer the oocyte perform on blastocyst formation.[4]

SMOOTH ENDOPLASMIC RETICULUM CLUSTER

Under inverted microscopy, smooth endoplasmic reticulum (SER) clusters can be morphologically distinguished from fluid-filled vacuoles. SER clusters are pronuclear sized, flat clear disk-like structures **(Fig. 5)**. Presence of SER cluster has been associated with poor fertilization and embryo development.[5,6]

REFRACTILE BODIES

The refractile body, so called because of its nature under bright-field microscopy. The evolution of this structure and its relationship to oocyte maturity and viability are not yet fully understood **(Figs. 6A and B)**.

POLAR BODY

First polar body is believed to indicate the postovulatory age of the oocyte. Different authors have found a significant relationship between first polar body (IPB) morphology and blastocyst formation, implantation and ongoing pregnancy **(Figs. 7A to F)**.[7]

According to Ebner et al.[8] categories of IPB have been described:

- *Grade 1:* Round or ovoid, intact (smooth surface)
- *Grade 2:* Round or ovoid, intact (rough surface)
- *Grade 3:* Fragmented
- *Grade 4:* Broken in two
- *Grade 5:* Huge IPB

PERIVITELLINE SPACE

Abnormalities of perivitelline space (PVS) could be enlargement at one or more areas or PVS granularity/fragments **(Figs. 8A to D)**.

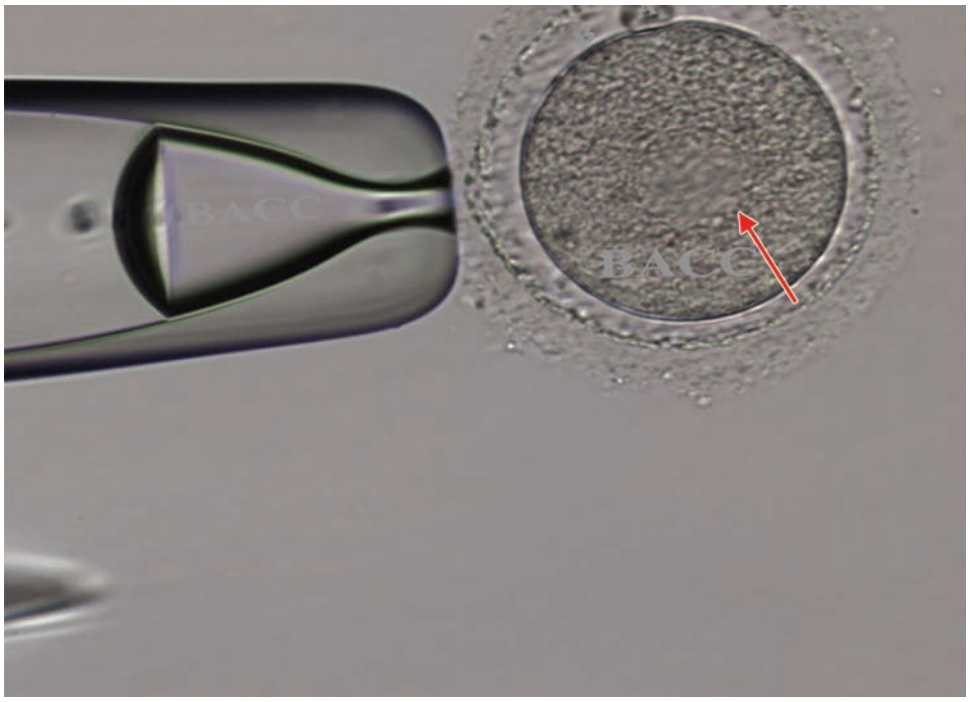


Fig. 5: Oocyte with smooth endoplasmic reticulum (SER) cluster (arrow).

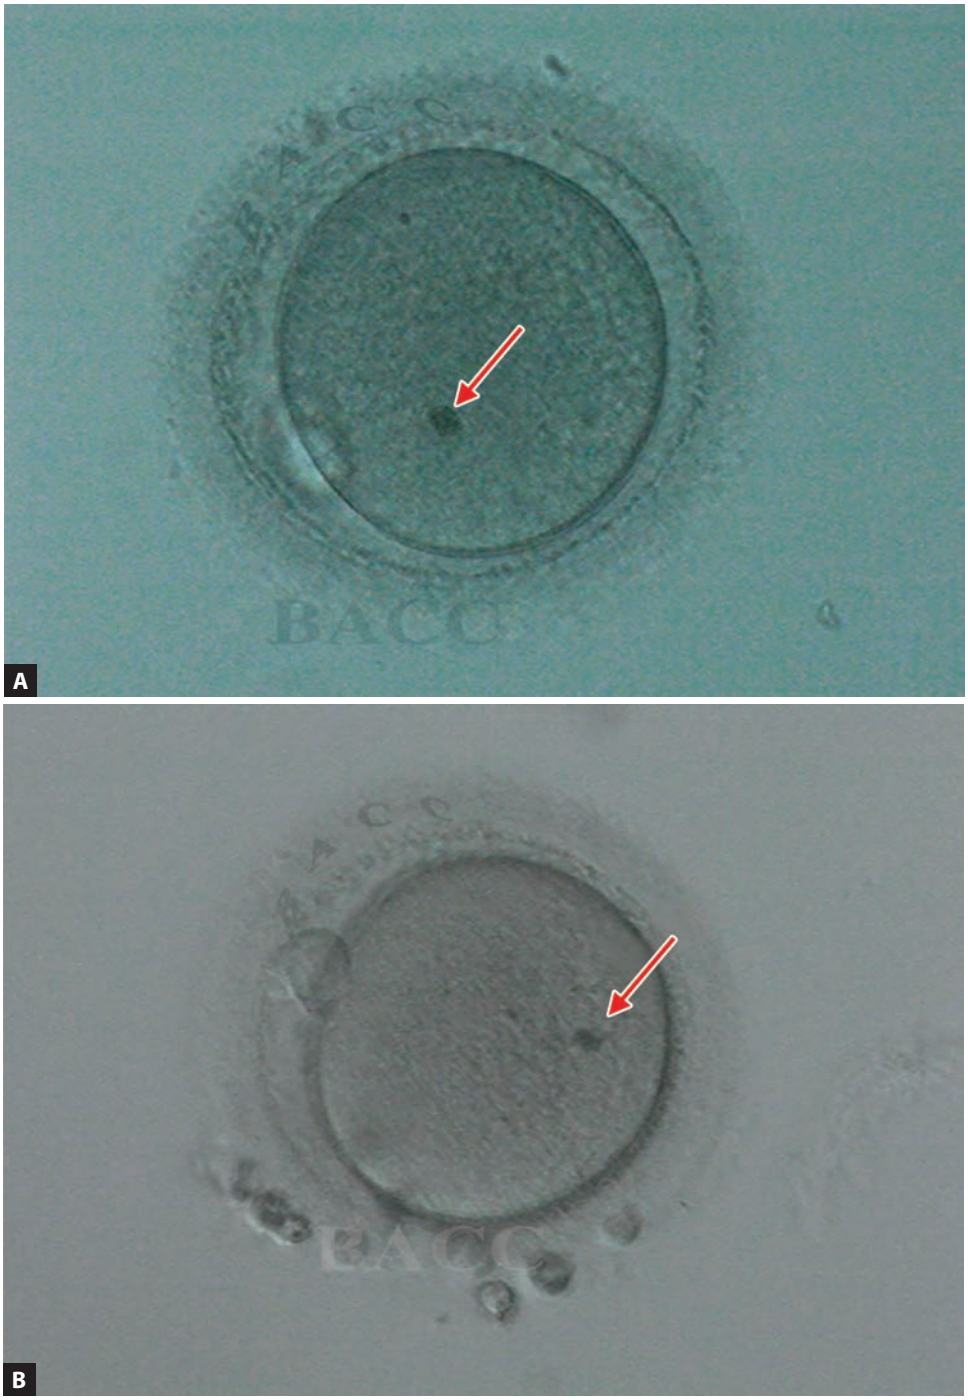

Figs. 6A and B: Refractile body (arrows).

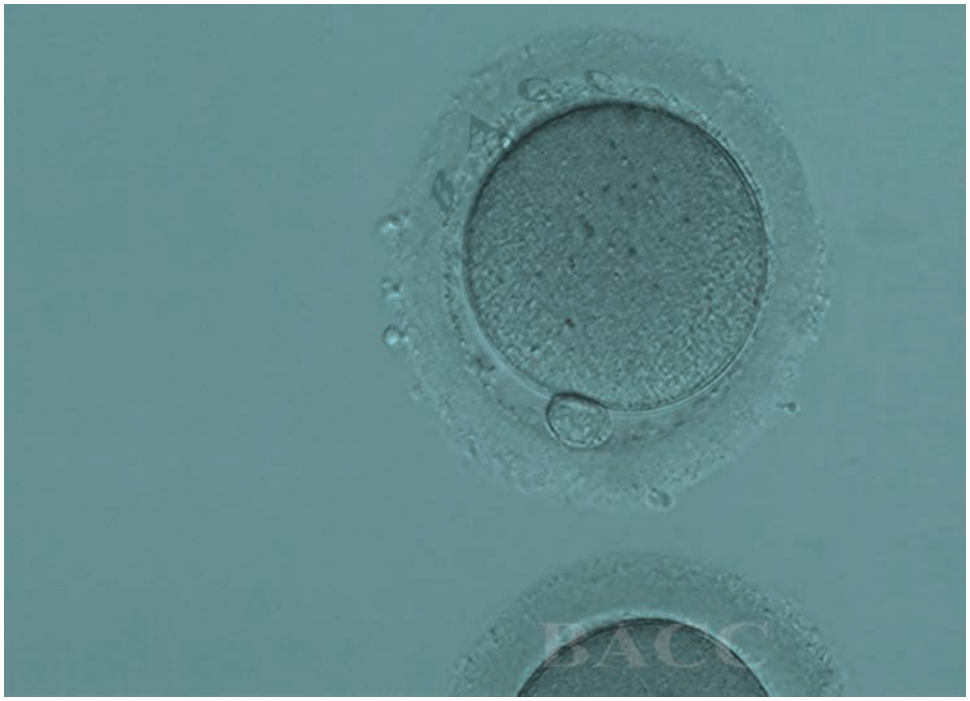

Fig. 7A: Polar body with smooth surface.

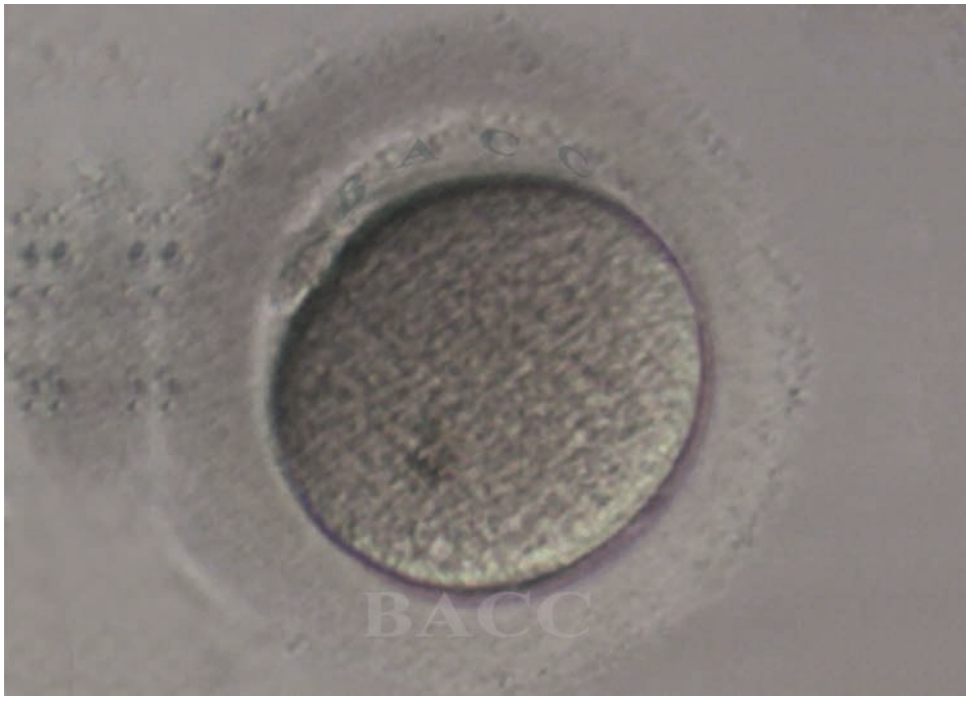

Fig. 7B: Polar body with rough surface.

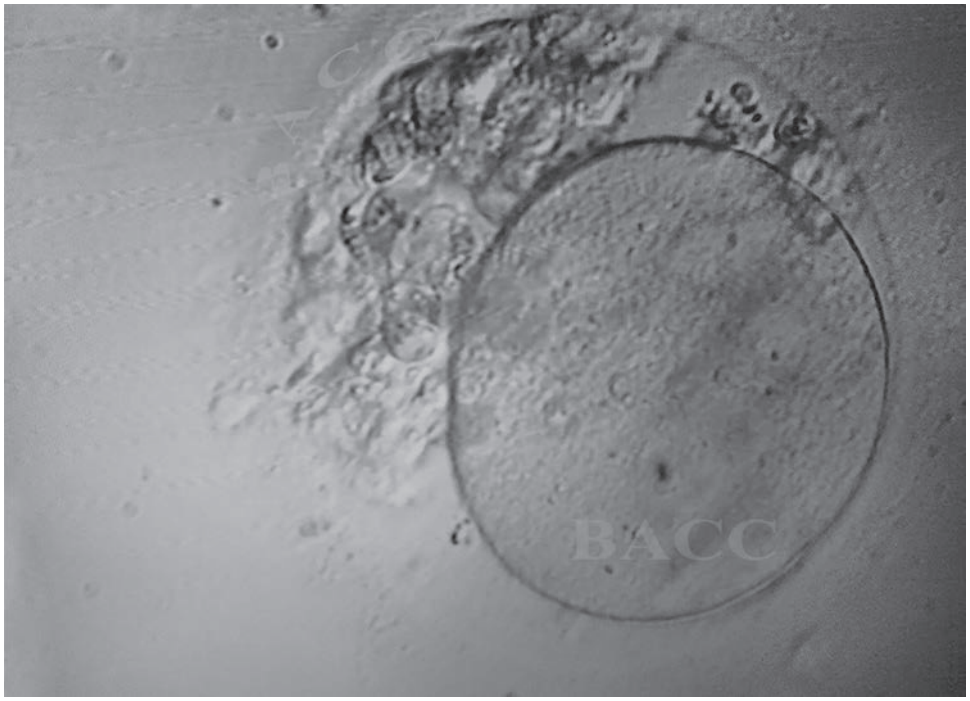

Fig. 7C: Fragmented polar body.

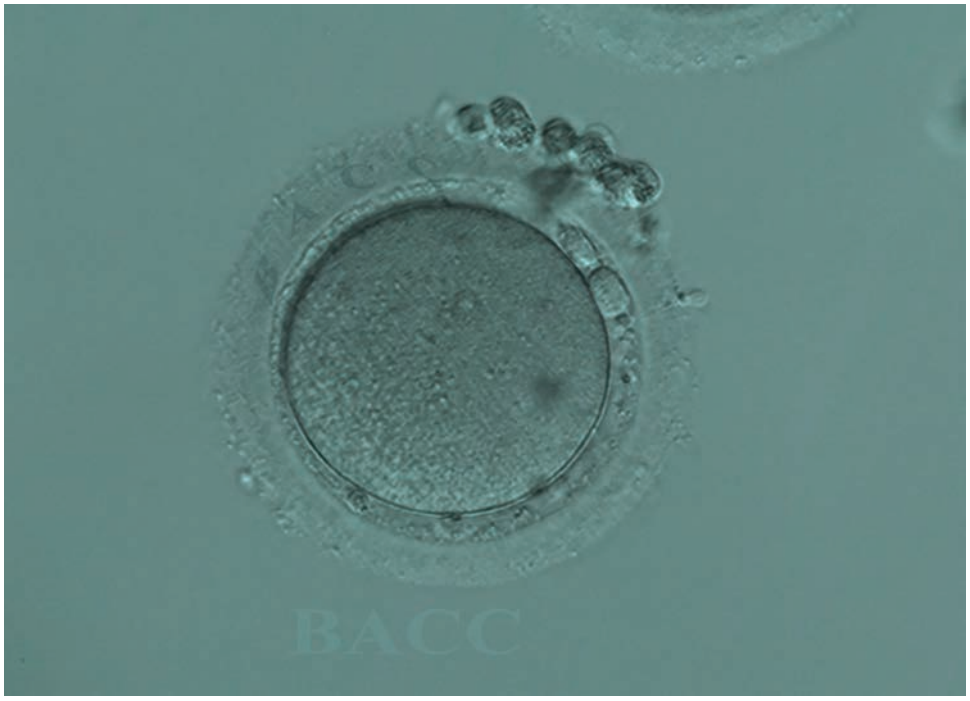

Fig. 7D: Polar body broken into two.

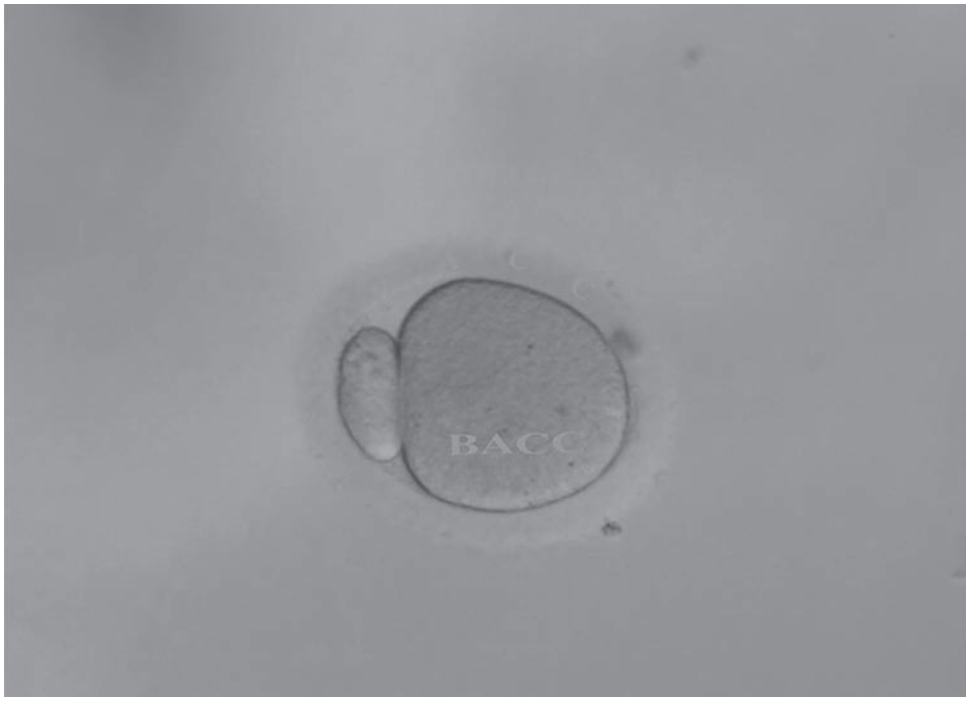

Fig. 7E: Large first polar body.

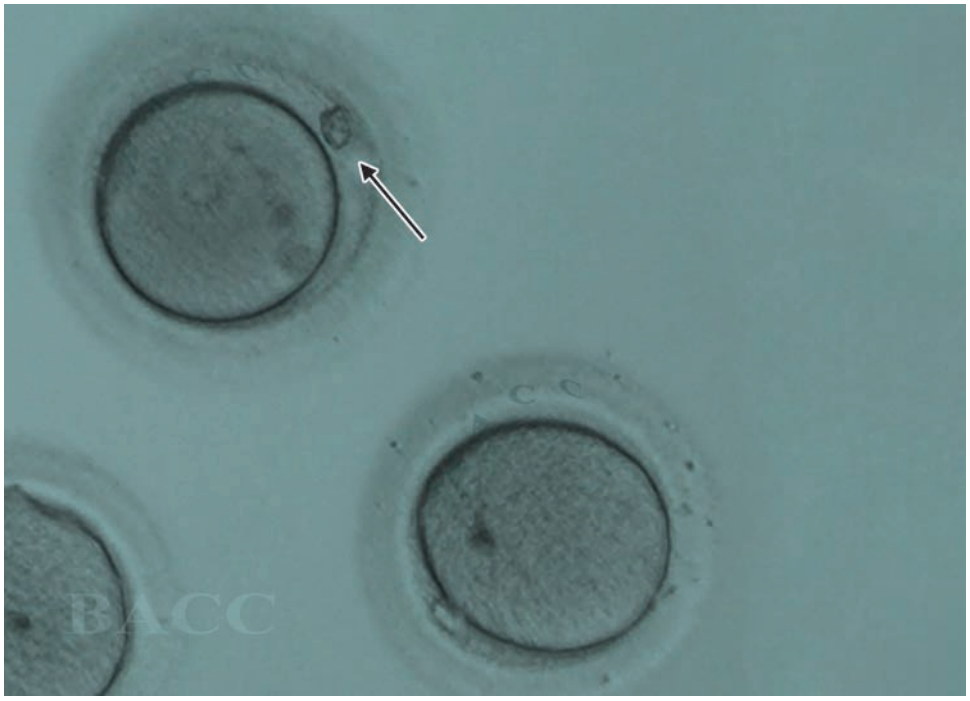

Fig. 7F: First polar body detached from ooplasm (arrow).

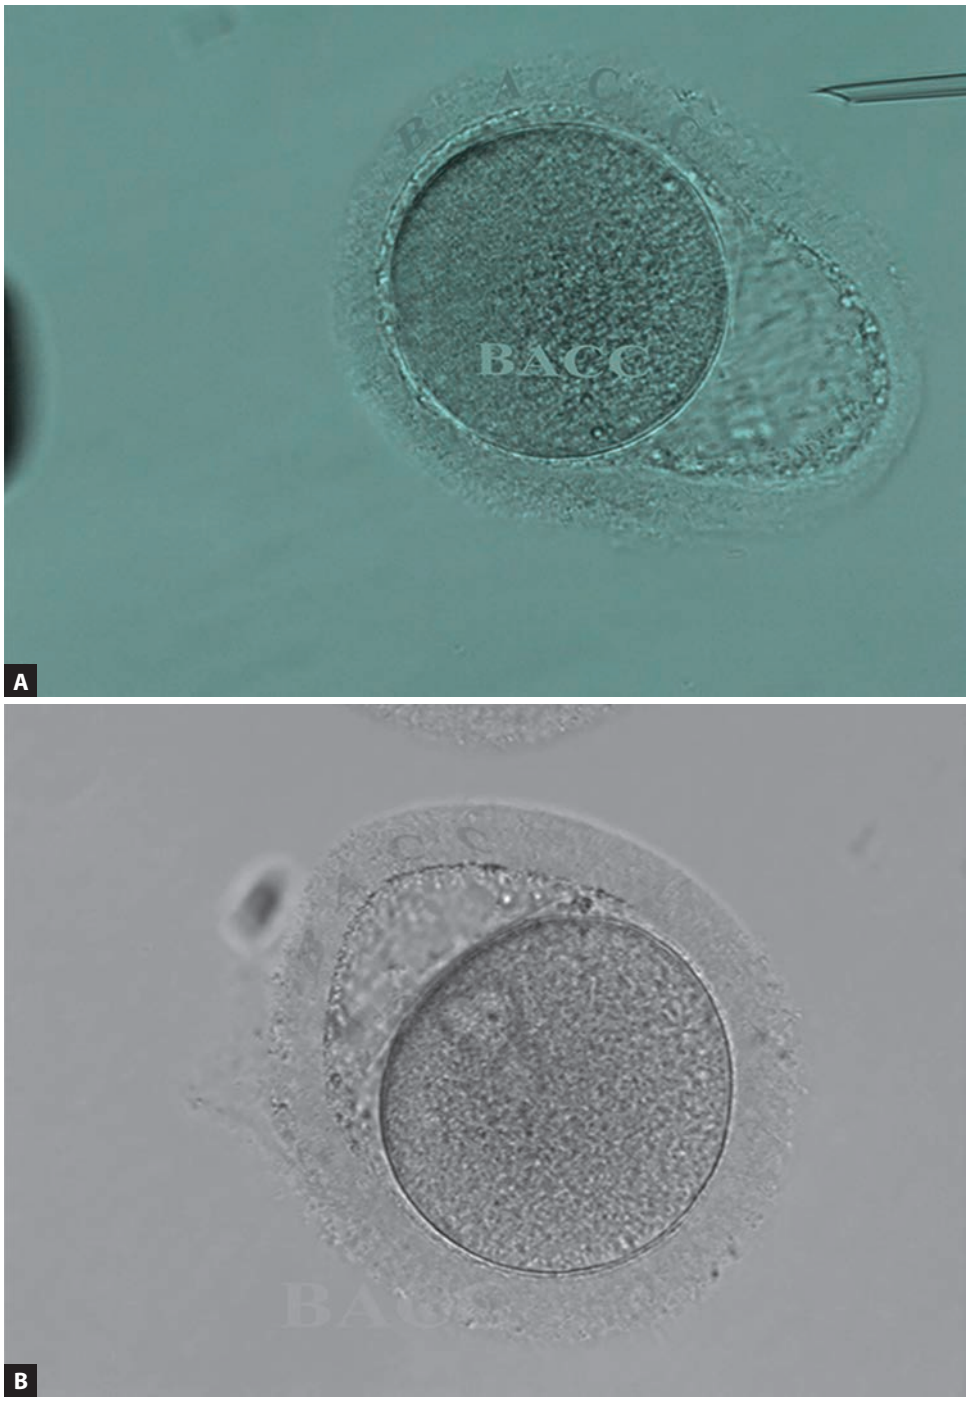

Figs. 8A and B: Increased perivitelline space with septa.

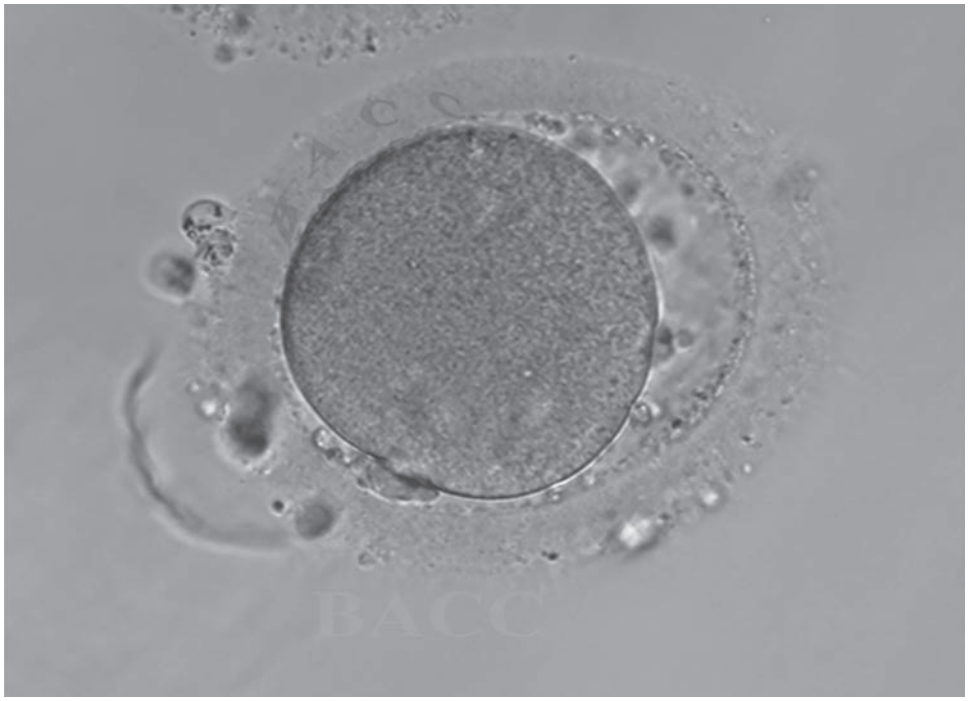

Fig. 8C: Increased perivitelline space with granulations.

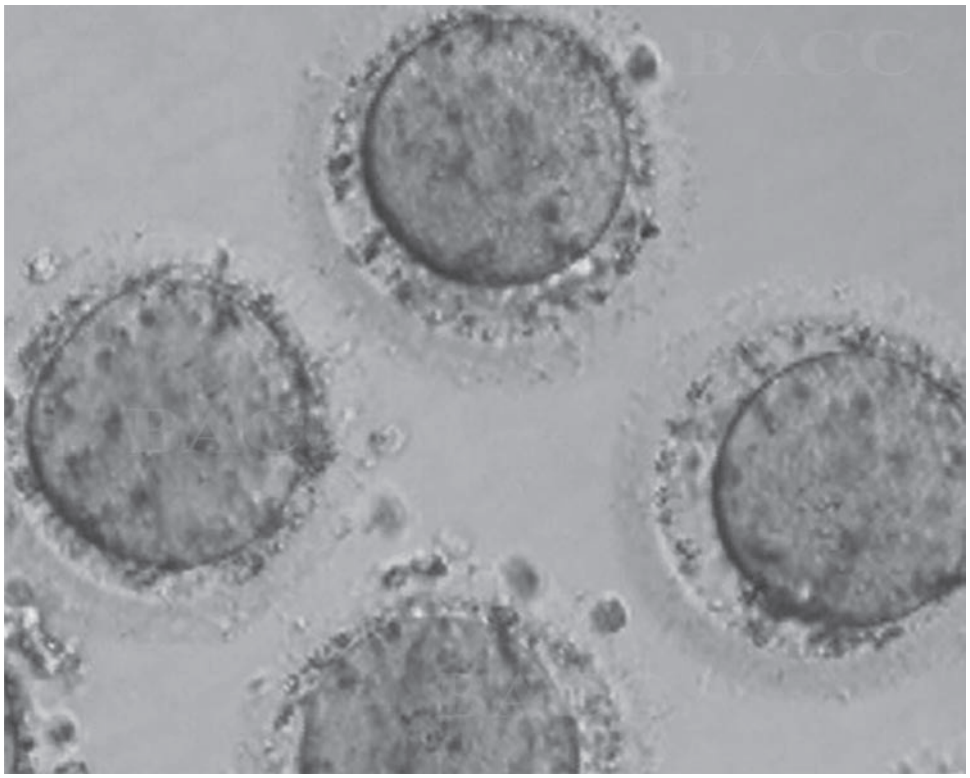

Fig. 8D: Increased perivitelline debris in the perivitelline space (PVS).

ZONA PELLUCIDA

The zona pellucida (ZP) is a transparent, extracellular matrix composed of defined glycoproteins built in a typical fibrogranular structure by noncovalent interactions.[9] Abnormalities of ZP can be in its thickness and sometimes even absent zona **(Figs. 9A to H)**.

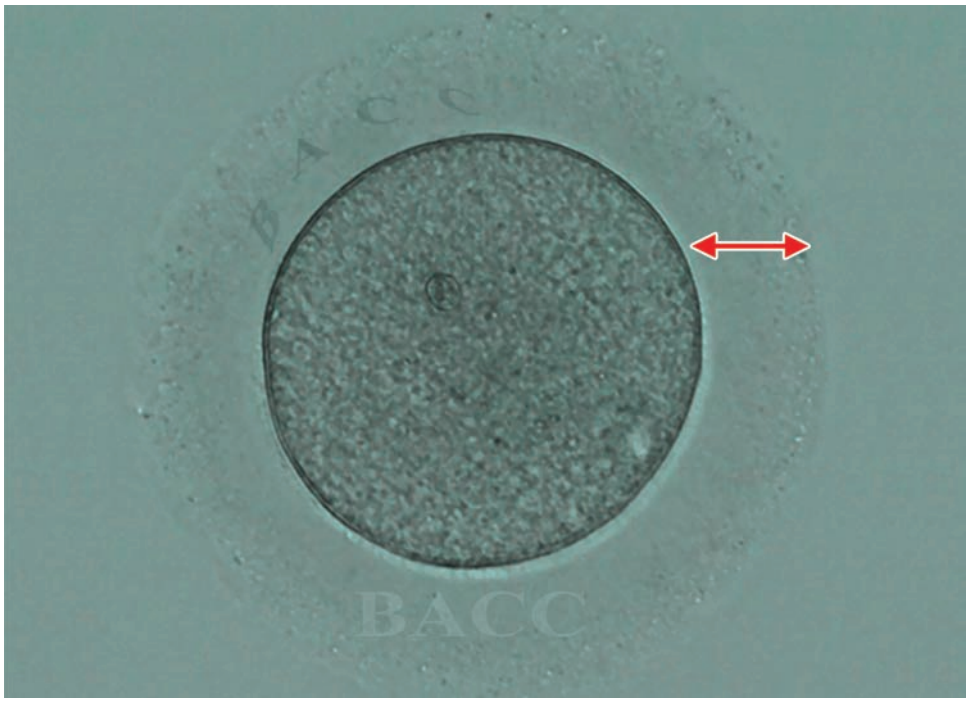

Fig. 9A: Thick zona pellucida surrounding the oocyte.

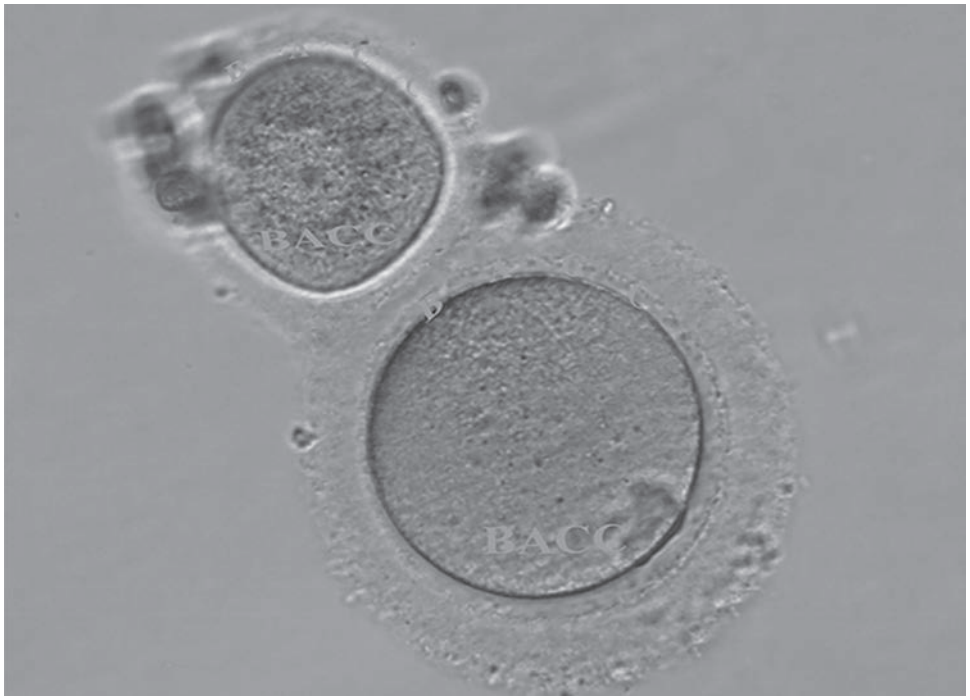

Fig. 9B: Two oocytes were recovered within a single zona pellucida, the smaller oocyte has a germinal vesicle and larger oocyte is metaphase I.

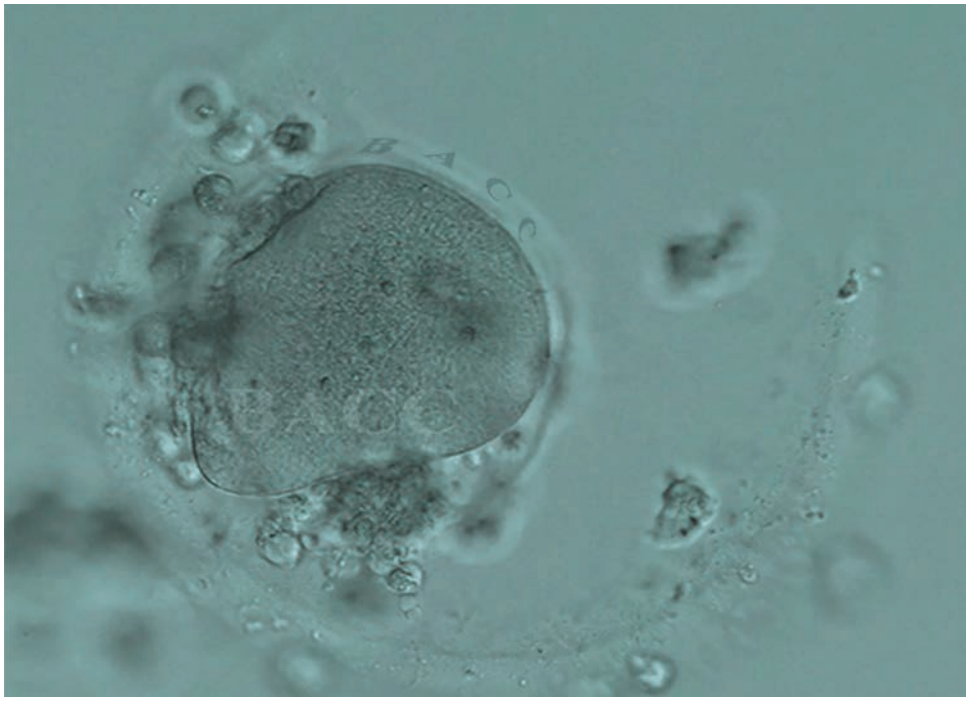

Fig. 9C: Oocyte with double zona.

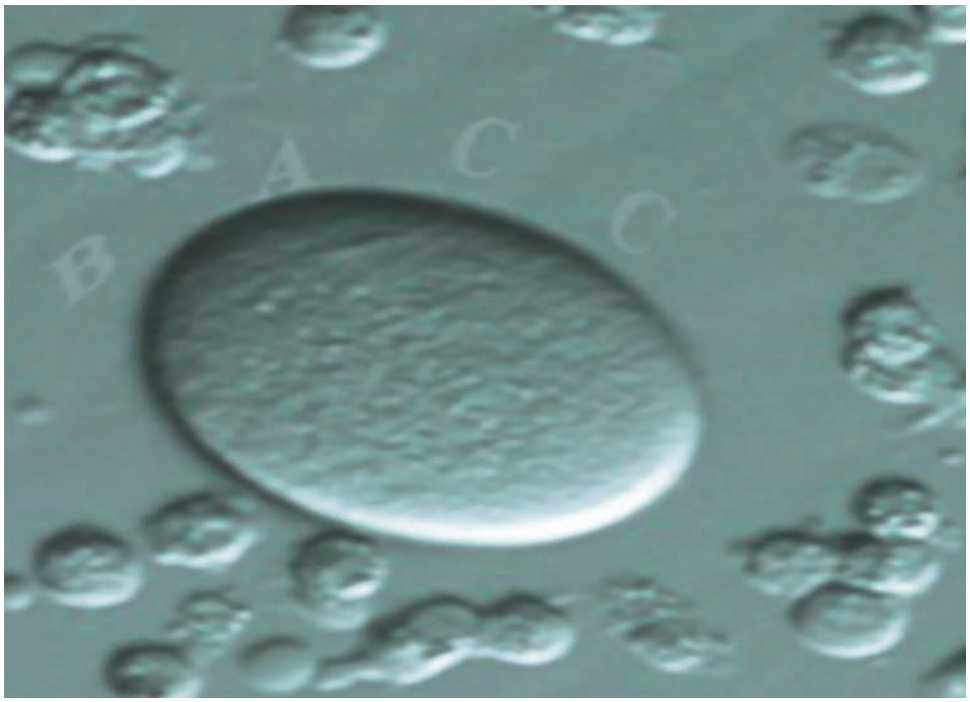

Fig. 9D: Oocyte with absent zona (one of the reason could be high suction pressure due to which zona pellucida can break).

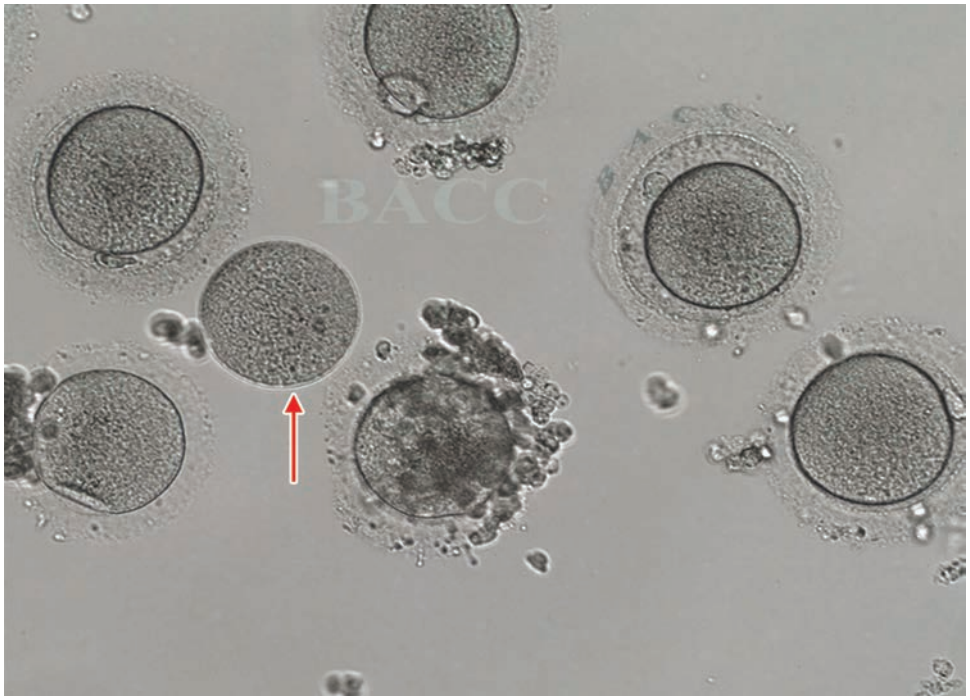

Fig. 9E: Oocyte cohort with one of the oocyte having absent zona (arrow).

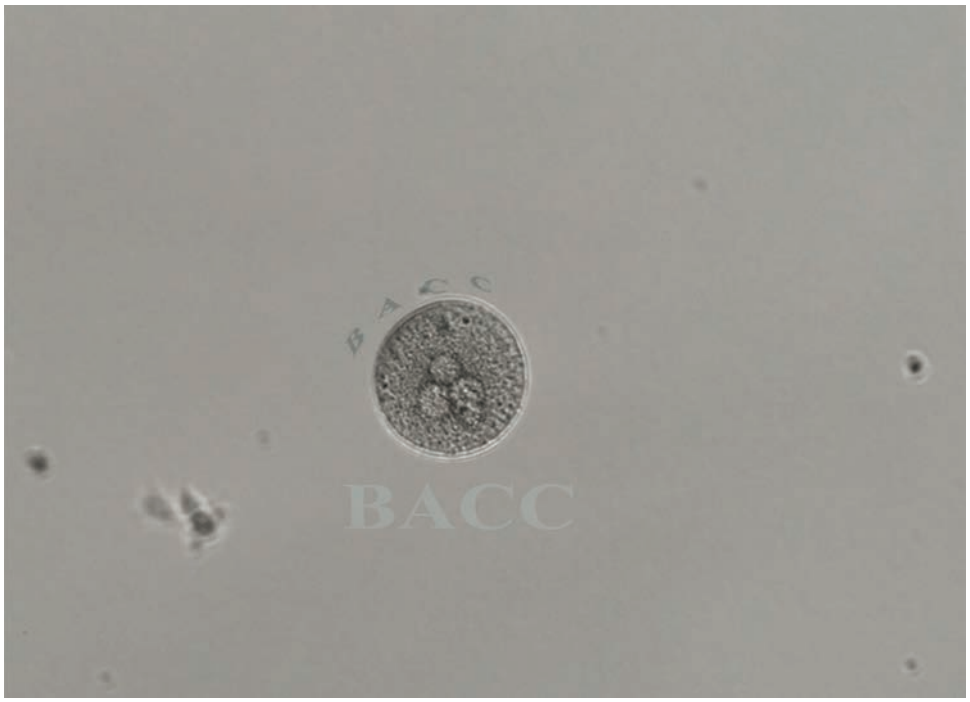

Fig. 9F: The same oocyte at 18 hours postinsemination showing evidence of fertilization, with two pronuclei, and a single vacuole.

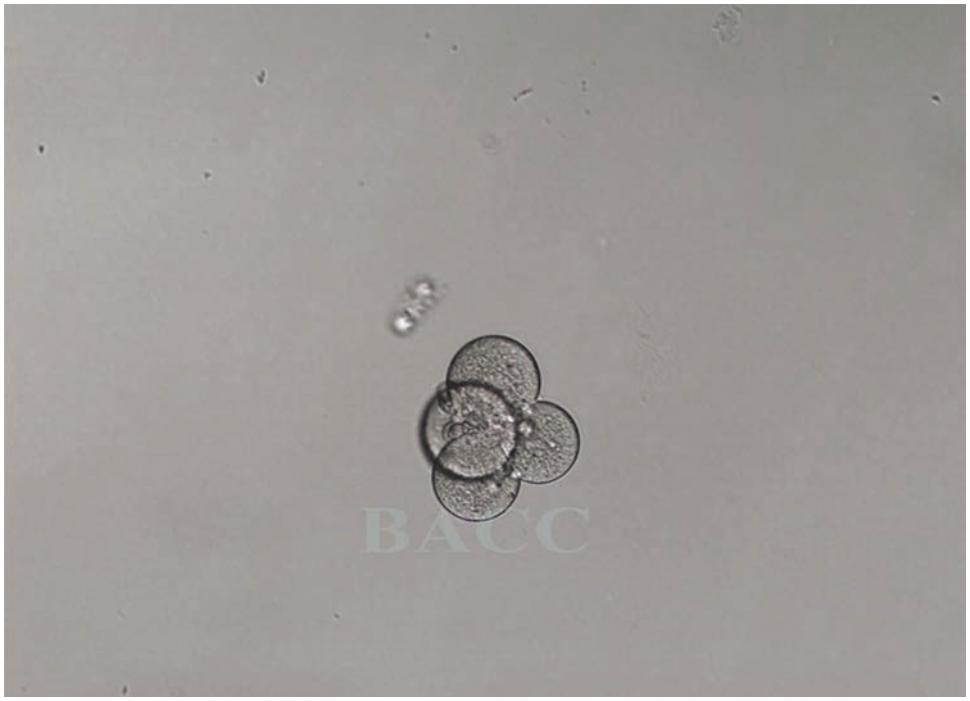

Fig. 9G: Four-cell embryo, with absent zona. (200x magnification). This is the same embryo which was obtained after fertilizing the oocyte with empty zona shown in the previous figures. The embryo got arrested at four-cell stage.

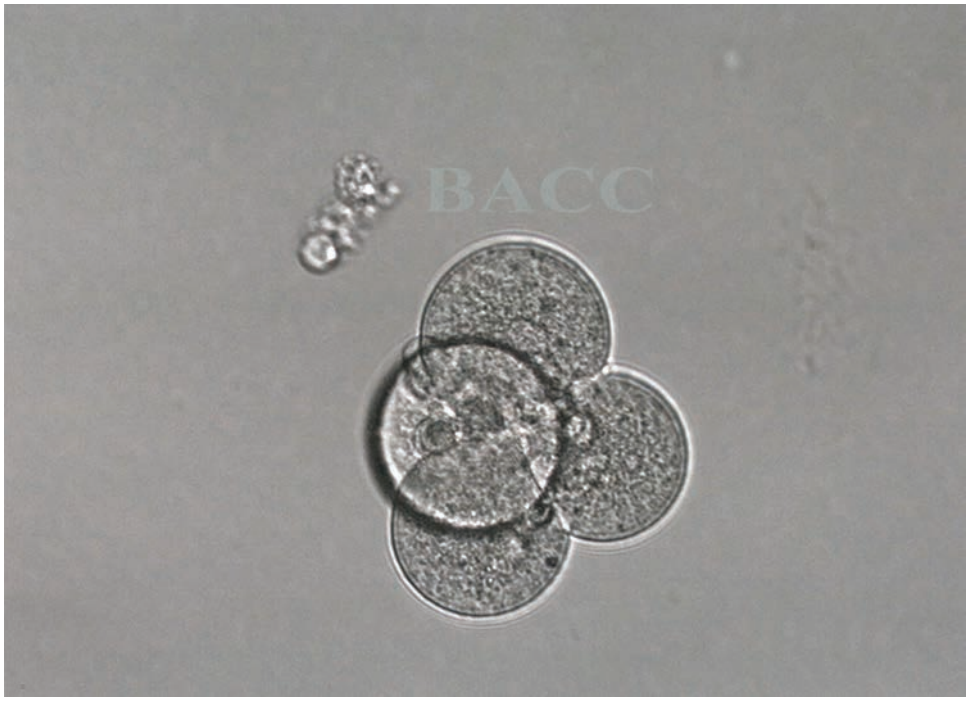

Fig. 9H: Four-cell embryo, with absent zona. (400x magnification)

CHAPTER 130

The Sperm

Anitha S Kumari K, Dileep Kumar R, Hemanth Kumar MA, Mohammed Ashraf C

INTRODUCTION

The sperm cell is a specialized cell and plays a role in transfer of paternal deoxyribonucleic acid (DNA) and activation of the mature egg. It is composed of three parts—head, mid-piece and tail. The head is connected to the mid-piece by a short region, the neck.

During evaluation of male infertility, semen analysis is the cornerstone of laboratory evaluation and helps to define the severity of male factor.

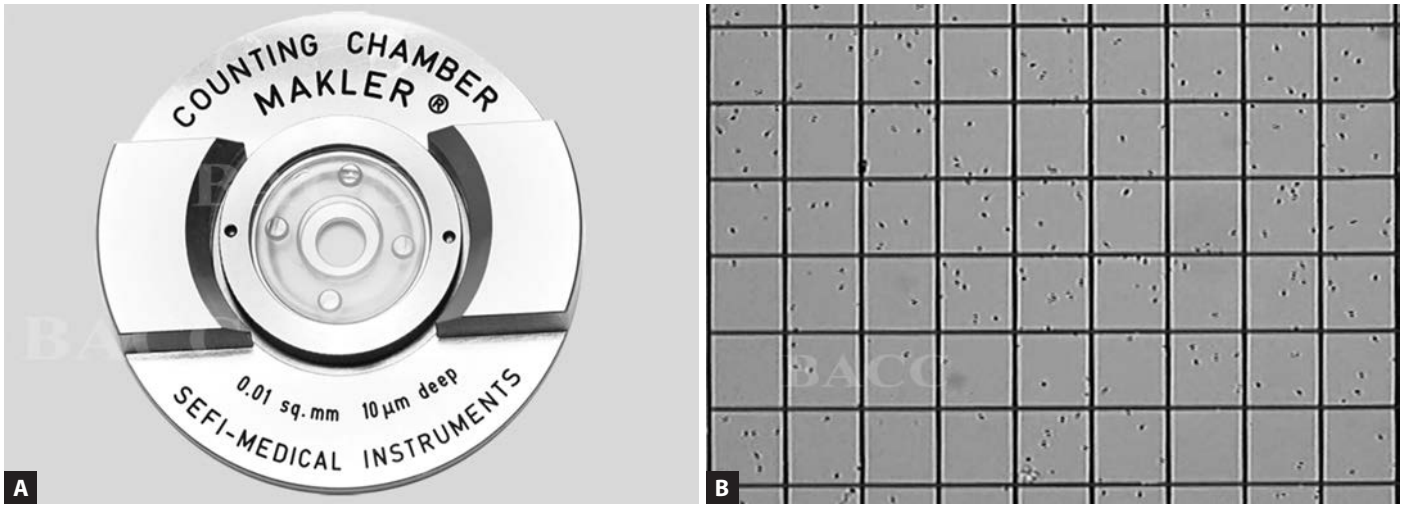
The semen analysis provides information on semen volume as well as sperm concentration, motility and morphology.[1]

Components of sperm evaluation include:

- Sperm count **(Figs. 1A and B)**
- Sperm motility **(Figs. 1A and B)**
- Sperm morphology **(Figs. 2A to C)**
- Globozoospermia **(Figs. 3A and B)**
- Sperm vitality **(Figs. 4A to C and 5A to C)**
- Sperm DNA fragmentation **(Figs. 6A and B)**

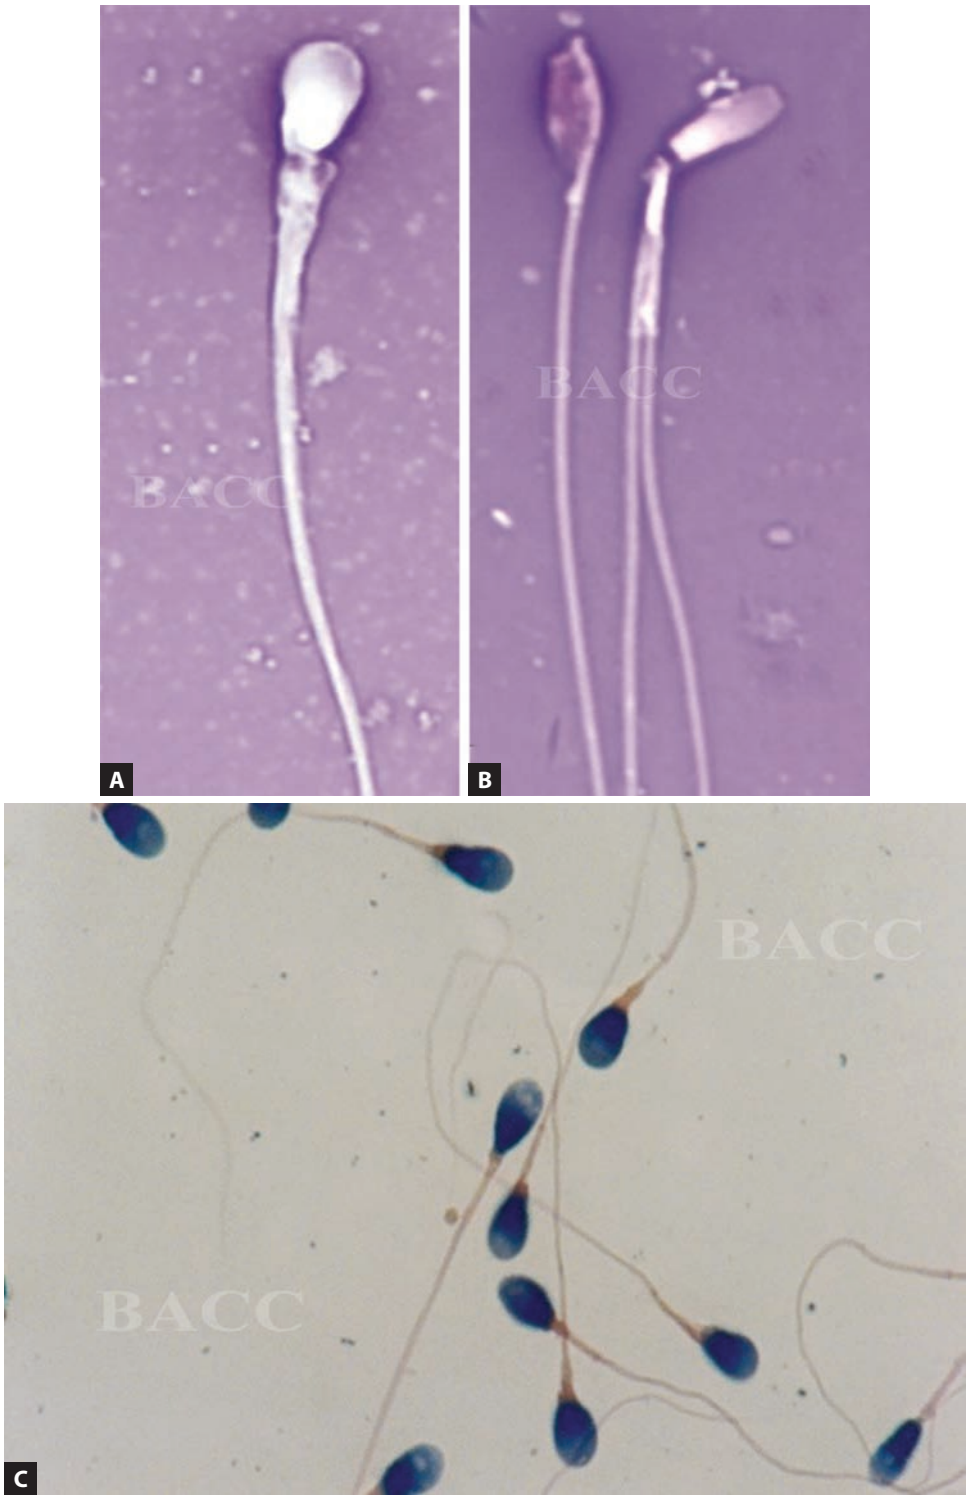
SPERM COUNT AND MOTILITY

Makler chamber is designed specifically for assessing the sperm concentration and motility. The advantage of Makler chamber is that no dilution is required to assess the semen sample **(Figs. 1A and B)**.



Figs. 1A and B: (A) Makler chamber; (B) Makler chamber charged with sperms at 200x magnification.

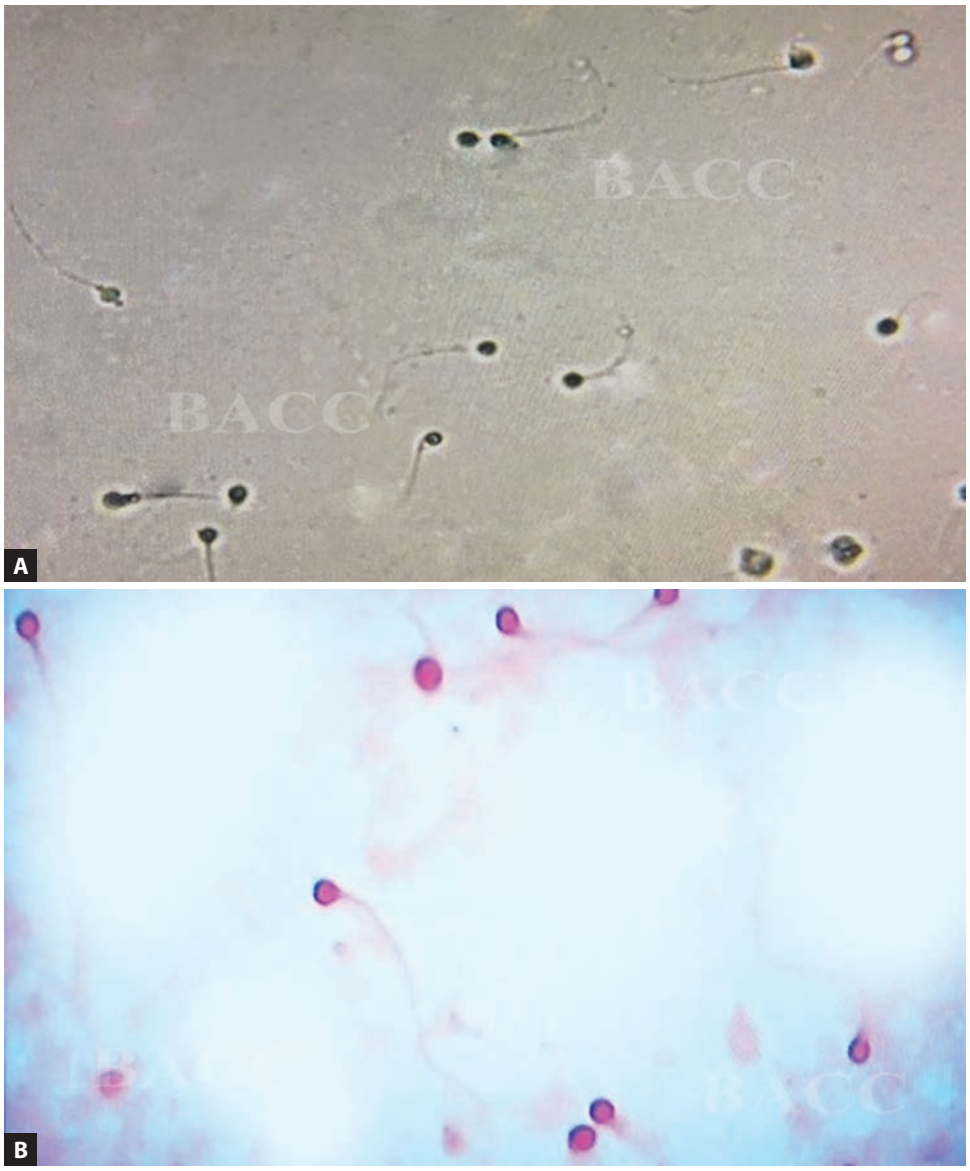
SPERM MORPHOLOGY (FIGS. 2A TO C)



Figs. 2A to C: Sperm morphology. (A) Eosin-Nigrosin stained smear showing sperm with defective mid-piece; (B) Eosin-Nigrosin stained smear showing sperm abnormalities. Sperm on the left showing amorphous head and sperm on the right showing duplication of tail; and (C) Sperm morphology with papanicolaou stain.

GLOBOZOOSPERMIA (ACROSOMAL AGENESIS)

Globozoospermia (round headed sperm syndrome) exhibits a partial or a complete lack of acrosome and acrosomal enzymes which make the sperm completely unable to penetrate the zona pellucida **(Figs. 3A and B)**.



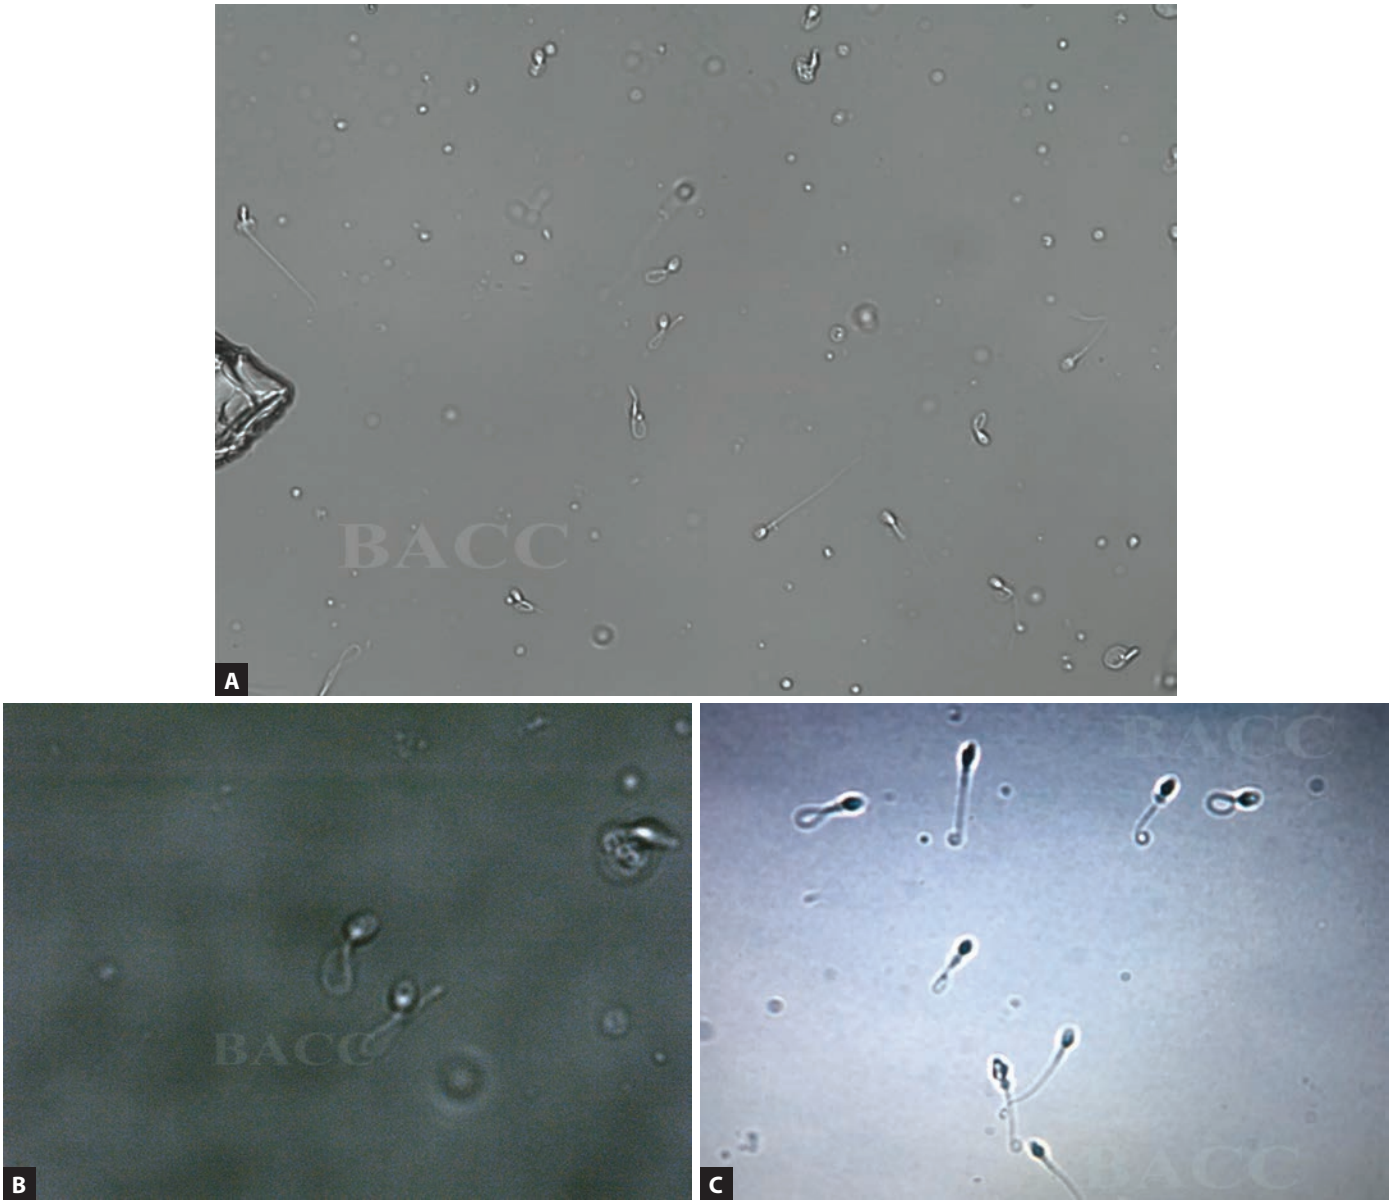
Figs. 3A and B: (A) Depicts globozoospermia in real time; (B) Depicts globozoospermia with eosin-hematoxylin staining technique.

SPERM VITALITY

Sperm vitality is a technique evaluated by assessing the membrane integrity of the cells. The two techniques exclusively used for sperm vitality include dye-exclusion method and hypo-osmotic swelling test.

Sperm Vitality by Hypo-osmotic Swelling Test

Hypo-osmotic swelling (HOS) test is used to determine the viability of the sperm. In the HOS test, viable non-motile sperm will swell and also show the curling of tail when incubated in a hypo-osmotic solution as shown in **Figures 4A to C**.



Figs. 4A to C: (A) Hypo-osmotic swelling test (200×); (B and C) Hypo-osmotic swelling test (400×).

Sperm Vitality by Dye Exclusion Method

In this method, the nonvital (dead cells) allows the entry of membrane-impermeant stains where the live one does not allow the diffusion of stain **(Figs. 5A to C)**.

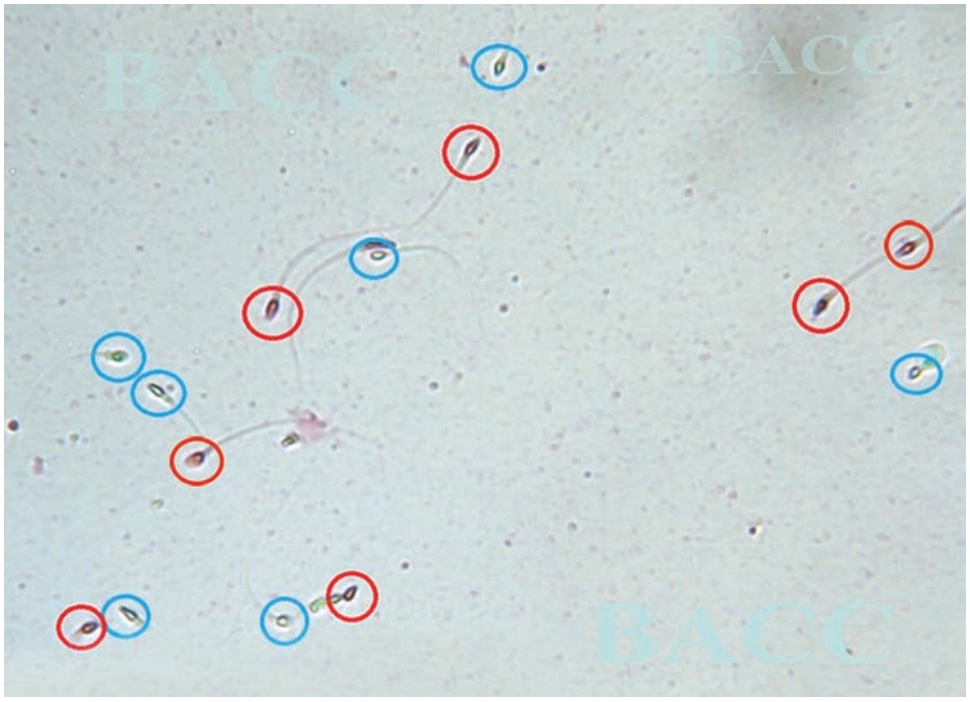


Fig. 5A: Dye-exclusion method with eosin stain. Red circle indicates spermatozoa with red or dark pink heads and are considered dead (membrane damaged). Blue circle indicates spermatozoa with white heads and is considered alive (membrane intact).

Fig. 5B: Sperm viability by staining. Eosin-Nigrosin stained smear showing, non-uptake of the dye by the sperm, indicating viability.

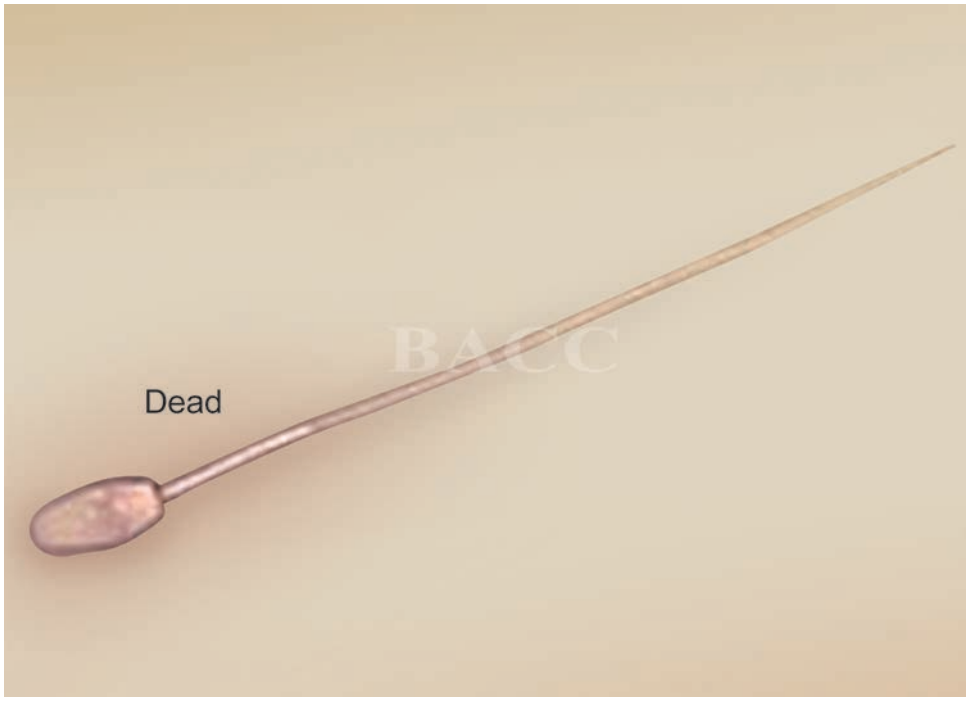

Fig. 5C: Sperm viability by staining. Eosin-Nigrosin stained smear showing, uptake of the dye by the sperm, indicating nonviability.

DEOXYRIBONUCLEIC ACID FRAGMENTATION INDEX

Deoxyribonucleic acid (DNA) integrity is important for normal embryo development. The term "DNA fragmentation" refers to denatured or damaged sperm DNA that cannot be repaired **(Figs. 6A and B)** shows the image of DNA fragmentation index (DFI).

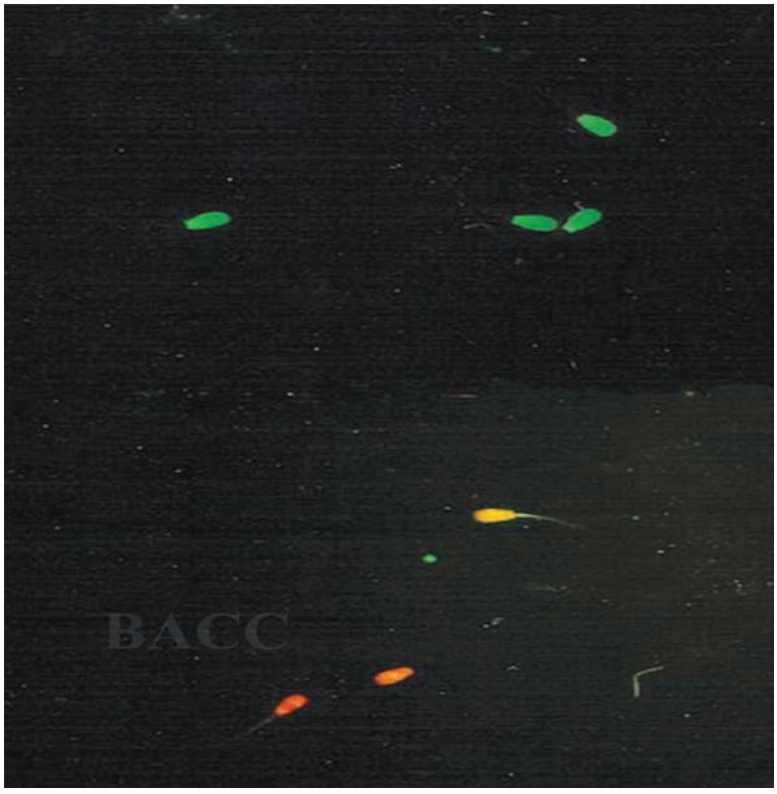

Fig. 6A: Deoxyribonucleic acid fragmentation index.

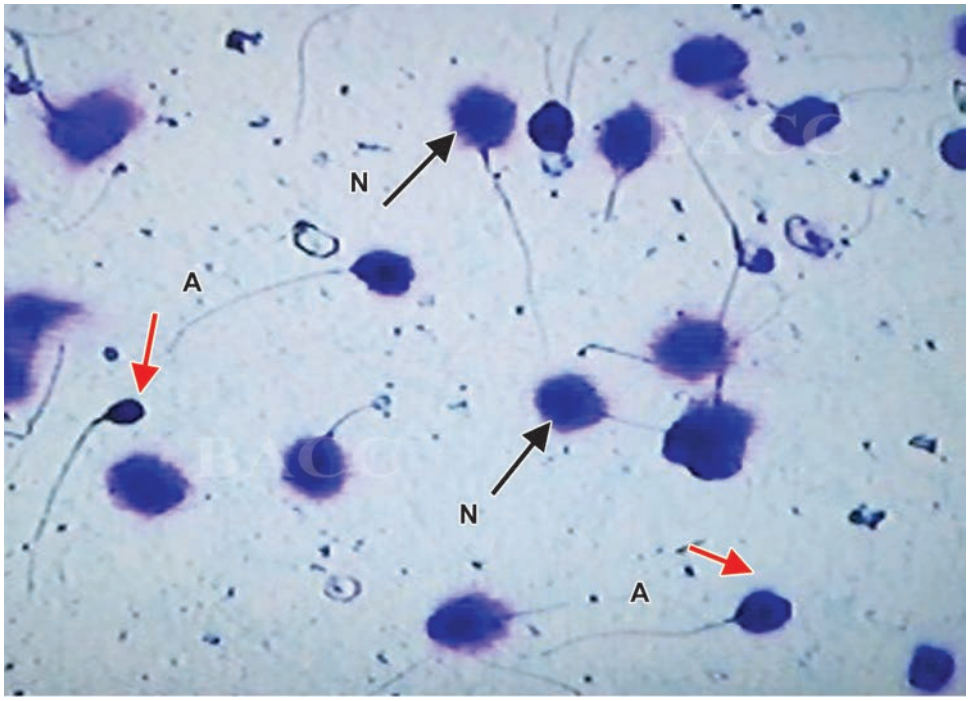

Fig. 6B: Deoxyribonucleic acid fragmentation index (DFI) using halosperm (based on SCD technique) where the normal forms show the halo and the sperms with abnormal DNA does not show halo. "A" represents sperms with fragmented DNA and "N" represents sperm cells with normal DNA.

CHAPTER 131

Normal Embryo Development

Bezar Ghan VV, Divyashree PS, Kamini A Rao

INTRODUCTION

Knowledge of the nature of embryo growth, and the handling and scoring of quality in human embryos are significant aspects for embryologists in in vitro fertilization (IVF) clinics.

Timing and reporting of observation of fertilized oocytes and embryos is very critical. This is because comparison of results between different laboratories becomes much easier and standardized.

According to Istanbul consensus 2011,[1] the expected stage of development at different points of time was standardized which is depicted in **Table 1** and **Figures 1 to 8**. The times given reflect the times at which these events occur in the majority of patients/cases.

TABLE 1: Timing of observation of fertilized oocytes and embryos and expected stage of development at each time point.

Type of observation	*Timing (hour postinsemination)*	*Expected stage of development*
Fertilization check (2 PN)	17 ± 1	Pronuclear stage
Syngamy check	23 ± 1 (post-ICSI) 28 ± 1 (post-IVF)	Expect 50% to be in syngamy (up to 20% may be at the two-cell stage)
Early cleavage	26 ± 1	Post-ICSI two-cell stage
Day-2 embryo assessment	44 ± 1	Four-cell stage
Day-3 embryo assessment	68 ± 1	Eight-cell stage
Day-4 embryo assessment	92 ± 2	Morula
Day-5 embryo assessment	116 ± 2	Blastocyst

(ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization; PN: pronuclear)

PRONUCLEAR STAGE (FIG. 1)

Fig. 1: Normally fertilized human oocytes in pronuclear stage, showing two prominent pronuclei and distinct nuclear precursor bodies.

SYNGAMY (FIG. 2)

Fig. 2: Normally fertilized oocyte in syngamy. Note the fusion of two pronuclei.

TWO-CELL STAGE (FIG. 3)

Fig. 3: Two-cell human embryo at 26 hours postinsemination. Nuclei are not visible and the elongated appearance of individual cells depicts further cell division is impending.

FOUR-CELL STAGE (FIG. 4)

Fig. 4: Four-cell stage human embryo, 44 hours postinsemination.

EIGHT-CELL STAGE (FIG. 5)

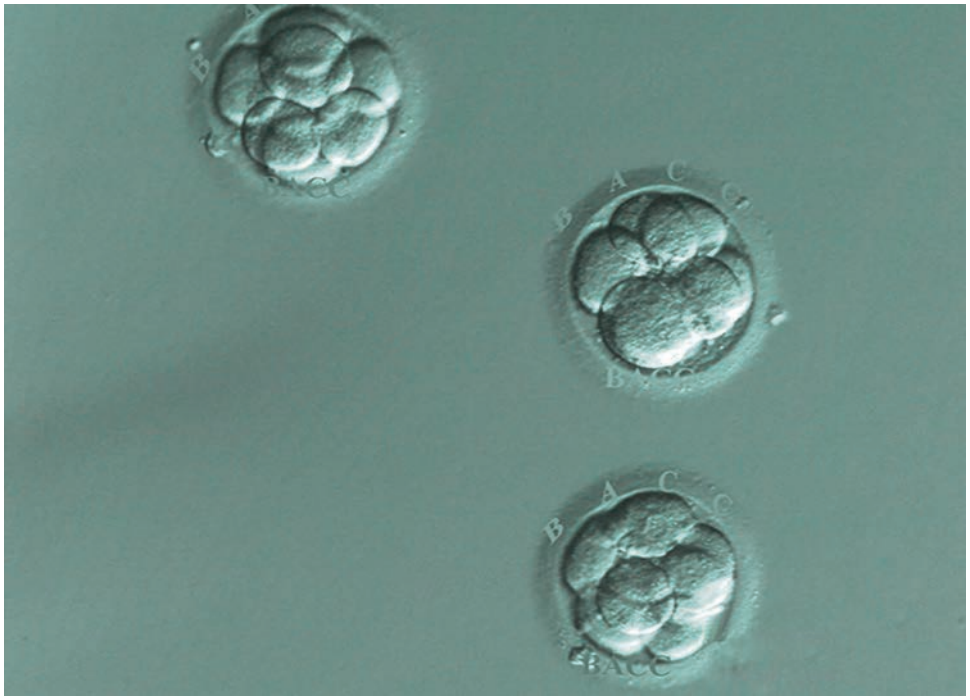

Fig. 5: An eight-cell embryo, 68 hours postinsemination.

COMPACTION (FIG. 6)

Fig. 6: Human embryo, 92 hours postinsemination. Note compaction, with cell membranes closely applied as tight junctions begin to form.

EARLY BLASTOCYSTS (FIG. 7A)

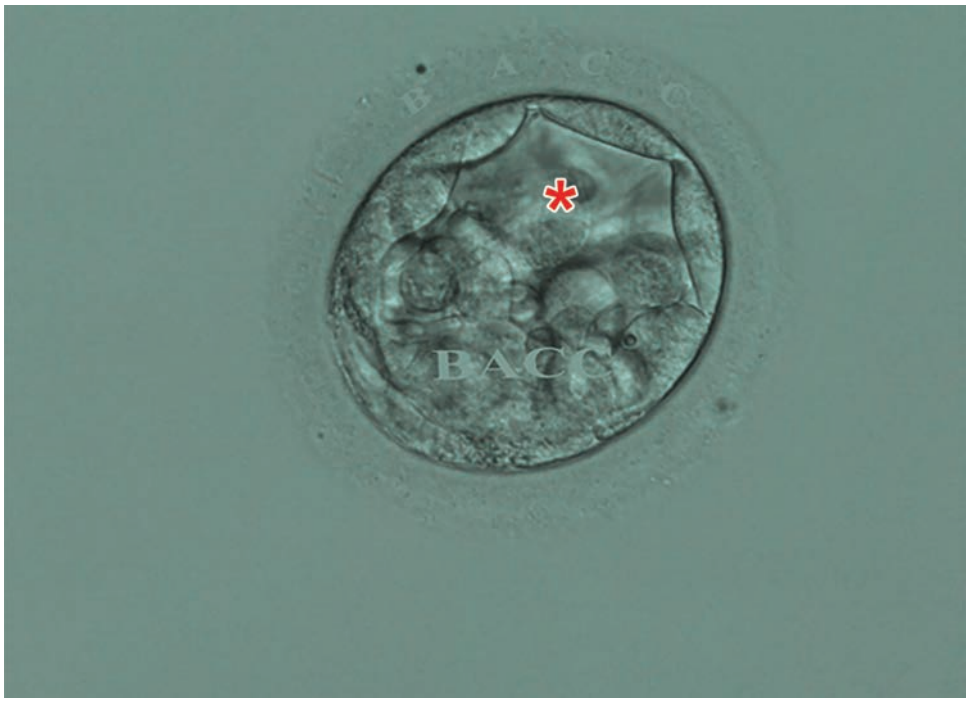

Fig. 7A: Human embryo in early blastocyst stage. Note the appearance of early cavity (asterix).

EXPANDED BLASTOCYSTS (FIG. 7B)

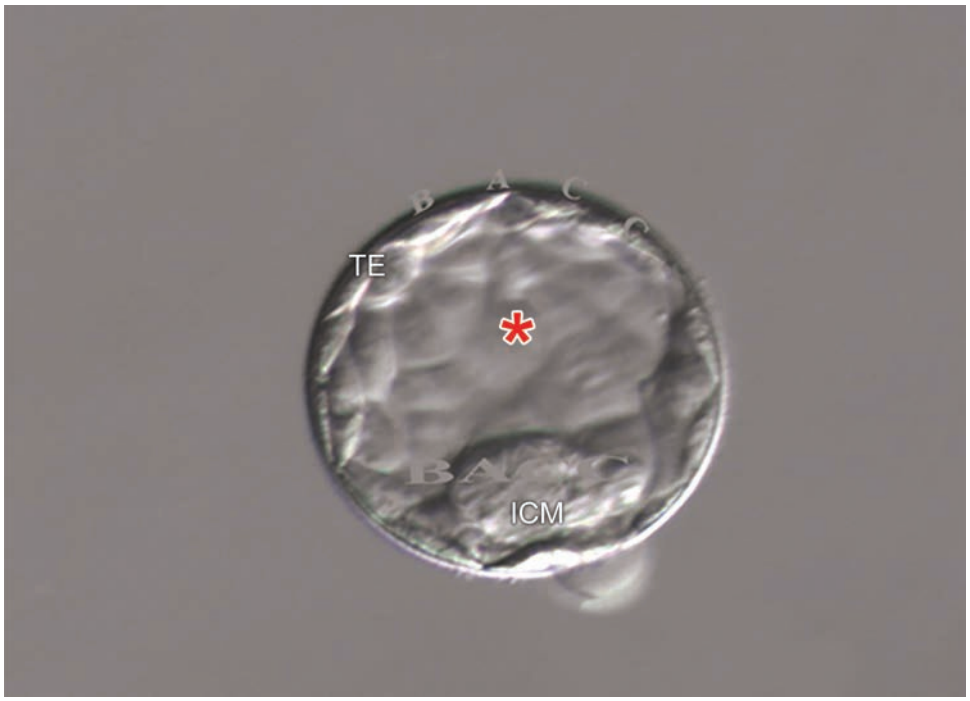

Fig. 7B: Fully expanded blastocyst, showing distinct inner cell mass (ICM), trophectoderm (TE) cells and blastocele cavity (asterix).

HATCHING BLASTOCYSTS (FIG. 7C)

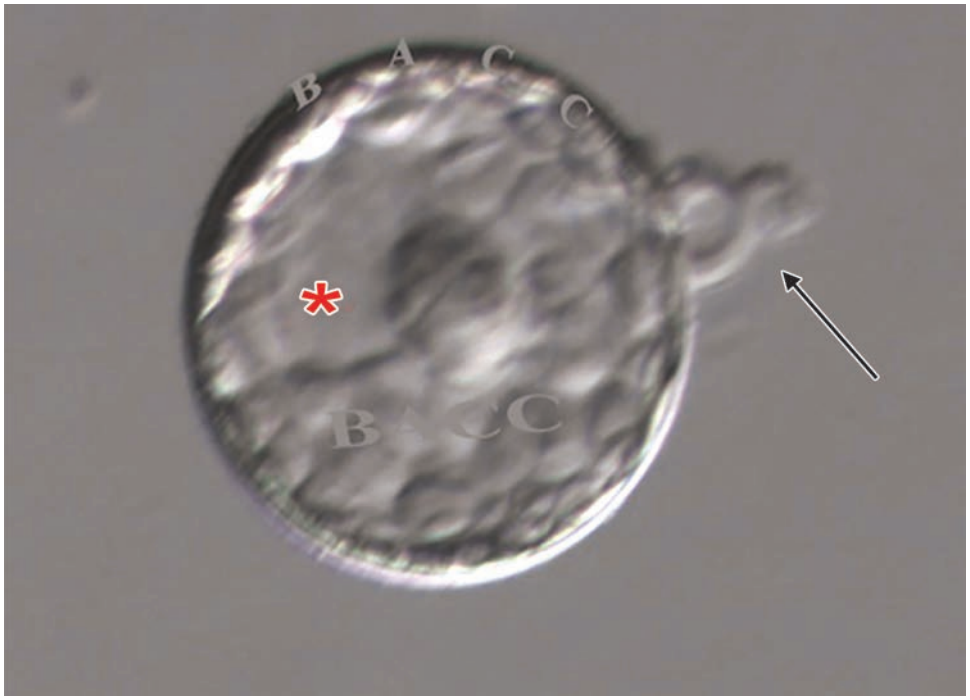

Fig. 7C: Early hatching of the blastocyst. Note the breaching of zona at the point of hatching (arrow) asterix-blastocele cavity.

HATCHED BLASTOCYSTS (FIG. 8)

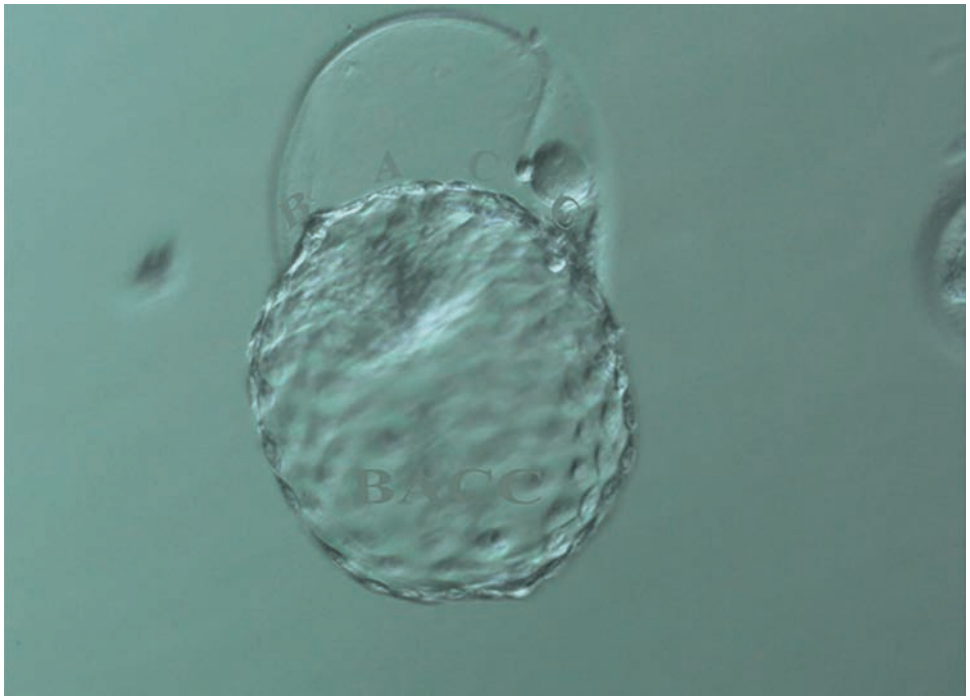

Fig. 8: Fully hatched blastocyst. Note the empty zona after blastocyst hatching.

CHAPTER 132

Embryo Scoring

Bezar Ghan VV, Divyashree PS, Anitha S Kumari K, Mohammed Ashraf C

INTRODUCTION

For standardized reporting and to minimize diversities in reporting of embryo scoring, Istanbul global consensus scoring system for embryo[1] has been used in the present chapter **(Tables 1 to 4)**.

TABLE 1: Consensus scoring system for pronuclei (Figs. 1 to 3).

Category	*Rating*	*Description*
1	Symmetrical	Equivalent to Z1 and Z2
2	Nonsymmetrical	Other arrangements, including peripherally sited pronuclei
3	Abnormal	Pronuclei with 0 or 1 nucleolar precursor bodies (NPBs)

SYMMETRICAL PRONUCLEI (FIGS. 1A TO C)

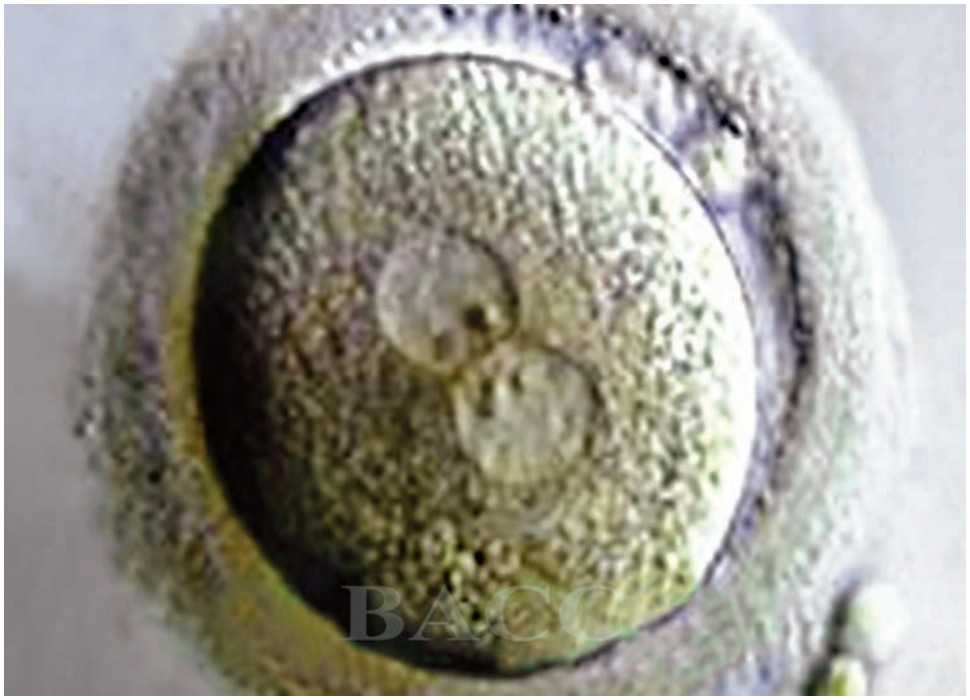

Fig. 1A: Human embryo in the pronuclear stage with two symmetrical pronuclei, equal number of nuclear precursor bodies (NPBs2), in juxtaposition and two polar bodies at 1 o'clock position.

Fig. 1B: Pronuclear stage embryo with centrally located symmetrical pronuclei, juxtaposed and equal nuclear precursor bodies (NPBs3), two interposed polar bodies at 8 o'clock position.

Fig. 1C: Embryo with two symmetrical pronuclei with juxtaposed nuclear precursor bodies (NPBs) unequal in number. Two polar bodies can be seen at the background.

NONSYMMETRICAL PRONUCLEI (FIGS. 2A AND B)

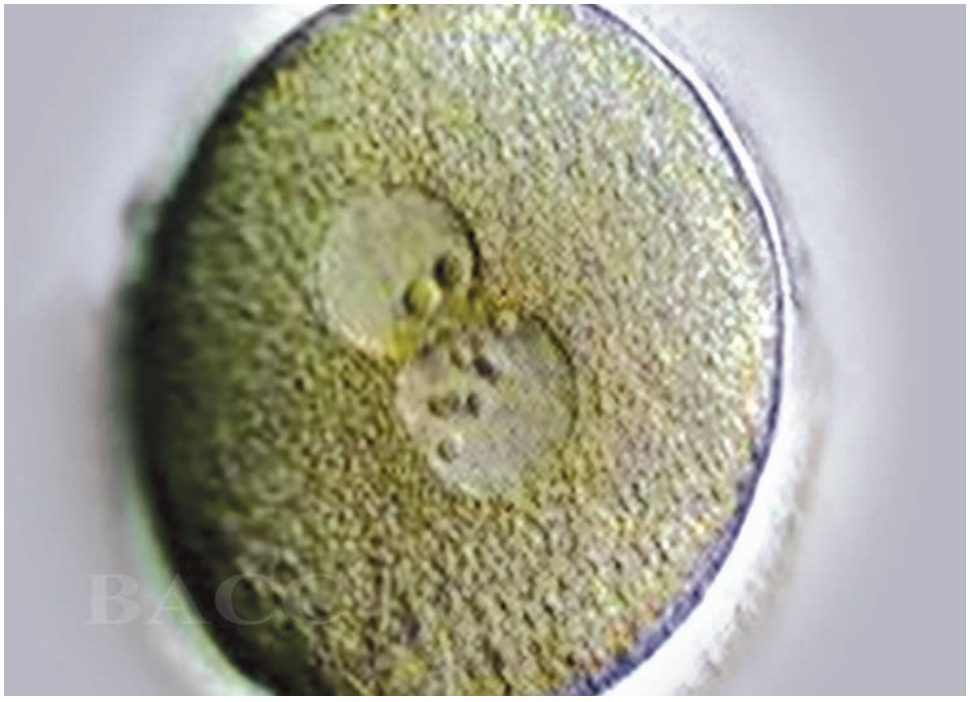

Fig. 2A: Human embryo in pronuclear stage, with two unequal pronuclei, and juxtaposed nuclear precursor bodies (NPBs) unequal in number.

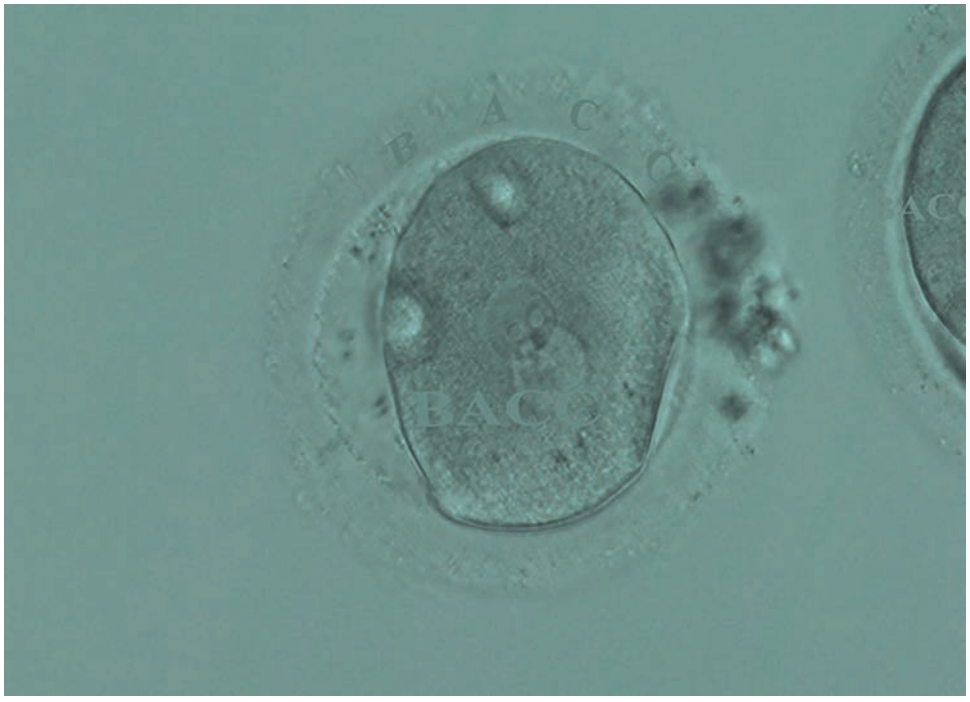

Fig. 2B: Two pronuclei unequal in size and two polar bodies at 9 o'clock and 11 o'clock position.

ABNORMAL PRONUCLEI (FIGS. 3A TO C)

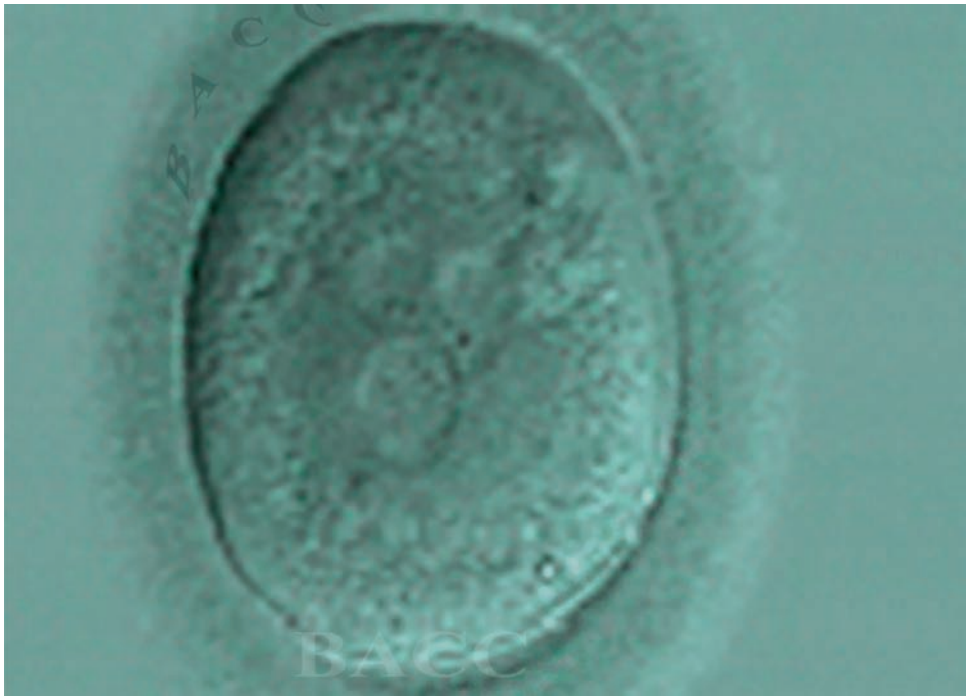

Fig. 3A: Abnormal zygote with three pronuclei.

Fig. 3B: An unfertilized, parthenogenetically activated human oocyte showing one prominent pronucleus and one of the two polar bodies.

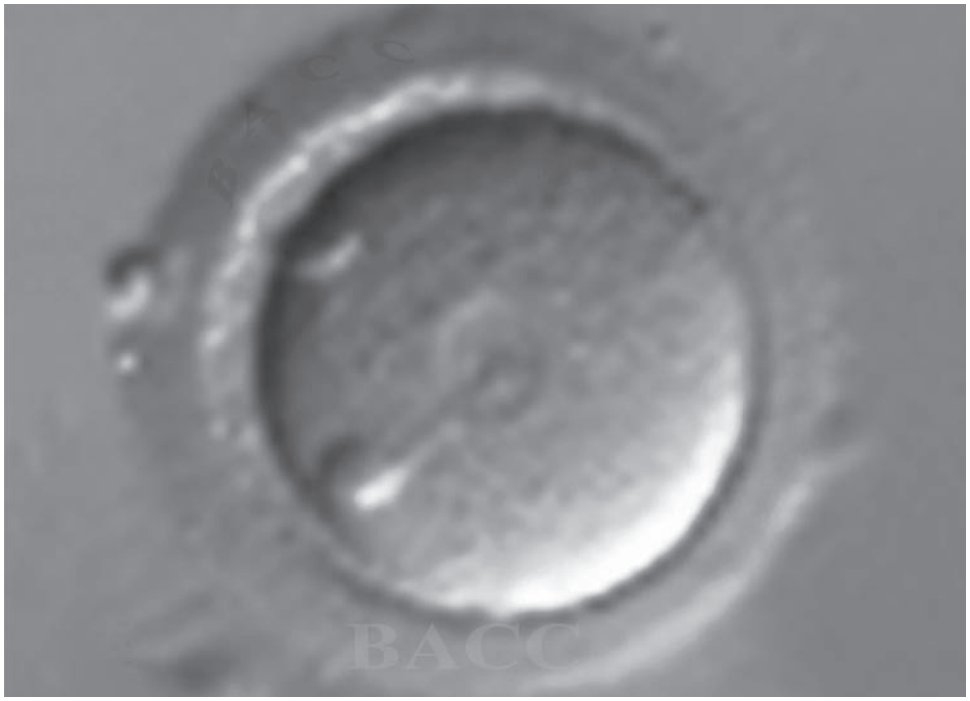

Fig. 3C: Abnormal zygote with single bulls-eye pronucleus (pronucleus with single NPB) and two polar bodies.

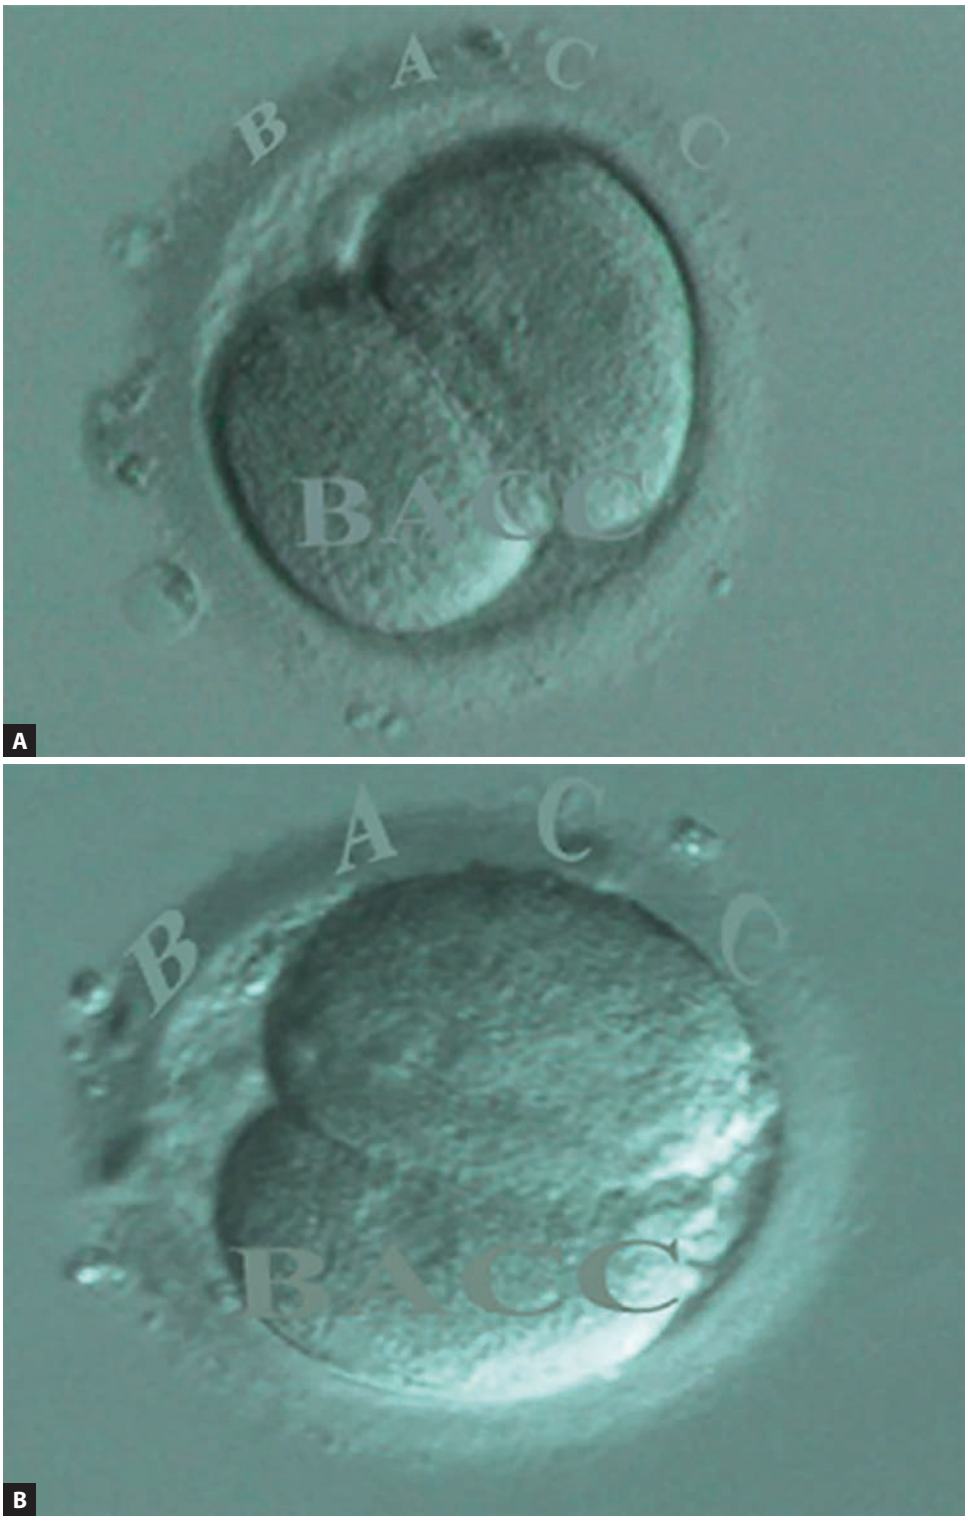
TABLE 2: Consensus scoring system for cleavage-stage embryos (in addition to cell number) (Figs. 4 to 6).

Grade	*Rating*	*Description*
1	Good	<10% fragmentation Stage-specific cell size No multinucleation
2	Fair	10–25% fragmentation Stage-specific cell size for majority of cells No evidence of multinucleation
3	Poor	Severe fragmentation (>25%) cell-size not stage-specific Evidence of multinucleation

TABLE 3: Consensus scoring system for day 4 embryos (Figs. 7A to F).

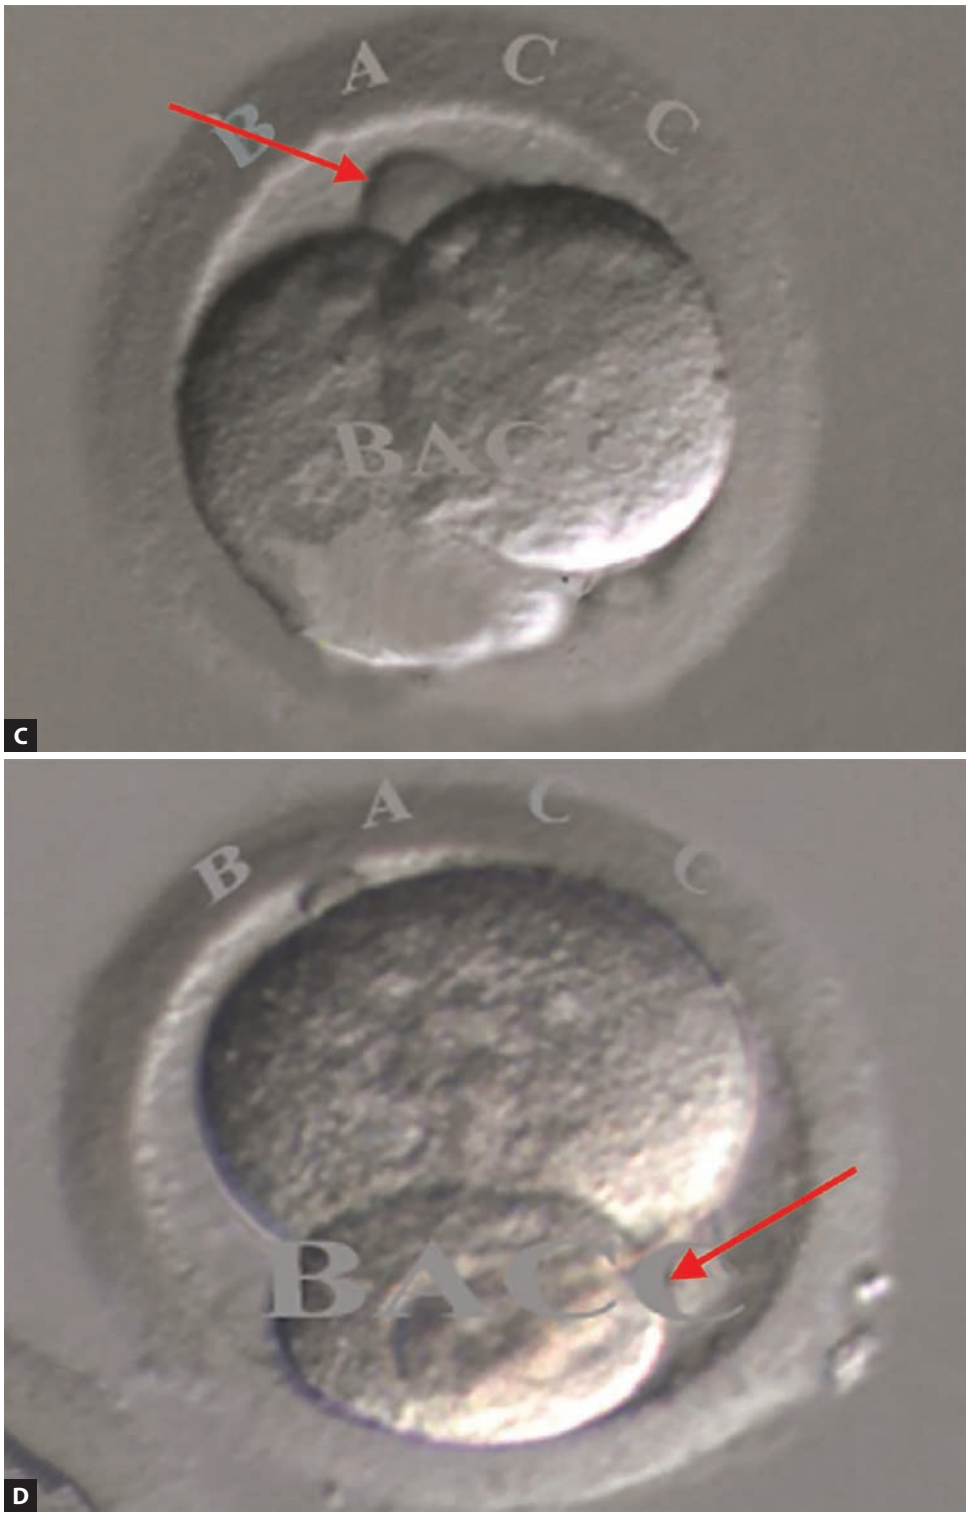
Grade	*Rating*	*Description*
1	Good	Entered into a fourth round of cleavage Evidence of compaction that involves virtually all the embryo volume
2	Fair	Entered into a fourth round of cleavage Compaction involves the majority of the volume of the embryo
3	Poor	Disproportionate compaction involving less than half of the embryo, with two or three cells remaining as discrete blastomeres

TWO-CELL GRADE 1 EMBRYOS (FIGS. 4A AND B)



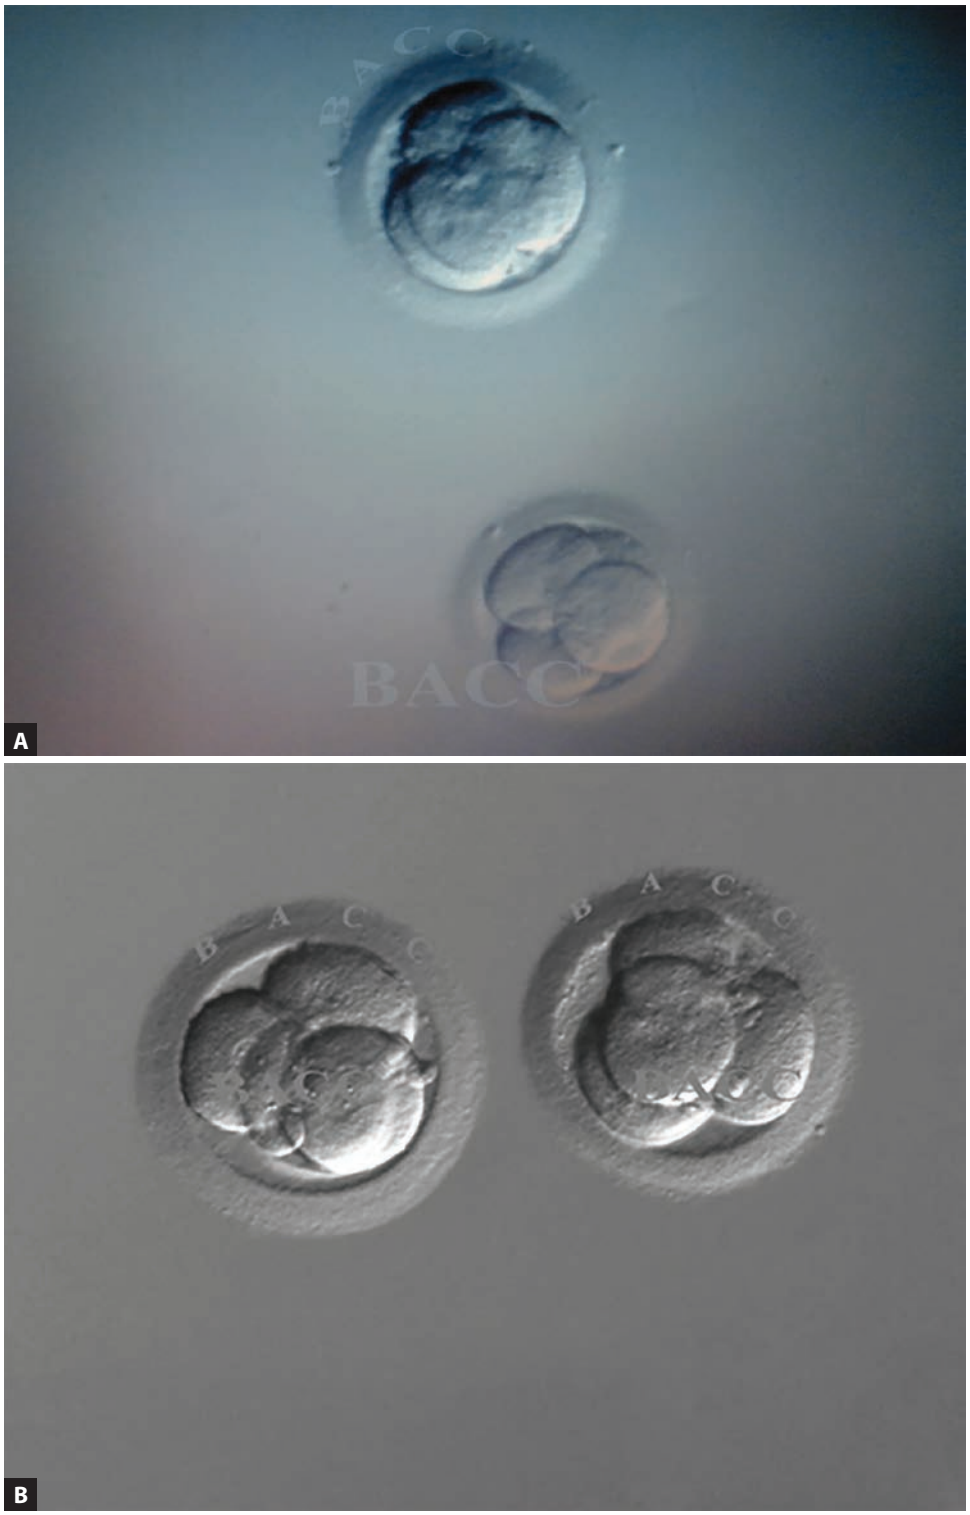
Figs. 4A and B: Two-cell, grade 1 human embryos. Note the stage-specific cell size and less than 10% fragmentation.

TWO-CELL GRADE 2 EMBRYOS (FIGS. 4C AND D)



Figs. 4C and D: Two-cell, grade 2 human embryos. Note unequal blastomeres and fragmentation (arrows).

FOUR-CELL GRADE 1 EMBRYOS (FIGS. 5A AND B)

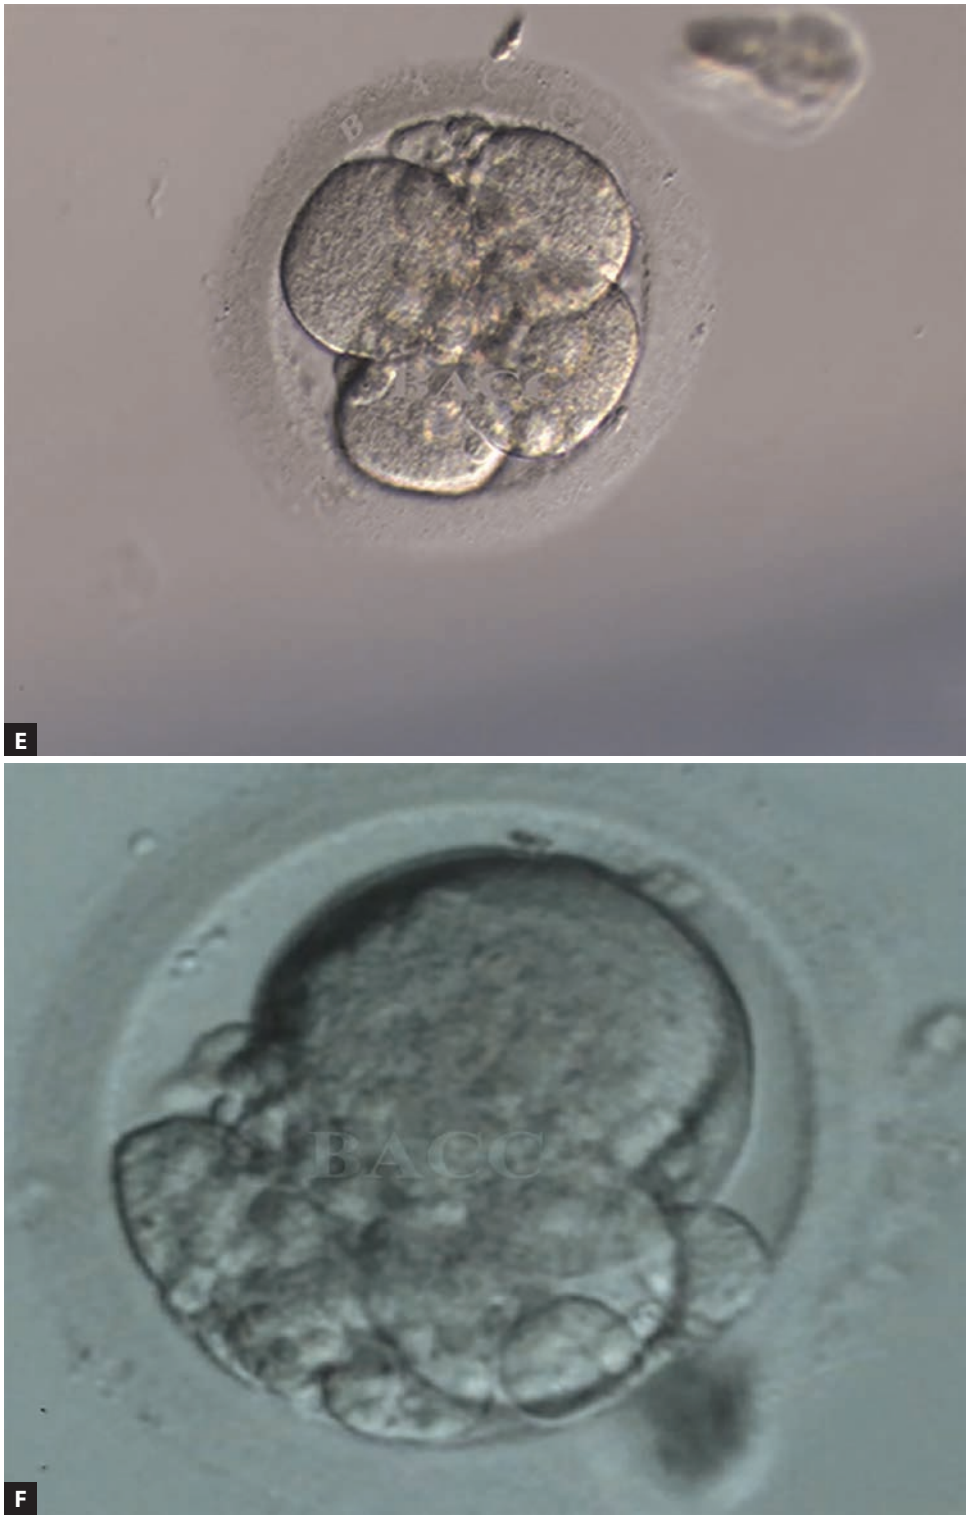


Figs. 5A and B: Four-cell, grade 1 human embryos. Note the stage-specific cell size and no fragmentation.

FOUR-CELL GRADE 2 EMBRYOS (FIGS. 5C AND D)

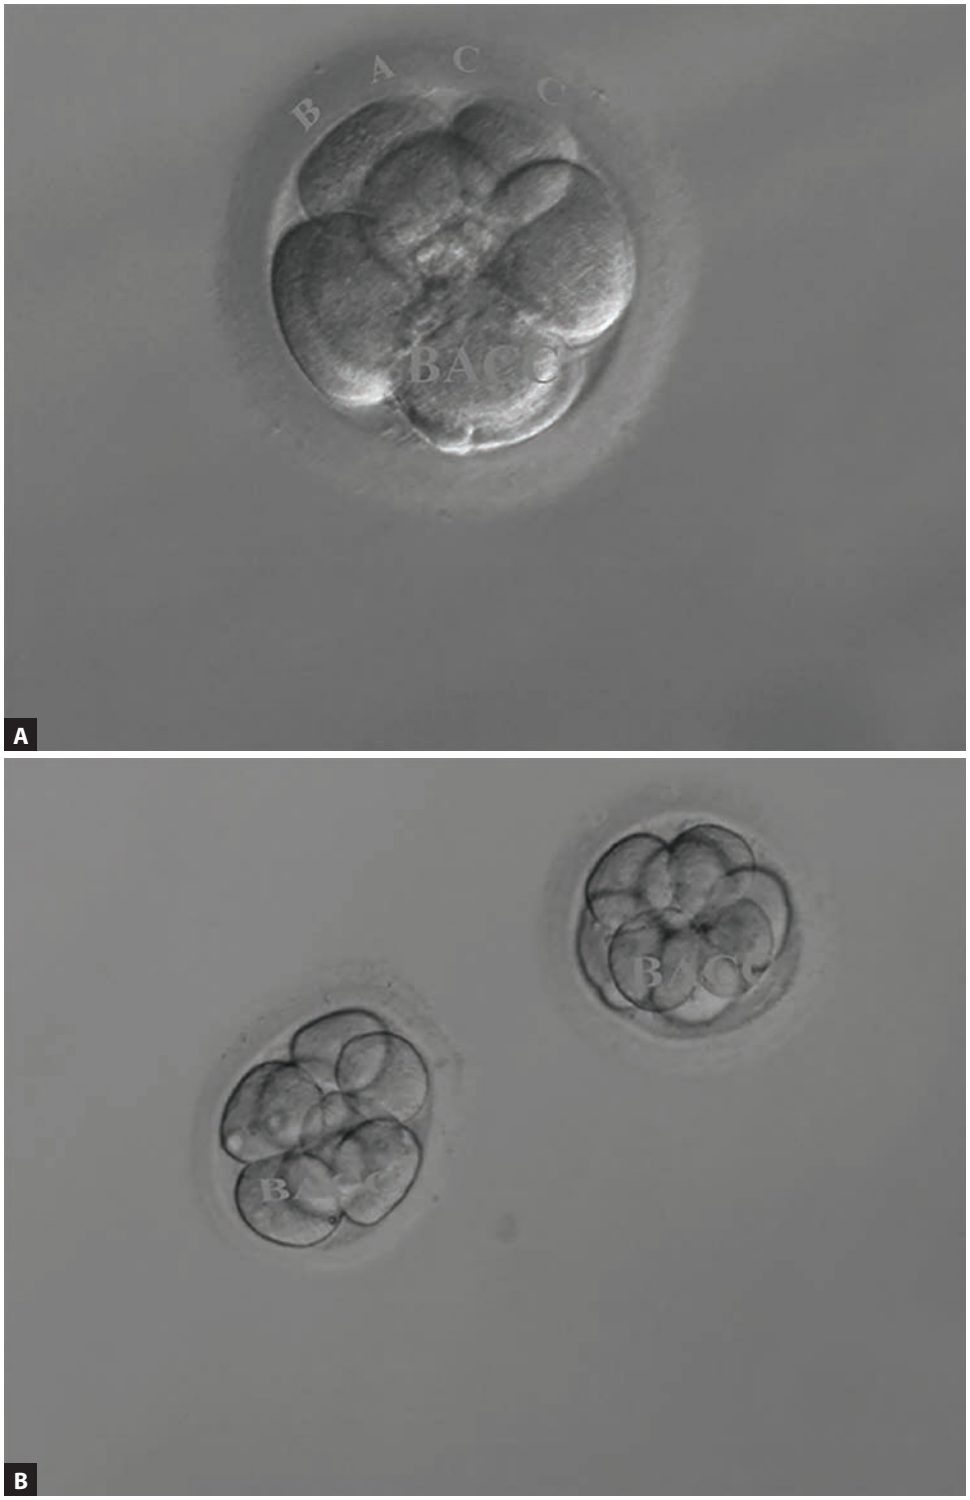
Figs. 5C and D: Four-cell, grade 2 human embryos (Note stage-specific cell size for majority of cells in Figure C and less than 25% fragmentation in Figure D).

FOUR-CELL GRADE 3 EMBRYOS (FIGS. 5E AND F)



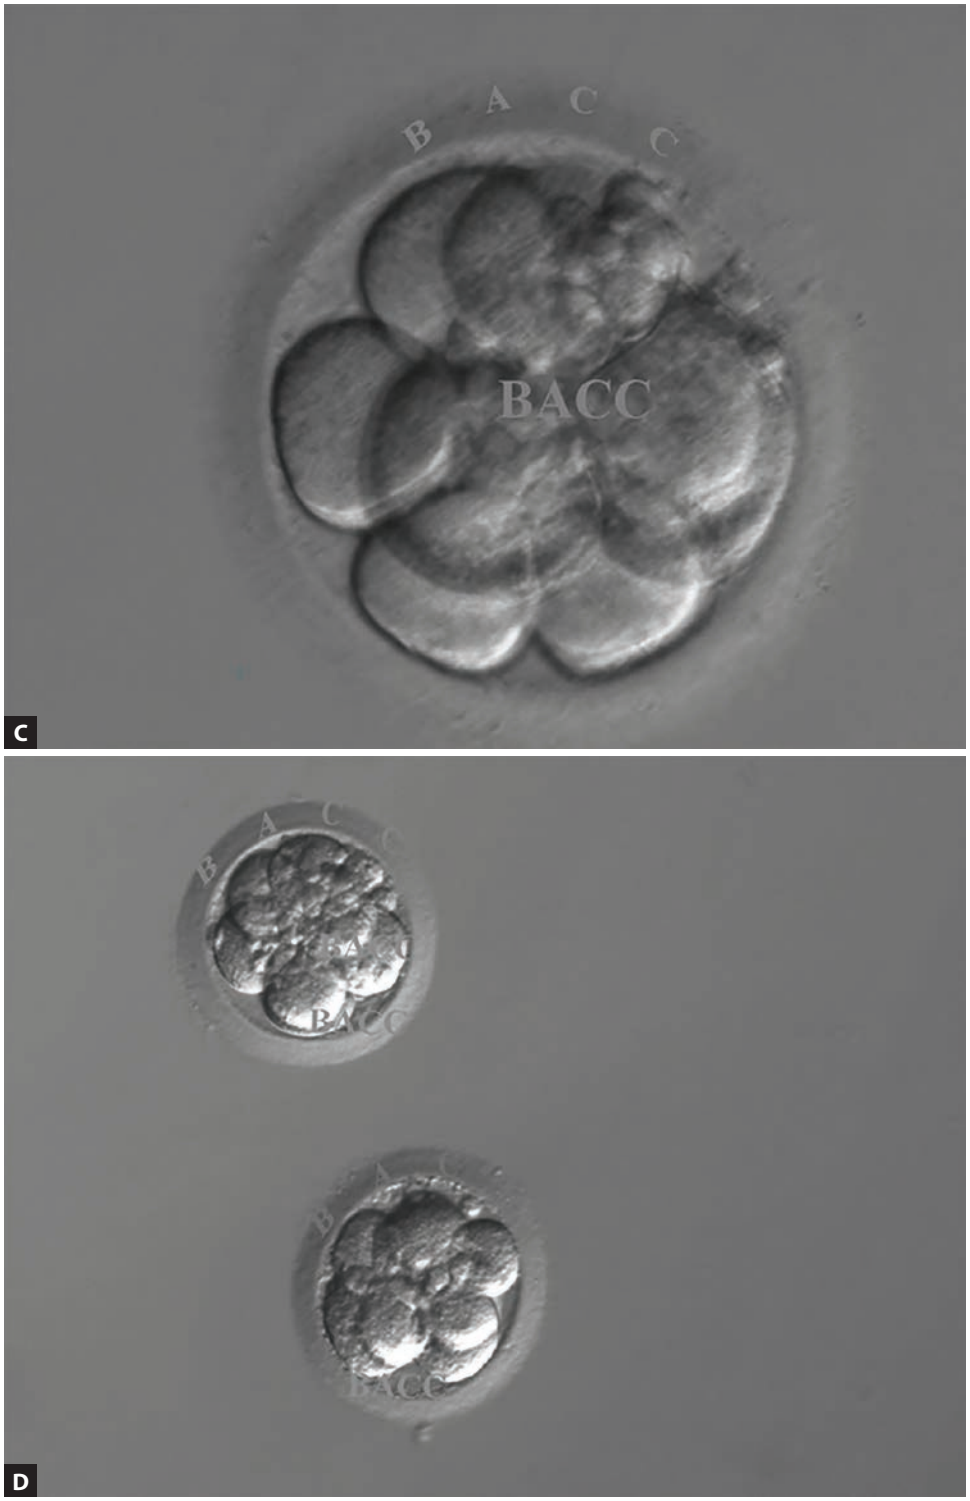
Figs. 5E and F: Four-cell, grade 3 human embryos (Note more than 25% fragmentation in Figure E, unequal blastomeres with fragmentation in Figure F).

EIGHT-CELL GRADE 1 EMBRYOS (FIGS. 6A AND B)



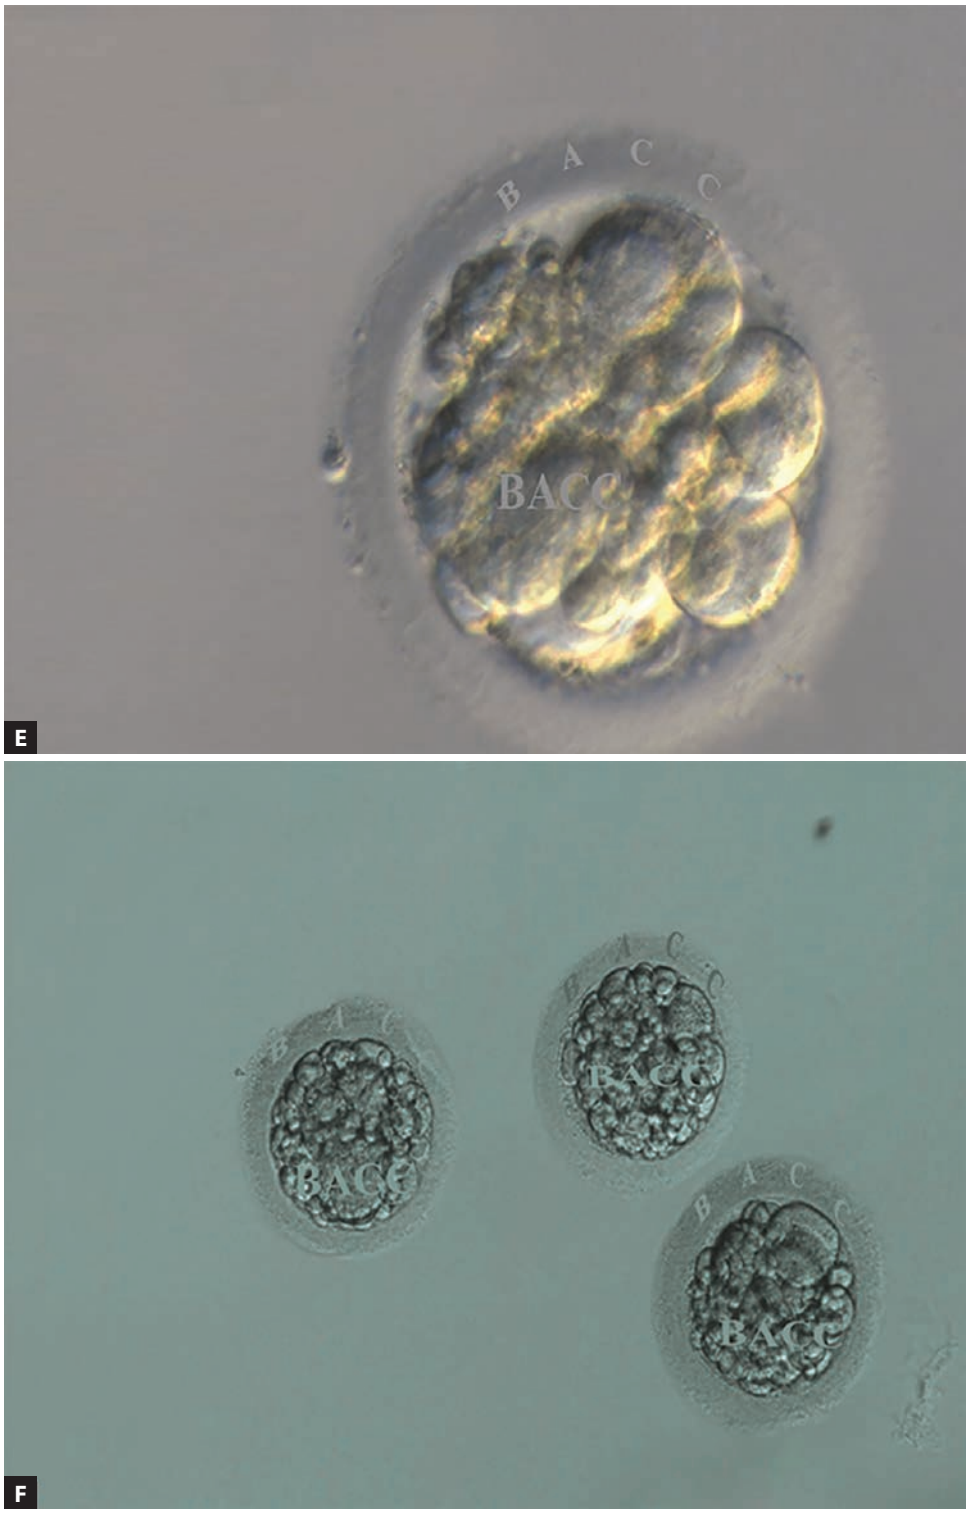
Figs. 6A and B: Eight-cell, grade 1 human embryos. Note the stage-specific cell size and no fragmentation.

EIGHT-CELL GRADE 2 EMBRYOS (FIGS. 6C AND D)



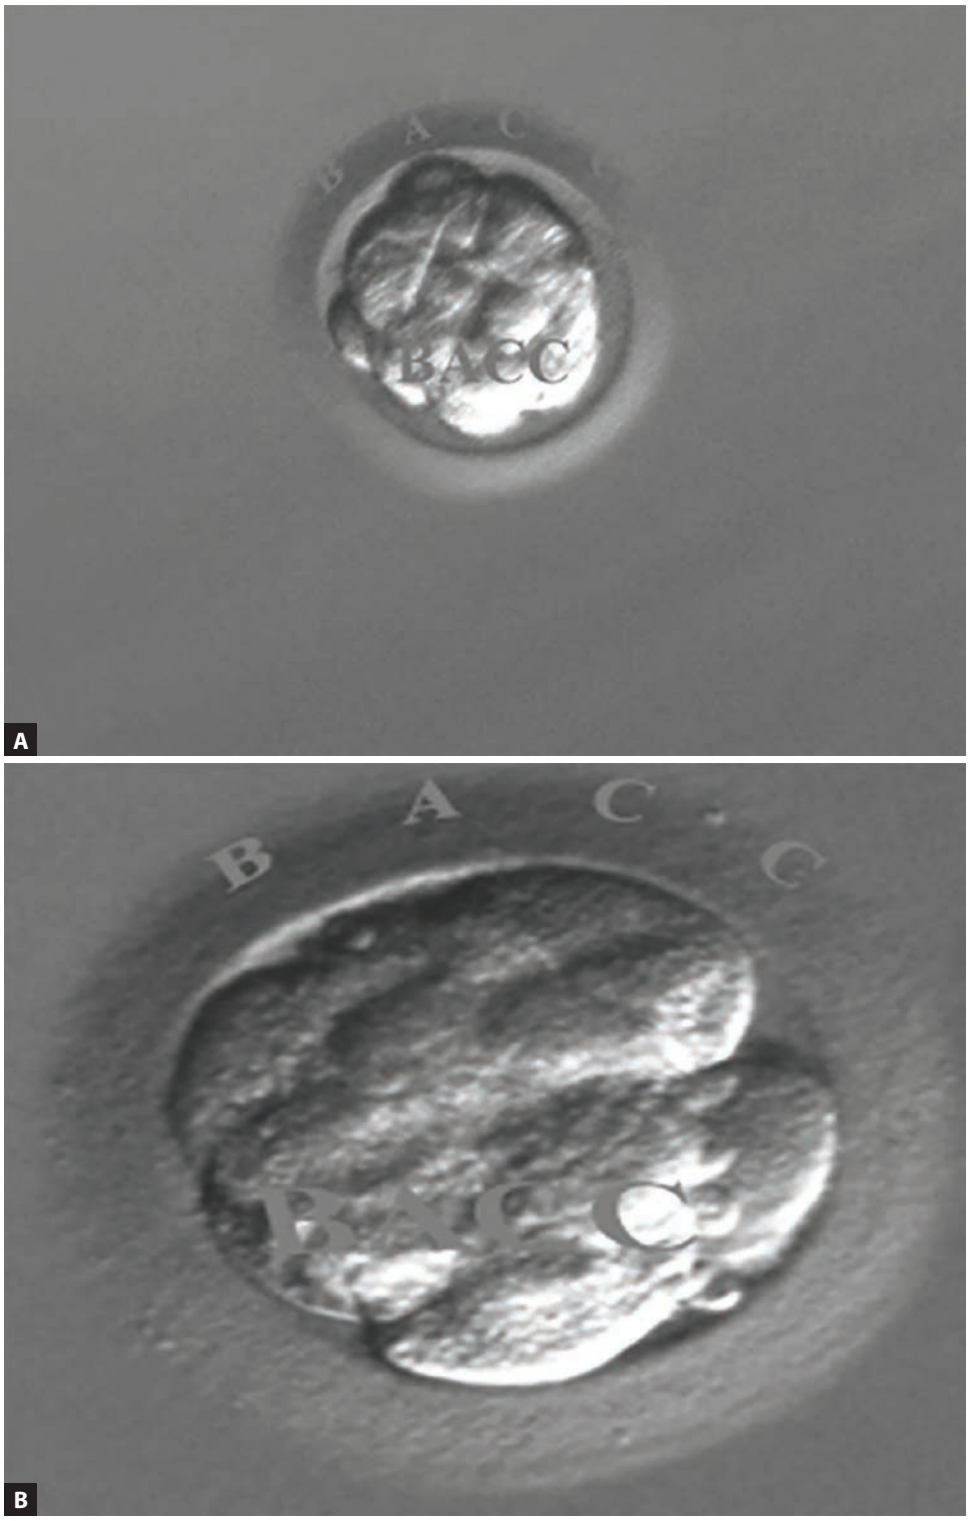
Figs. 6C and D: Eight-cell, grade 2 human embryos. Note less than 25% fragmentation.

EIGHT-CELL GRADE 3 EMBRYOS (FIGS. 6E AND F)



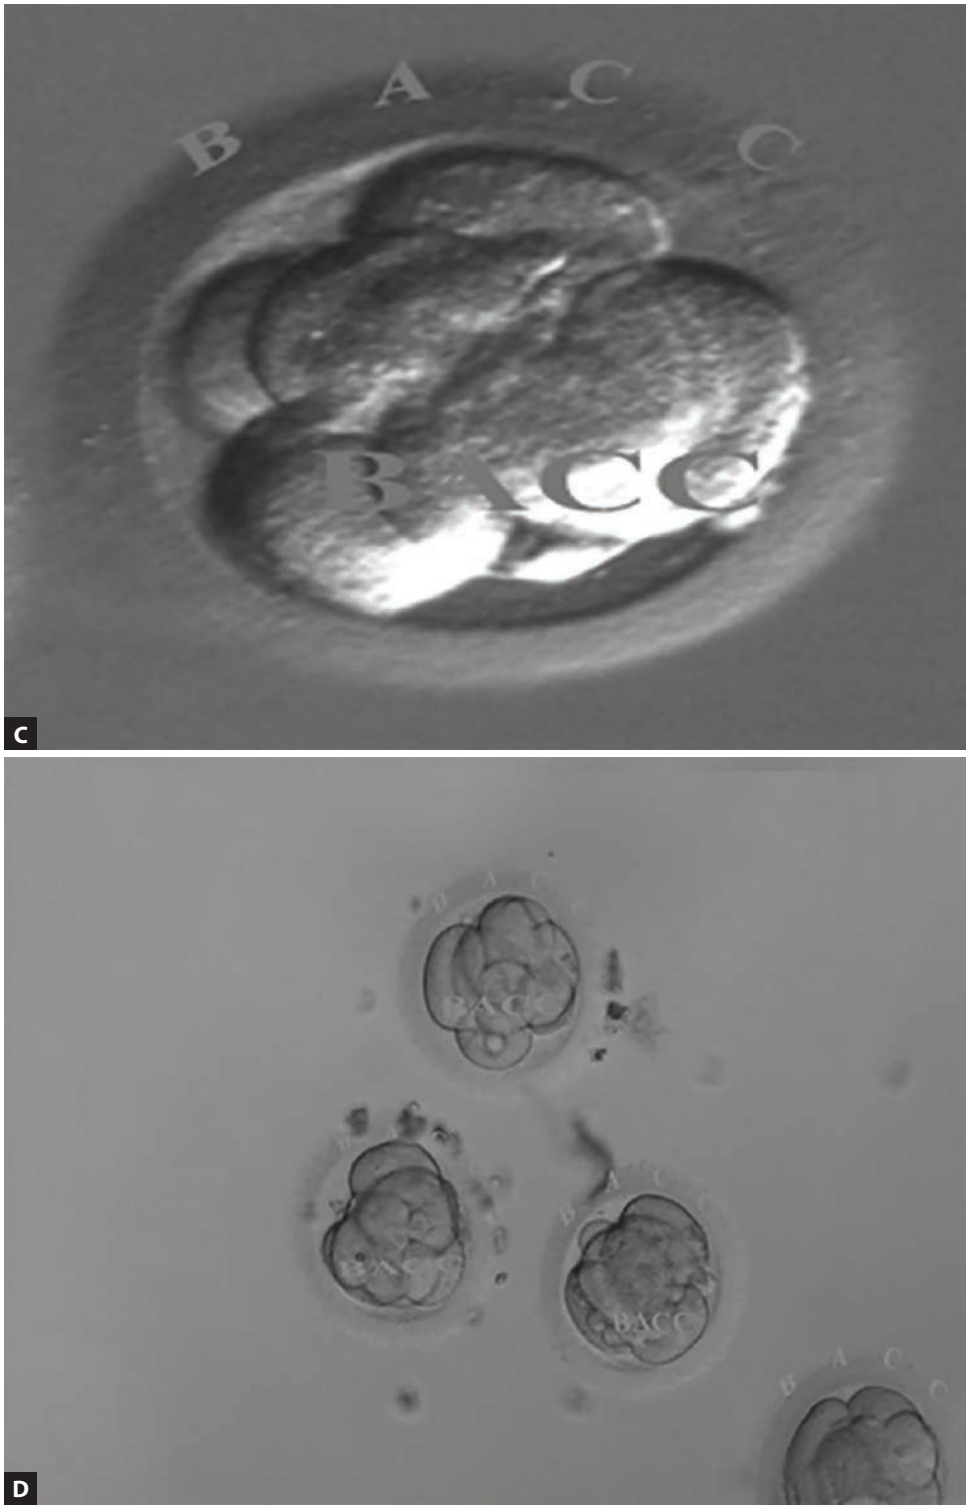
Figs. 6E and F: Eight-cell, grade 3 human embryos. Note more than 25% fragmentation.

GRADE 1, DAY 4 EMBRYOS (FIGS. 7A AND B)



Figs. 7A and B: Grade 1, day 4 embryos with evidence of compaction involving almost all the embryo volume.

GRADE 2, DAY 4 EMBRYOS (FIGS. 7C AND D)

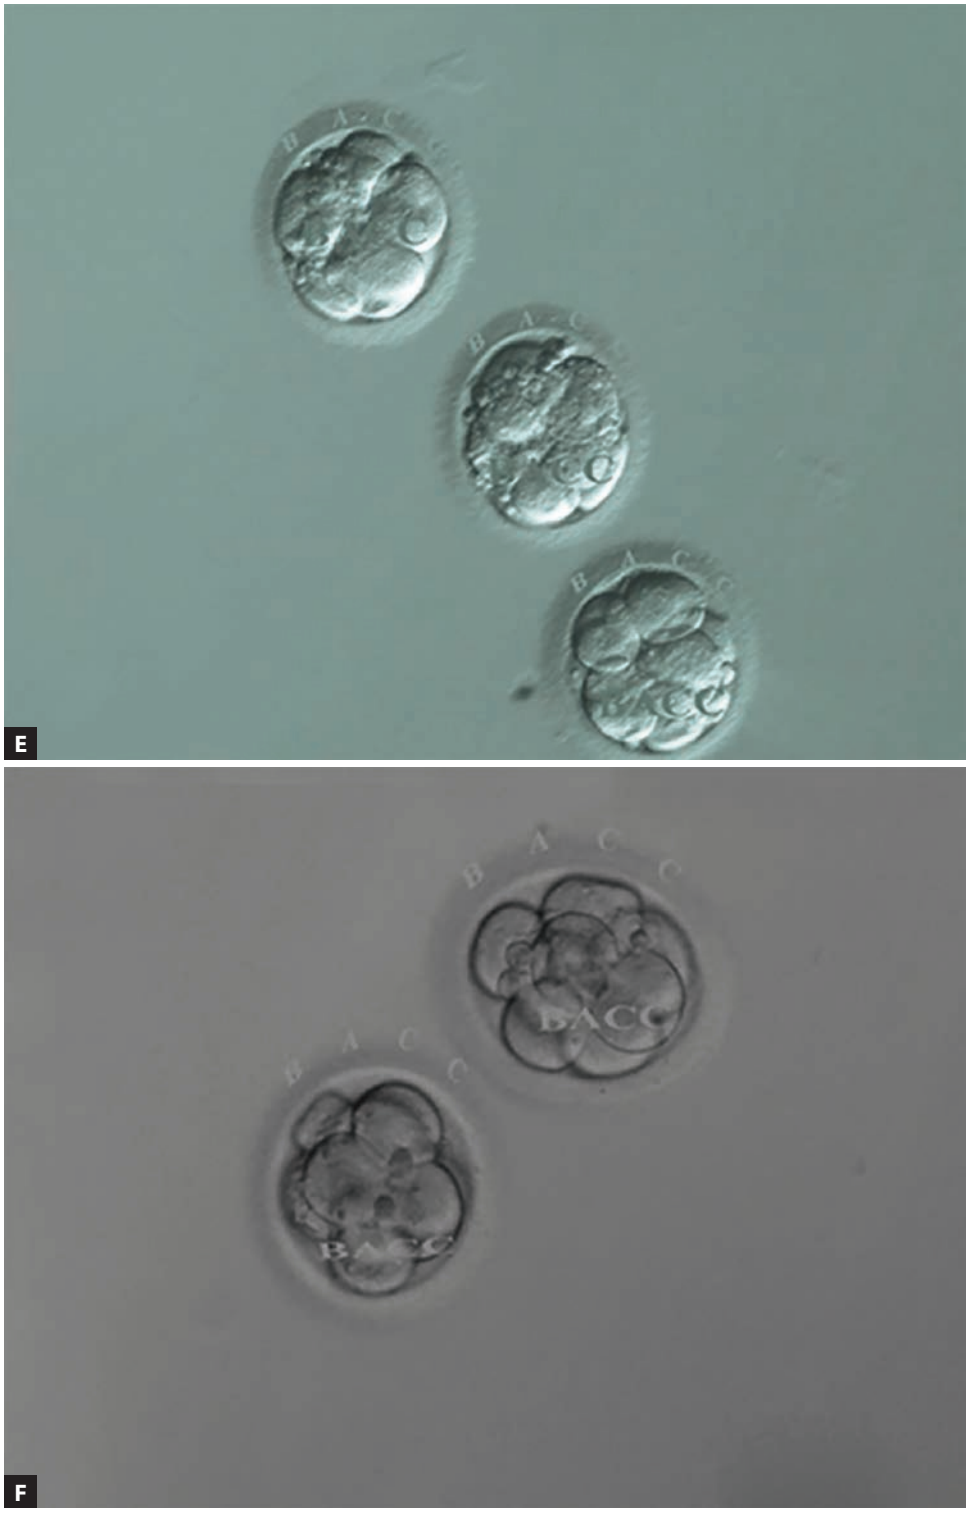


Figs. 7C and D: Grade 2, day 4 embryos with compaction involving majority of the embryo volume.

GRADE 3, DAY 4 EMBRYOS (FIGS. 7E AND F)

The scoring system for blastocysts is a combination of the stage of development and of the grade of the inner cell mass (ICM) and of the trophectoderm (TE). It is a numerical interpretation of the Gardner scale.[2,3] The "*stages of development*" is graded as:

- *Early blastocyst*: Cavity is just beginning to form and cell types not distinguishable.
- *Expanded blastocyst*: Cavity is fully formed, contains 100–125 cells, and is still contained in zona pellucida (ZP).



Figs. 7E and F: Grade 3, day 4 embryos with disproportionate compaction and with a few discrete blastomeres.

TABLE 4: Consensus scoring system for blastocysts.

	Grade	*Rating*	*Description*
Stage of development	1 2 3 4		Early Blastocyst Expanded Hatched/Hatching
Inner cell mass	1	Good	Prominent, easily discernible, with many cells that are compacted and tightly adhered together
	2	Fair	Easily discernible, with many cells that are loosely grouped together
	3	Poor	Difficult to discern, with few cells
Trophectoderm	1	Good	Many cells forming a cohesive epithelium
	2	Fair	Few cells forming a loose epithelium
	3	Poor	Very few cells

- *Hatched blastocyst*: Embryo is outside the ZP and contains more than 150 cells.

In the **Figures 8 to 12,** different blastocysts in different stages of development and in different grades have been explained. **Figures 8A to E** show early blastocyst in different grades. **Figures 9A and B** show blastocysts in different grades. **Figures 10A to E** show expanded blastocysts. **Figures 11A and B** show hatching blastocyst. **Figures 12A and B** show hatched blastocyst.

EARLY BLASTOCYST (FIGS. 8A TO E)

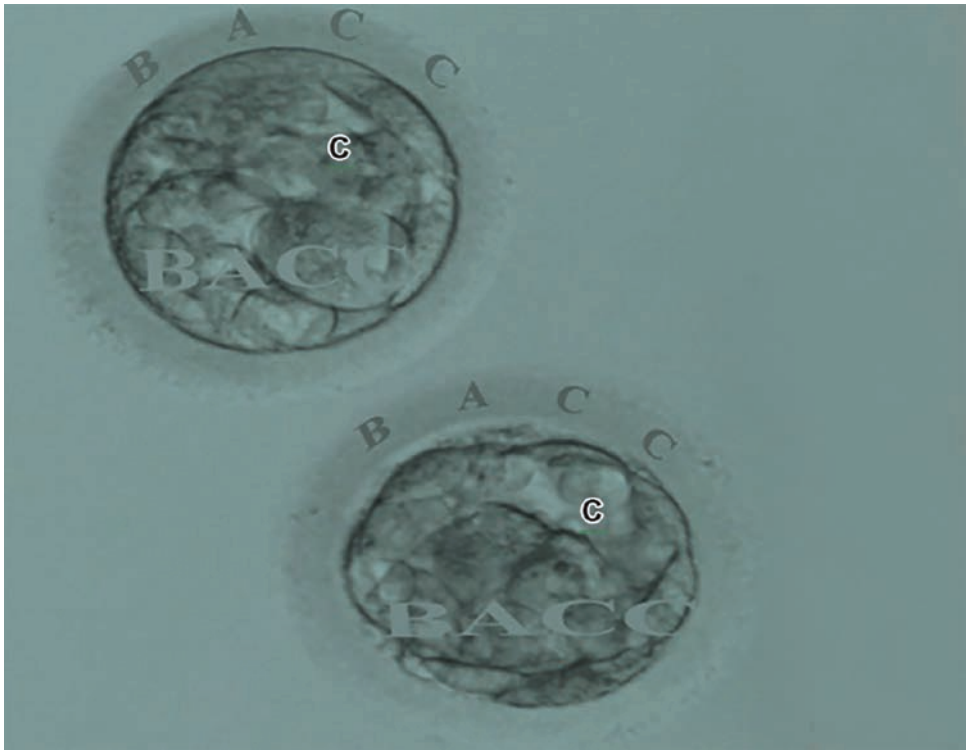


Fig. 8A: Cavitation "C" commencing in an early blastocyst, with indistinguishable cell types.

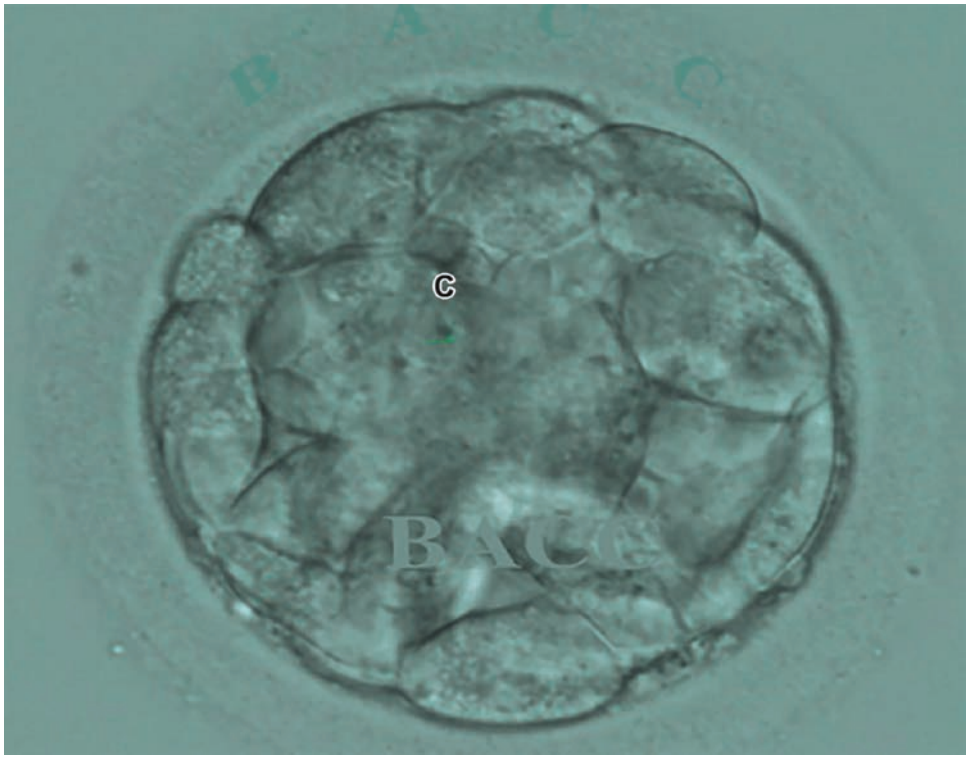

Fig. 8B: Mid-cavitating blastocyst with indistinguishable cell types.

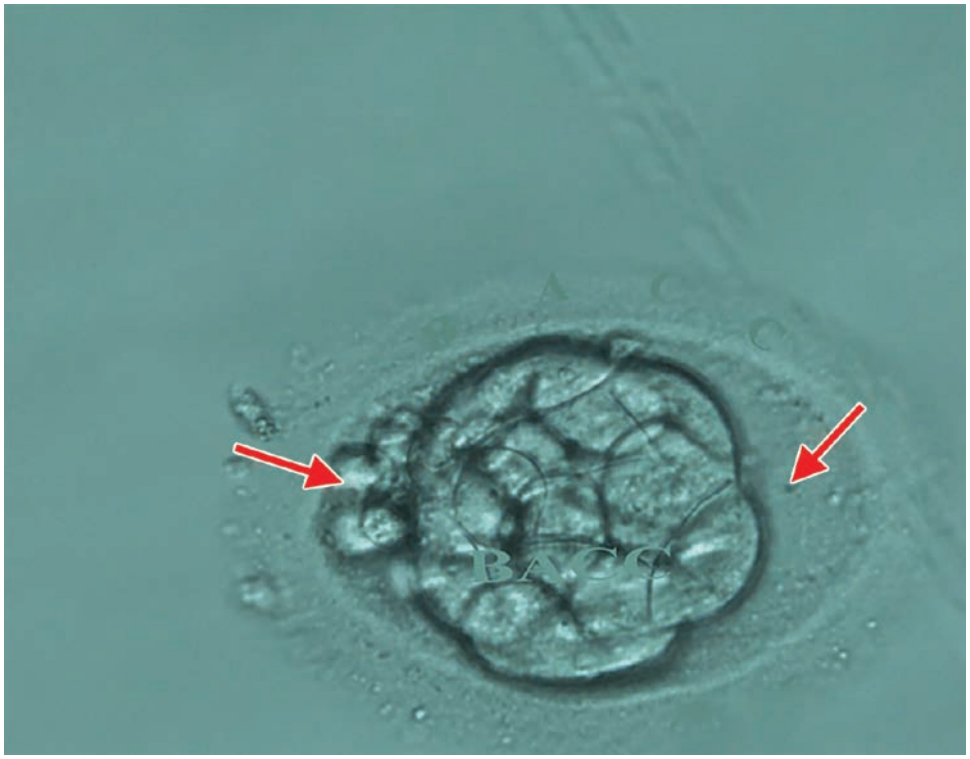

Fig. 8C: Early mid-cavitating blastocyst, with indistinguishable cell types. Note the fragmentation (arrow) and debris (arrow) in perivitelline space.

Fig. 8D: An early blastocyst with the cavity occupying more than 50% of the volume of the embryo. Note the flattened squamous-like trophectoderm cells lining left half of the cavity.

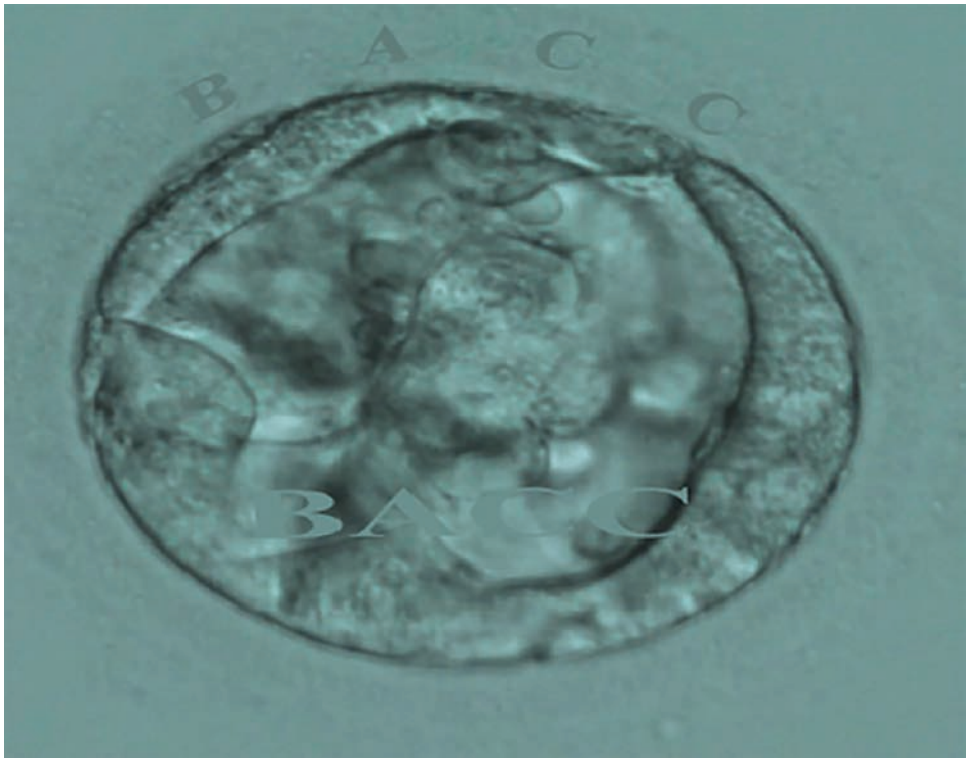

Fig. 8E: An early blastocyst with the cavity occupying more than 50% of the volume of the embryo. The overall volume of the blastocyst remains unchanged with thinning of the zona pellucida. Note the flattened squamous-like trophectoderm cells lining the cavity.

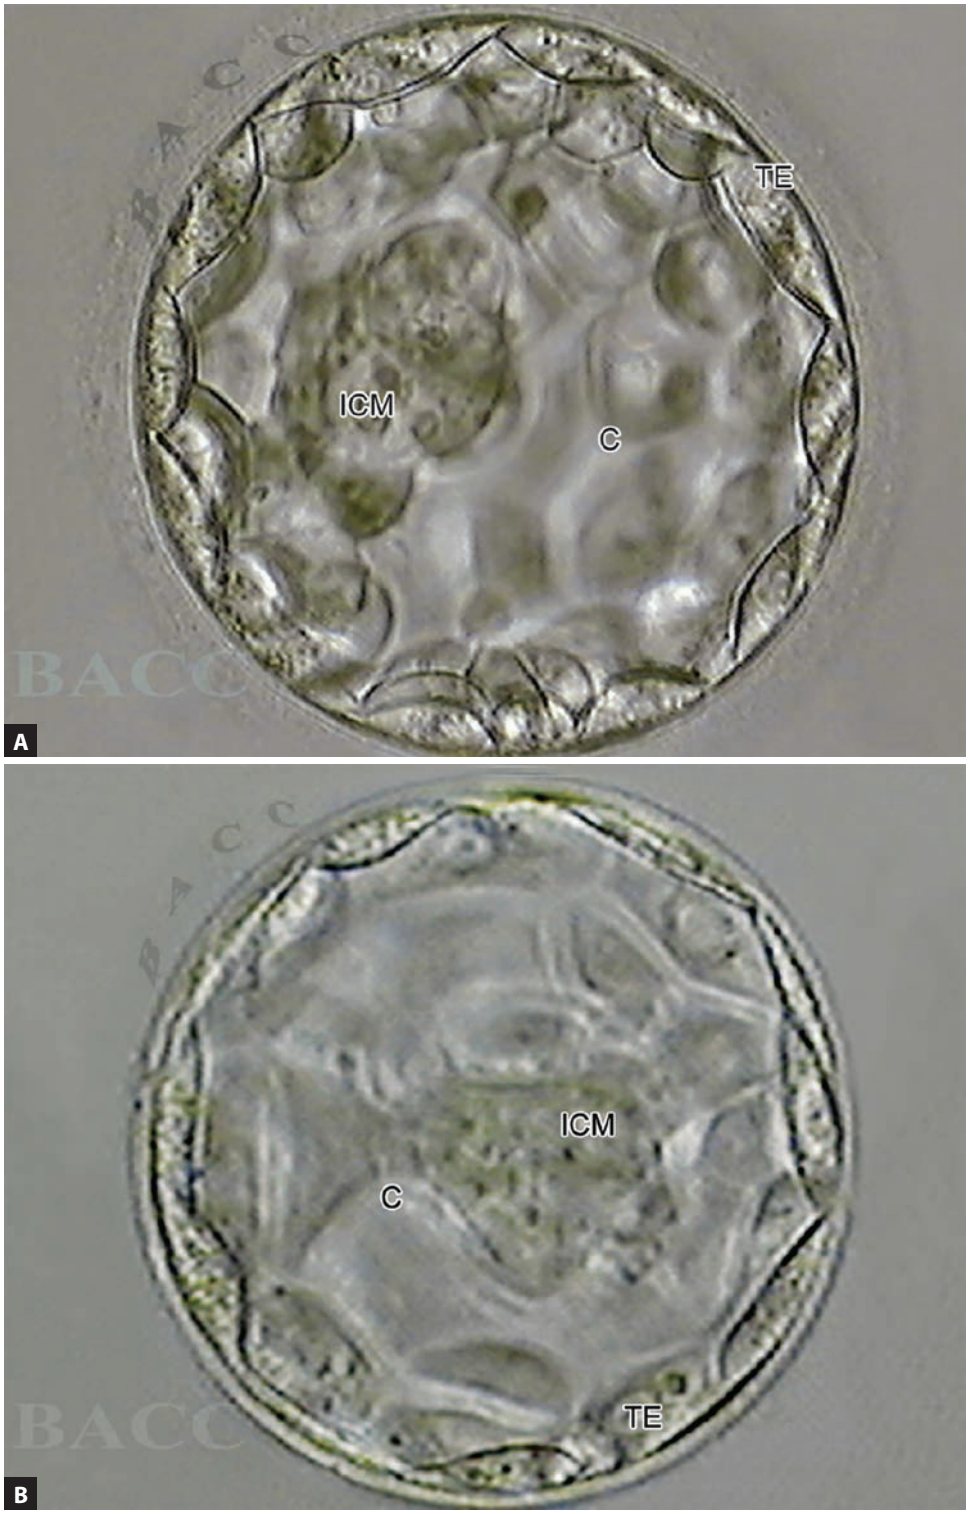
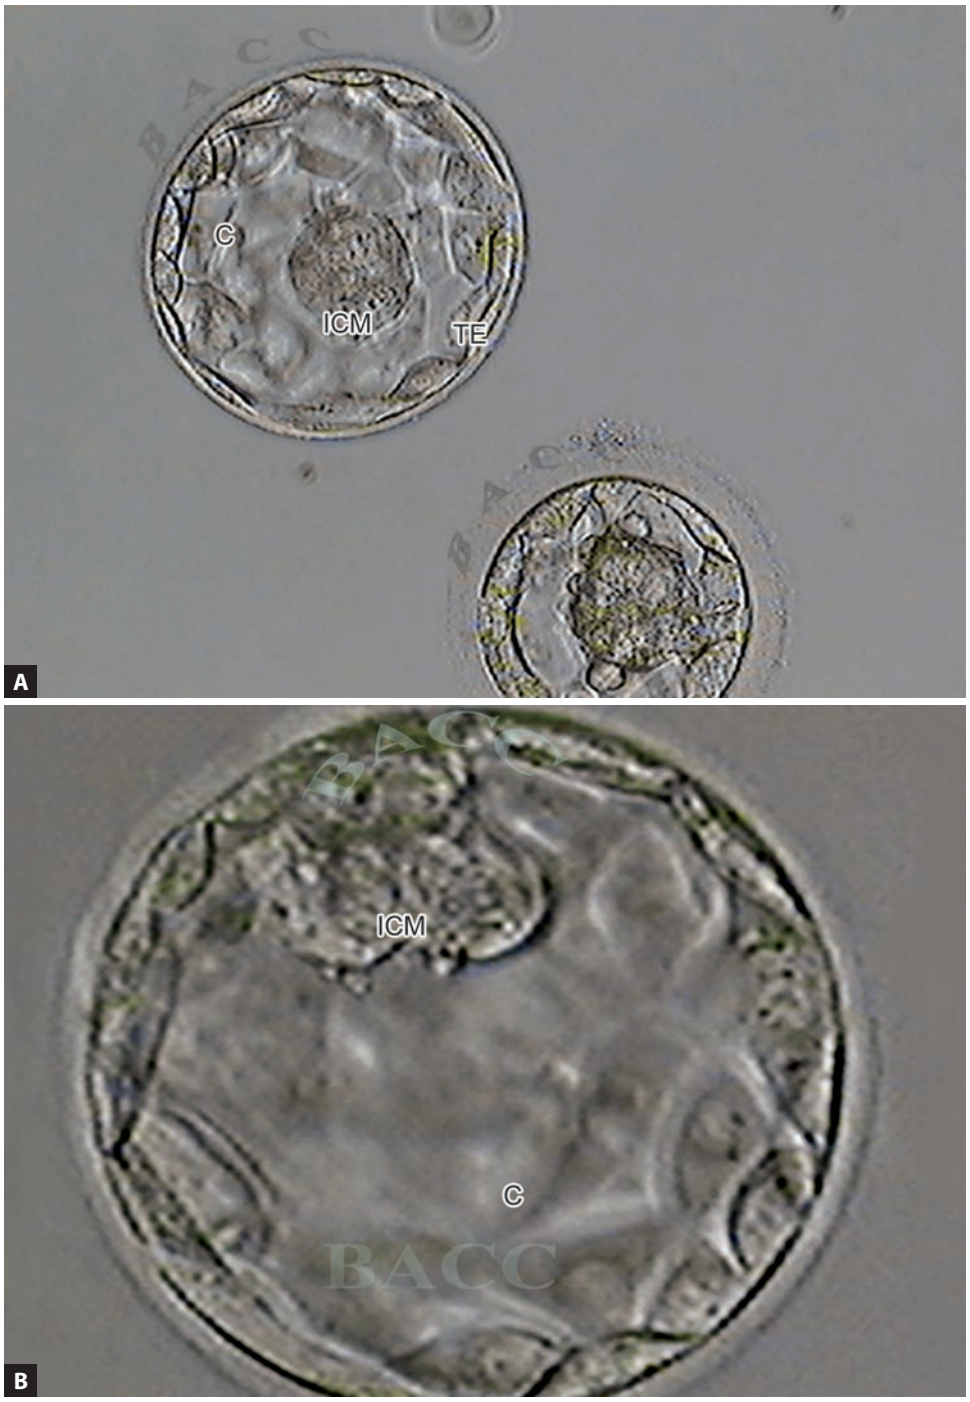
BLASTOCYST (FIGS. 9A AND B)

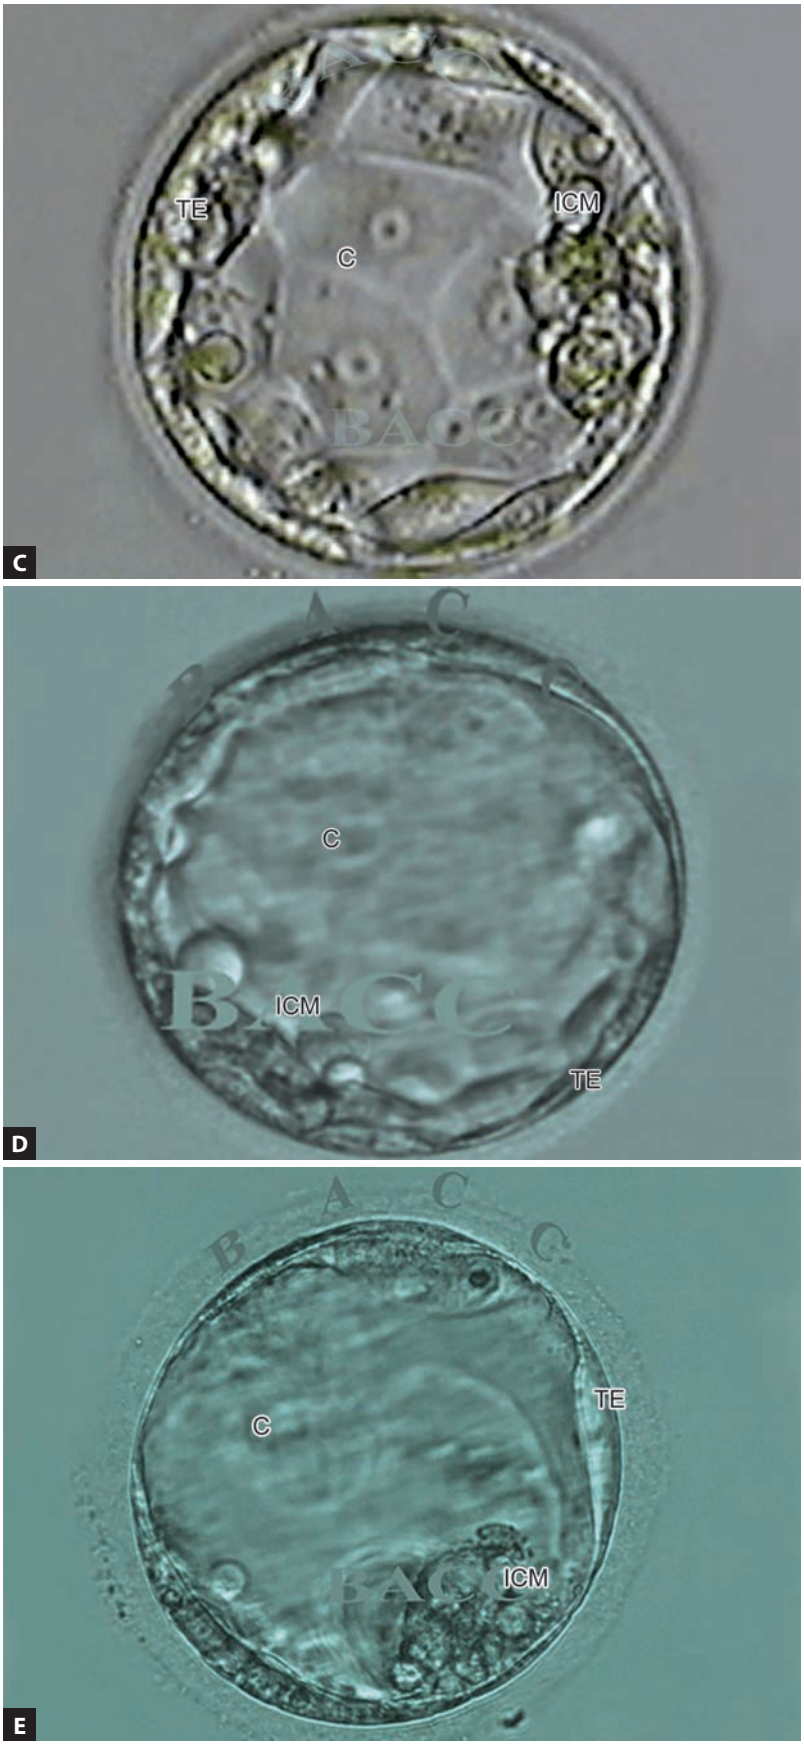


Figs. 9A and B: (A) Grade 3:1:1 showing, distinct compact inner cell mass (ICM) and trophectoderm (TE); (B) Grade 3:2:1 showing a cavity occupying the total volume of the embryo.

EXPANDED BLASTOCYST (FIGS. 10A TO E)

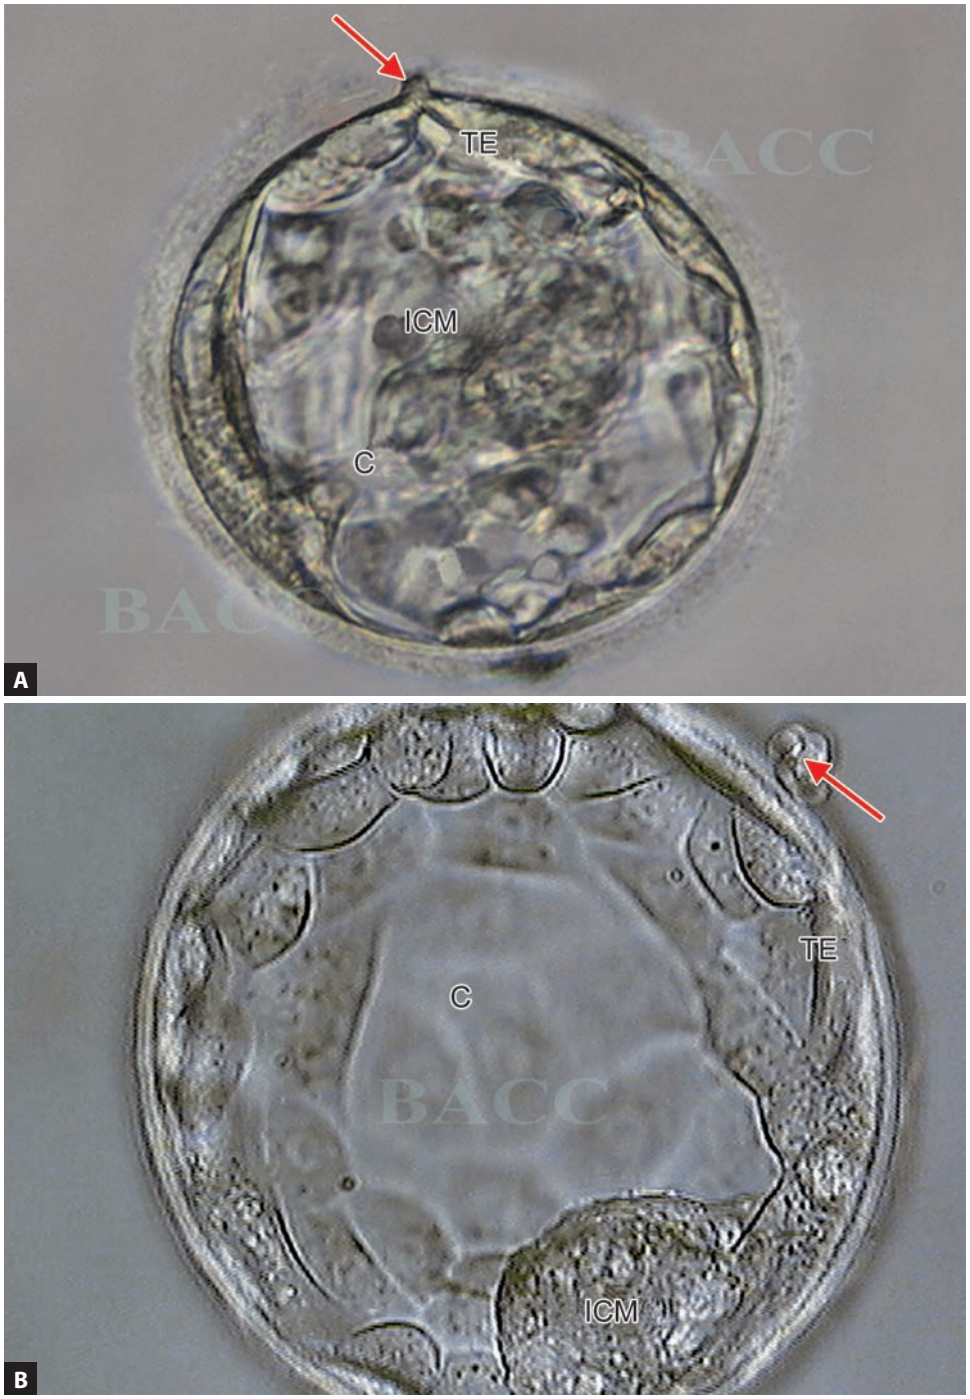


Figs. 10A and B: Expanded blastocyst. (A) Grade 3:1:1. The inner cell mas (ICM) cells are tightly compacted. The blastocele volume is now larger than the original volume of the embryo; (B) Grade 3:1:1. The ICM cells are tightly compacted. The blastocele volume is now larger than the original volume of the embryo.



Figs. 10C to E: (C) Grade 3:3:2. The blastocyst volume is large. The inner cell mas (ICM) is difficult to discern with few cells, the trophectoderm (TE) cells are loosely attached and few in number; (D and E) Grade 3:3:3. The blastocyst volume is larger than the original volume. The ICM is difficult to discern with few cells. The TE cells are very few in number.

HATCHING BLASTOCYSTS (FIGS. 11A AND B)



Figs. 11A and B: (A) Hatching blastocyst (Grade 4:2:2). The hatching blastocyst showing a large inner cell mass (ICM), with many cells that are loosely grouped together, trophectoderm (TE) cells are few in number with a loose epithelium. TE cells are herniating through a breach (arrow) in the thinned zona pellucida (ZP) at the 12 o'clock position; (B) Hatching blastocyst (Grade 4:1:1) showing a large, compact ICM at 5 o'clock position in this view. There are many TE cells of equivalent size lining the blastocele cavity and several TE cells are herniating through a breach (arrow) through the thinned ZP at 1 o'clock position.

HATCHED BLASTOCYSTS (FIGS. 12A AND B)

Figs. 12A and B: (A) Hatched blastocyst (Grade 4:1:1) showing a large, compact, crescent-shaped inner cell mass (ICM) retained within the zona pellucida (ZP) (arrow). There are many trophectoderm (TE) cells and almost 75% of the blastocyst has herniated out through a breach in the ZP; (B) completely hatched blastocyst (Grade 4:1:1) showing compact ICM and many TE cells.

MORPHOLOGY OF POOR QUALITY BLASTOCYSTS

These groups of blastocysts exhibit low cell numbers and higher degree of chromosomal aberrations. Poor quality blastocysts consists of various morphological subtypes namely blastocysts with excessive fragmentation, cytoplasmic strings, vacuoles, necrotic cells and trophoblast vesicles.

TROPHOBLAST VESICLE (FIG. 13)

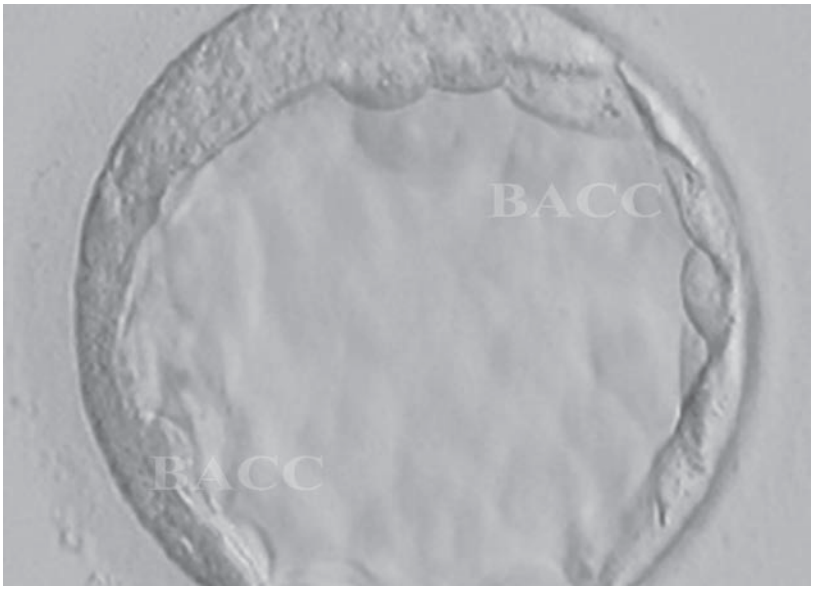


Fig. 13: Trophoblastic vesicle with a dominant blastocyst cavity. Blastocyst with no visible inner cell mass and a rudimentary trophectoderm.

NECROTIC FOCI (FIGS. 14A AND B)

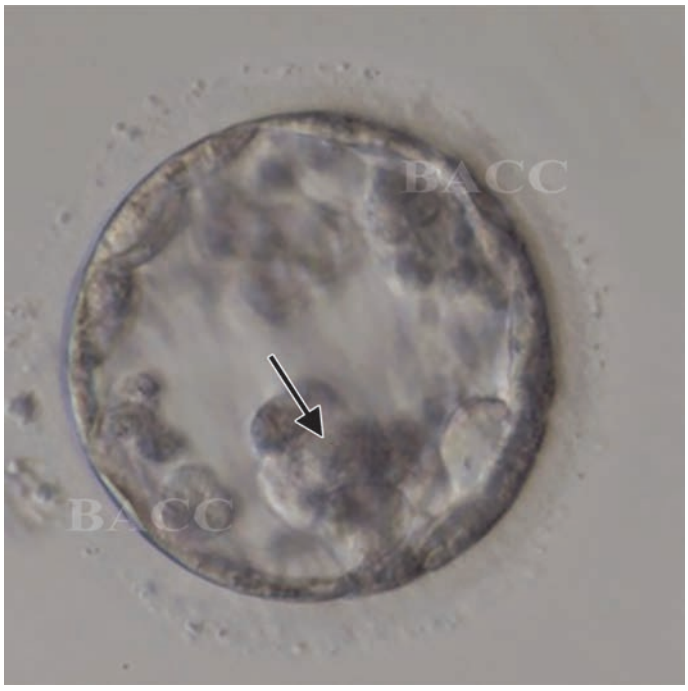

Fig. 14A: Early blastocyst showing dark, degenerative changes (arrow).

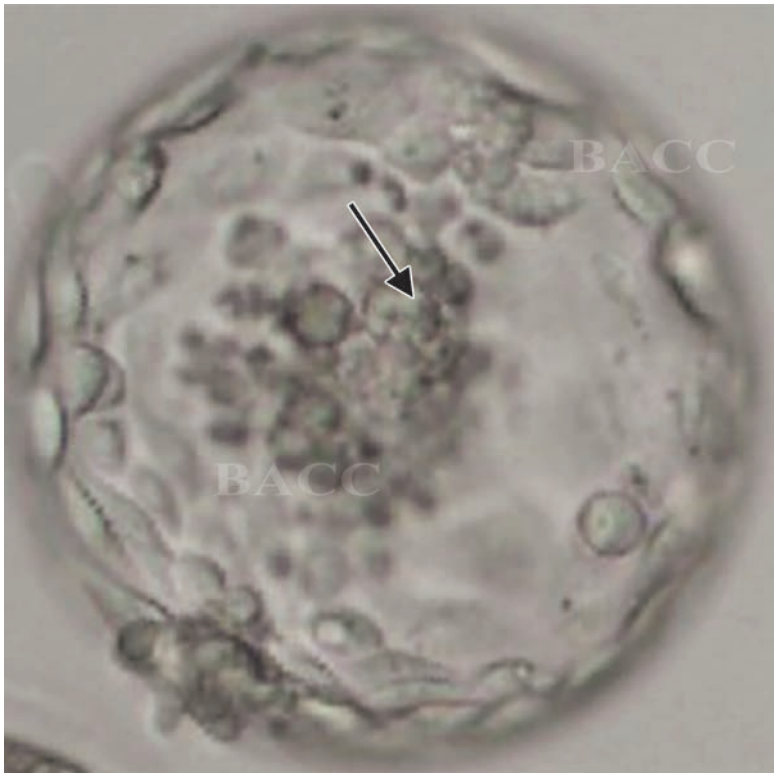

Fig. 14B: Hatching blastocyst showing necrotic foci (arrow).

VACUOLES (FIGS. 15A AND B)

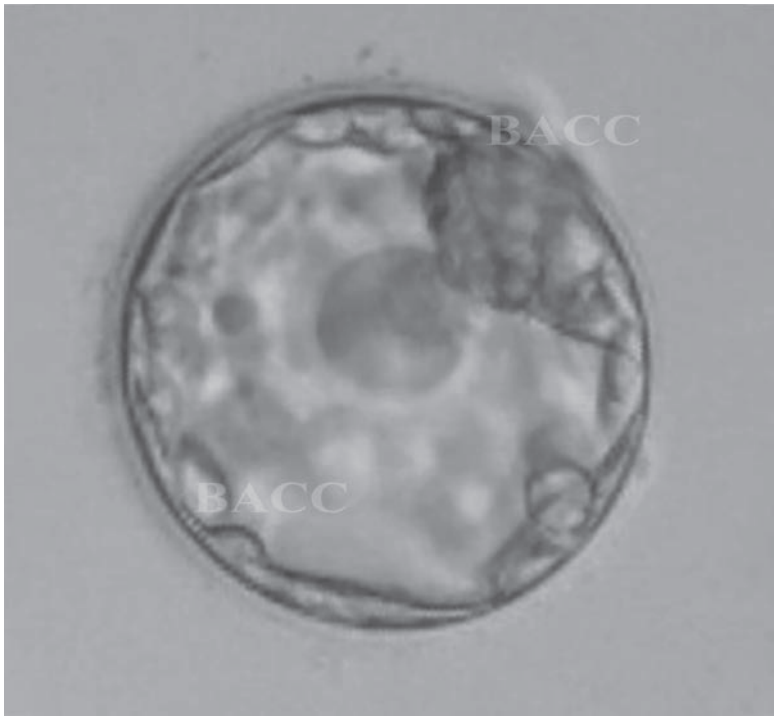

Fig. 15A: Expanded blastocyst in which a large vacuole can be seen in close proximity to ICM.

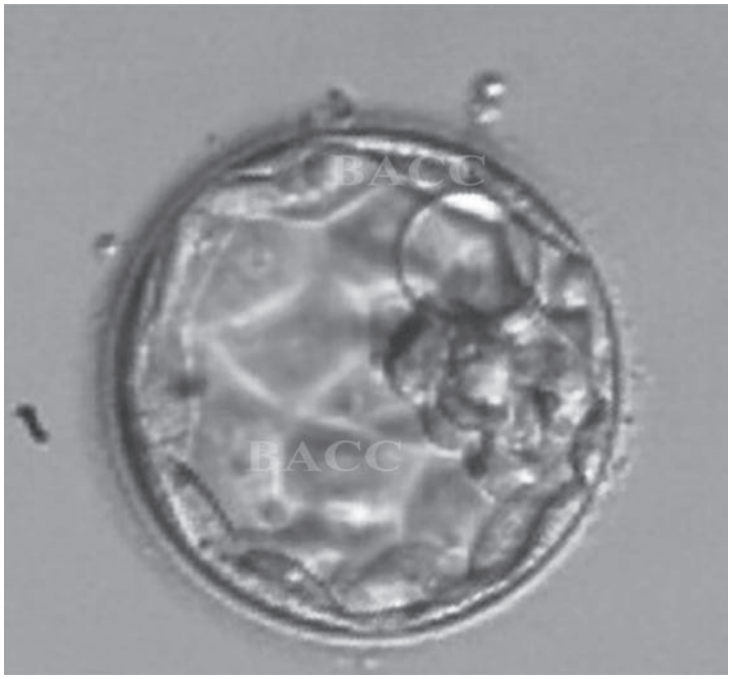

Fig. 15B: Late blastocyst showing vacuole in close vicinity to trophectoderm and ICM.

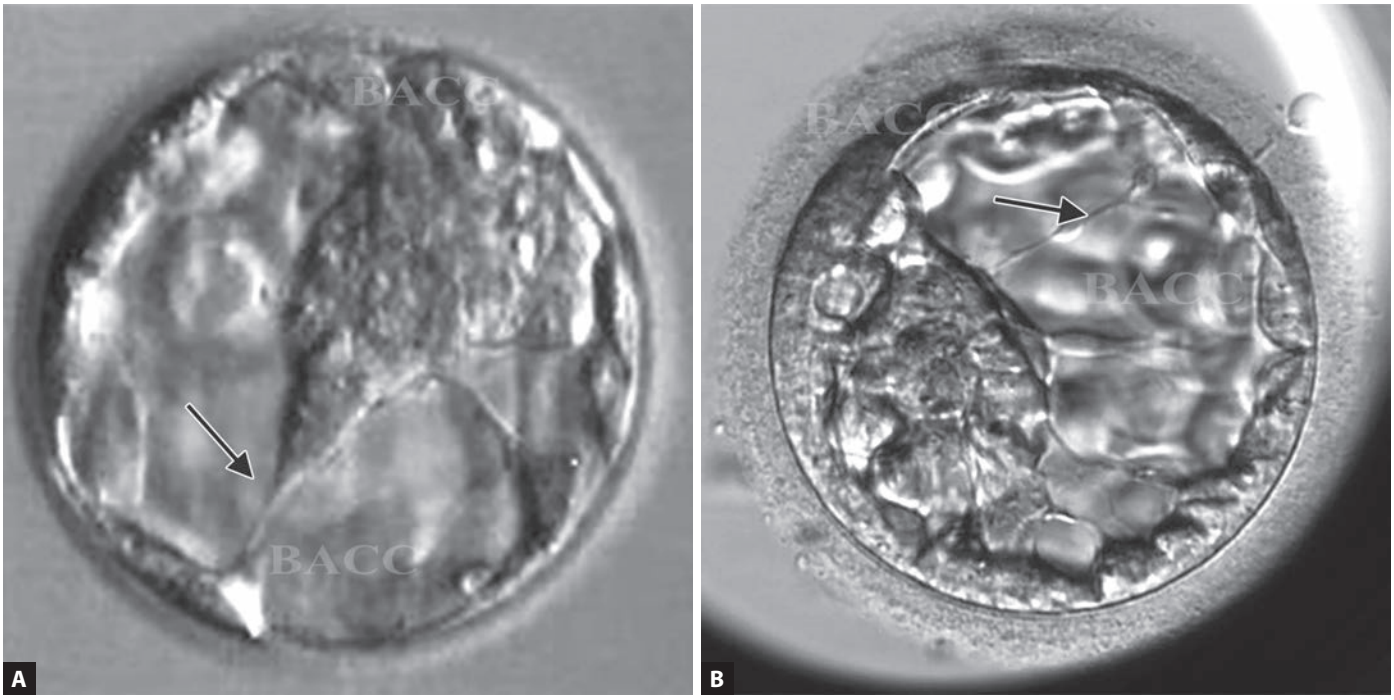
CYTOPLASMIC STRINGS (FIGS. 16A AND B)



Figs. 16A and B: Blastocyst showing cytoplasmic strings (arrows) which represent polarized flow of cells from the polar to the mural trophectoderm which tend to withdraw as the cells reach their destination. When the cytoplasmic strings persist even in the expanded phase, it marks the developmental liability of the blastocysts.

Bezar Ghan VV, Divyashree PS

OOCYTE INSEMINATION IN IN VITRO FERTILIZATION

The mature oocytes are preincubated for 3–6 hours before insemination, as it is well known that an additional period of time is required for cytoplasmic maturation after extrusion of first polar body.

The standard insemination concentration is 100,000 (1 lakh) normal motile sperms per mL. 100 µL microdroplet with sperm suspension is prepared in 35 mm Petri dish with oil overlay.

After checking the oocyte cumulus complex (OCC), a single OCC is transferred into 100 µL of sperm droplet and kept inside the incubator **(Fig. 1)**.

After overnight incubation, cumulus and coronal cells are carefully removed. The cytoplasm of dissected oocyte is examined for the presence of pronuclei and two polar bodies for confirmation of fertilization.

INTRACYTOPLASMIC SPERM INJECTION

Intracytoplasmic sperm injection (ICSI) procedure entails the deposition of a single spermatozoon directly into the ooplasm, thus bypassing the zona and oolemma.

The procedure is carried out on an inverted microscope at 200–400× magnification, using multiple micromanipulation devices (micromanipulator, microinjectors and micropipettes) **(Fig. 2)**.

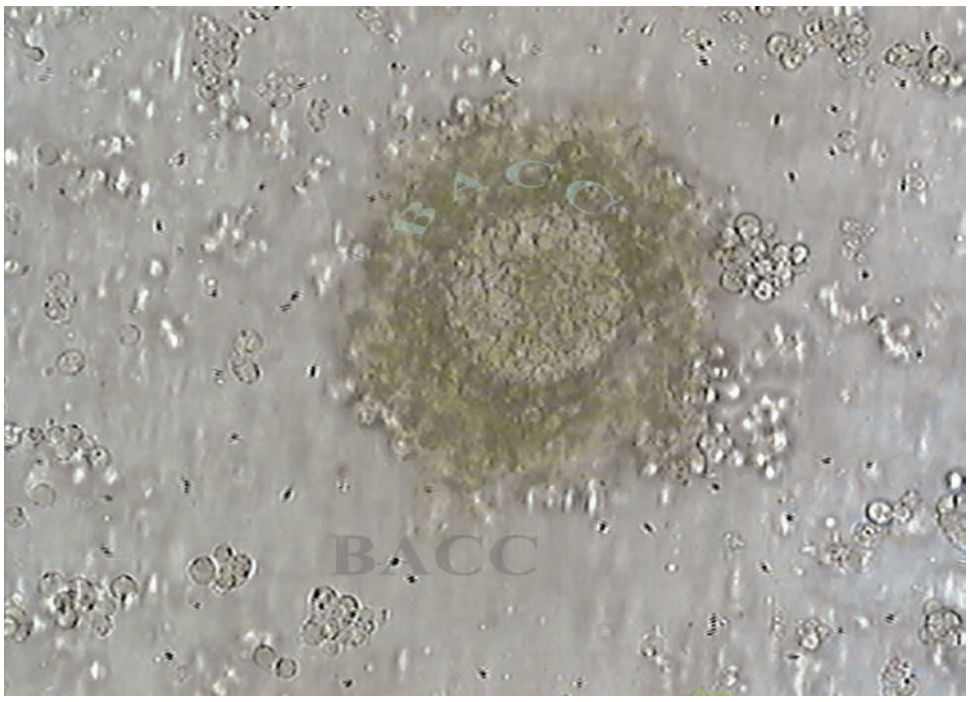

Fig. 1: Oocyte cumulus complex (OCC) charged with sperms for in vitro fertilization (IVF).

Fig. 2: Inverted microscope with micromanipulator research instrument (RI).

Intracytoplasmic sperm injection procedure involves following steps:

- Preparation of ICSI dish
- Semen/sperm preparation
- Preparation and evaluation of oocytes
- Alignment and equilibration of micropipettes
- Sperm immobilization
- Oocyte manipulation
- Microinjection of the oocyte.

Preparation of Intracytoplasmic Sperm Injection Dish (Fig. 3)

Central droplets of 5 µL of PVP (polyvinylpyrrolidone) solution.

At the periphery of PVP droplets, 5 µL droplets of HEPES/MOPS buffered media numbered from 1 to 7.

Sperms are suspended in the central PVP droplet, whereas each oocyte is placed in the surrounding HEPES/MOPS buffered droplets.

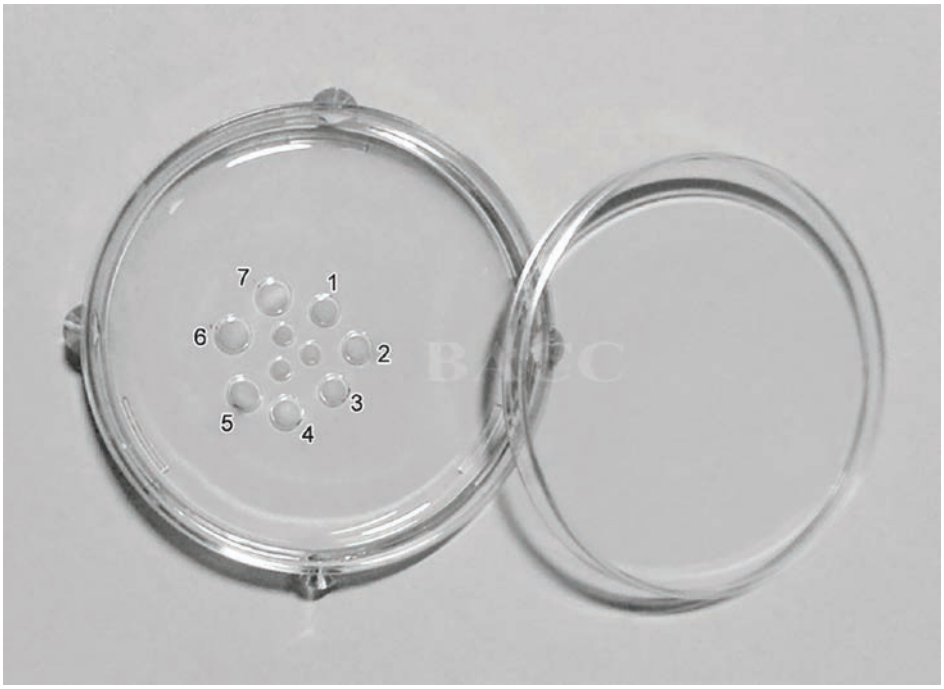

Fig. 3: Intracytoplasmic sperm injection dish.

These droplets are covered with light-weight oil.

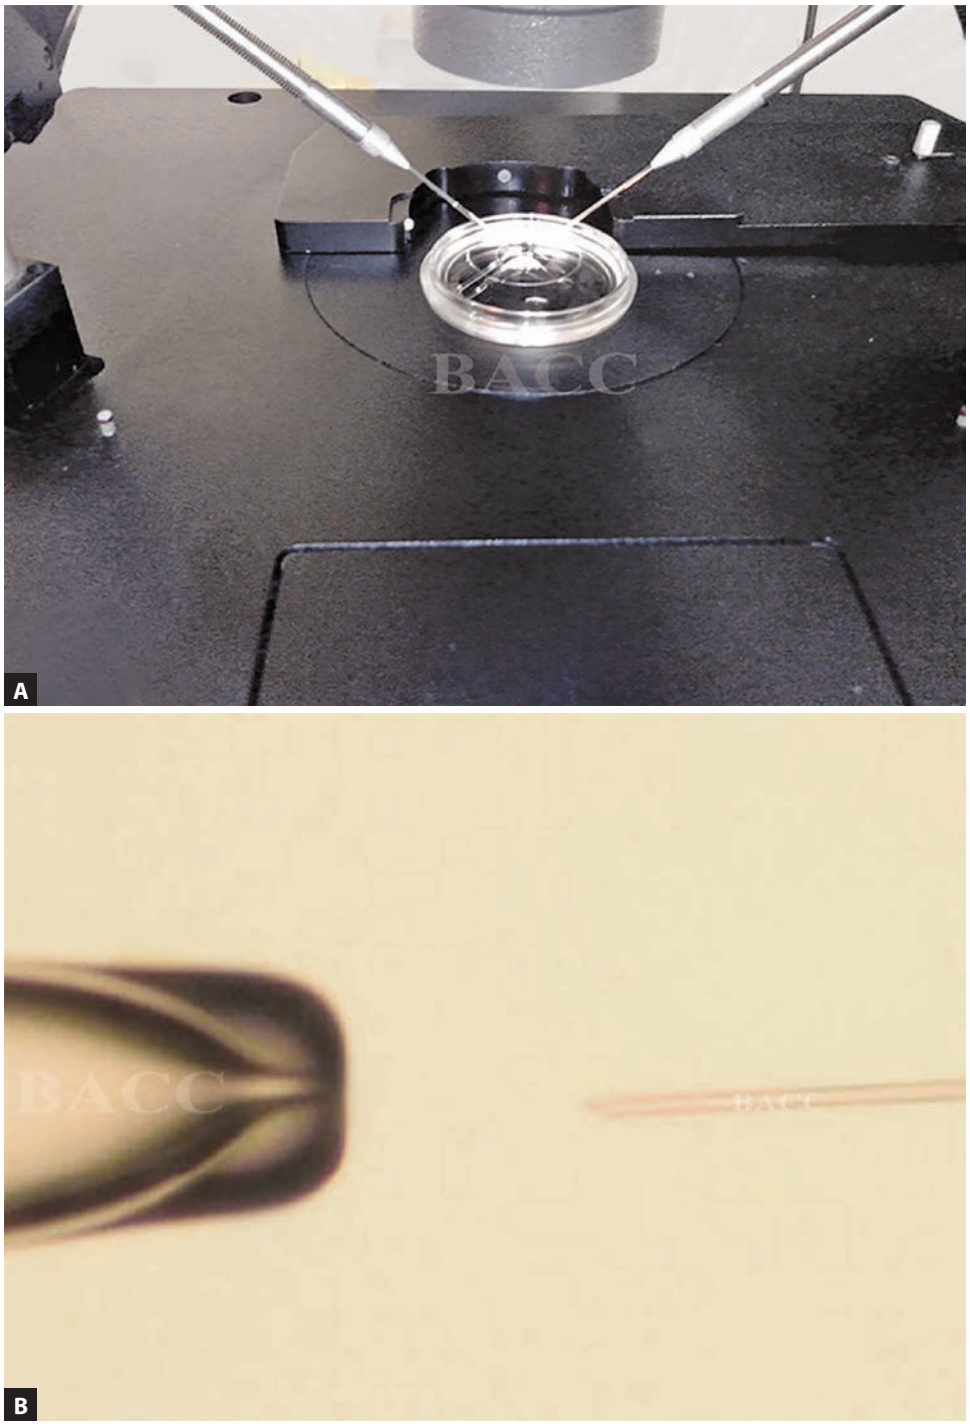
Sperm and oocyte evaluation are discussed in detail in the initial chapters.

Alignment and Equilibration of Micropipettes

Proper alignment of micropipettes makes the micro-injection much easier.

Alignment of micropipettes is best done through microscope, initially under lesser magnification for coarse adjustment and then under higher magnification for fine adjustments.

After alignment both the pipettes should now be seen as shown in **Figures 4A and B**, like straight tools facing each other with their tips focused.



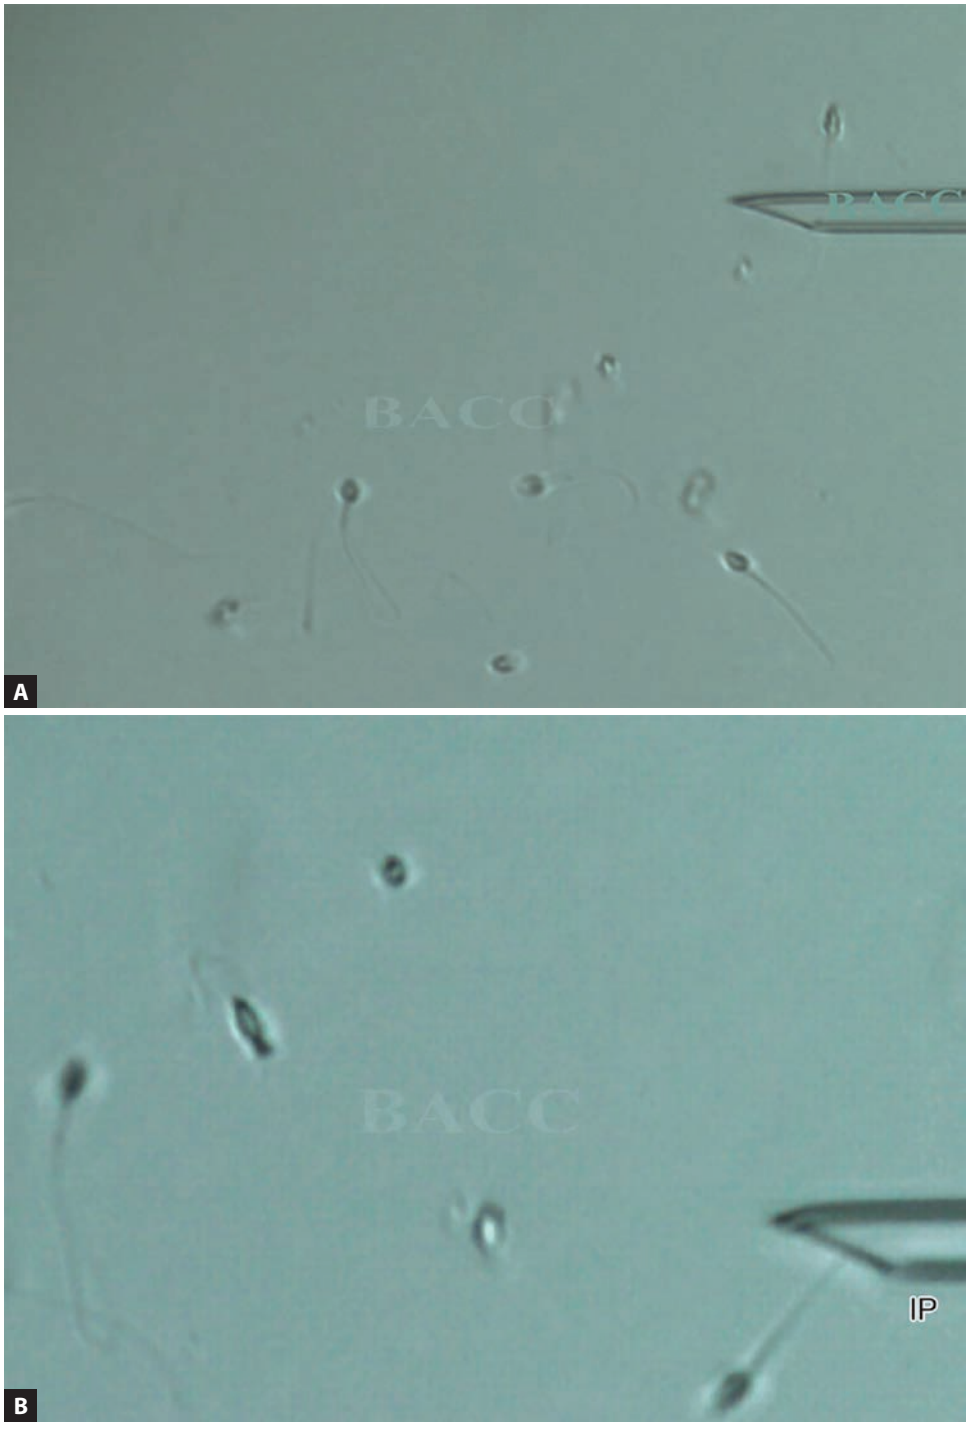
Figs. 4A and B: Properly aligned micropipettes through inverted microscope.

Sperm Immobilization

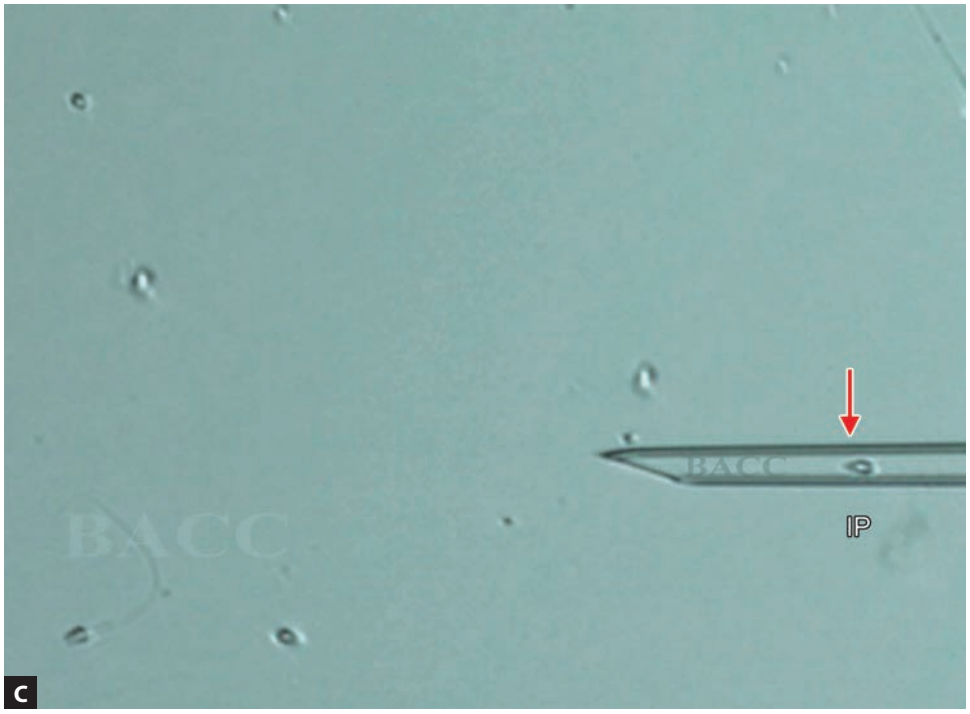
Sperm immobilization is one of the important steps during ICSI as it ensures release of oocyte activation factor into the ooplasm, thus favoring fertilization.

During this process, morphologically normal sperm is selected and it is immobilized either by touching or crushing the tail beyond the midpiece as shown in **Figure 5A**.

After immobilization, sperm is aspirated into injection pipette with its tail first **(Fig. 5B)**. **Figure 5C** showing sperm inside the injection pipette before ICSI.



Figs. 5A and B



Figs. 5A to C: Sperm immobilization.

Oocyte Manipulation

Oocyte manipulation should be very gentle.

Two points to be kept in mind during oocyte manipulation. (1) Oocyte holding with adequate pressure to aid microinjection, not too high which can damage the oocyte and not too less which can cause slippage during microinjection. (2) The polar body should be positioned in 6 or 12 o'clock position, as shown in **Figure 6**, to avoid damage to the spindle apparatus.

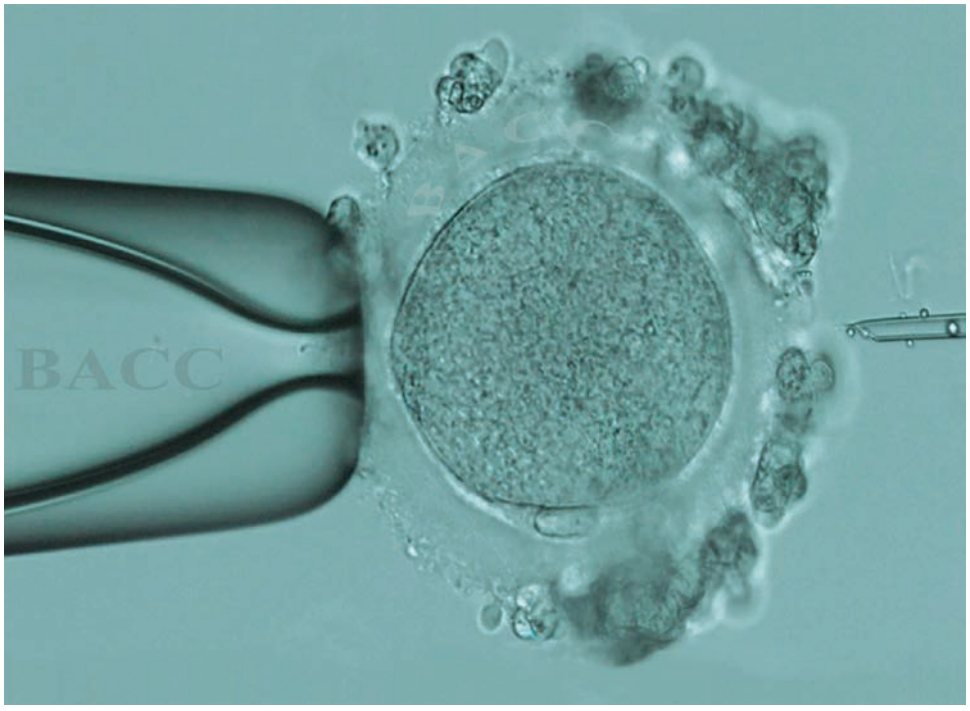


Fig. 6: Oocyte holding and positioning of polar body. Metaphase II oocyte held with holding pipette with polar body at 6 o'clock position.

Microinjection of the Oocyte

After holding the oocyte in position, injection pipette containing immobilized sperm is brought near the zona. Sperm is stabilized in the injection pipette before advancing the injection pipette into the ooplasm. Injection pipette is now gently pushed into the ooplasm, past ZP and oolemma, leaving behind the point of indentation at the site of penetration **(Figs. 7A and B)**.

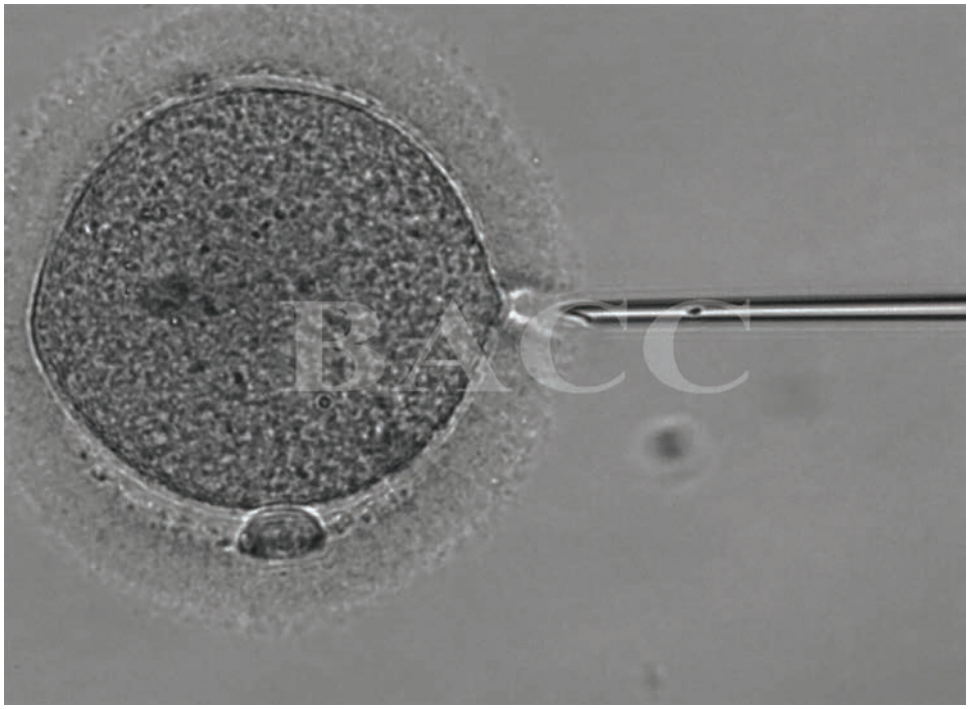

Fig. 7A: The micropipettes and the oocyte in position before intracytoplasmic sperm injection (ICSI).

Fig. 7B: The injection pipette holding sperm inside, piercing the oolemma.

After piercing the oolemma, ooplasm is gently aspirated into injection pipette until oolemma is broken and the cytoplasmic contents mixed with sperm is released back into the ooplasm **(Figs. 7C to E)**.

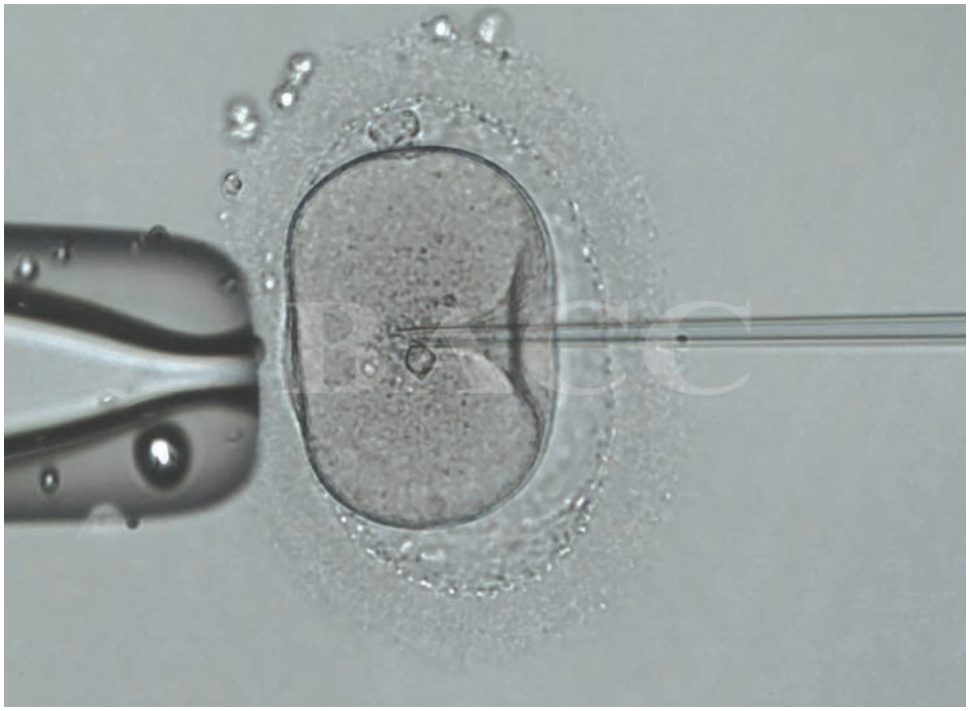

Fig. 7C: Injecting pipette penetrating into the oocyte.

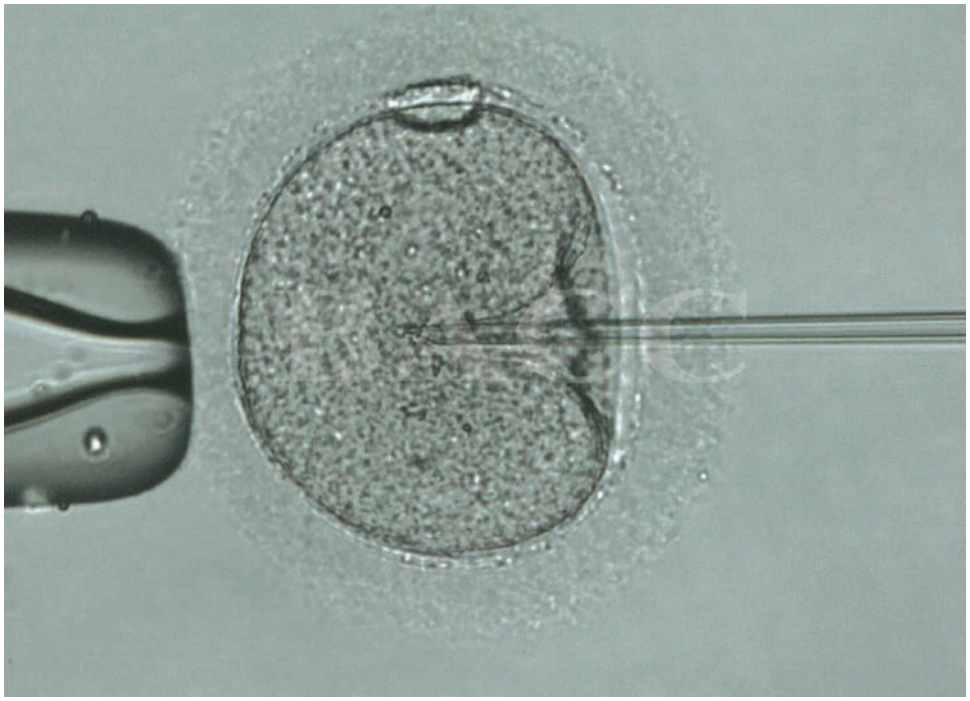

Fig. 7D: Sperm and cytoplasmic contents are gently expelled into the oocyte.

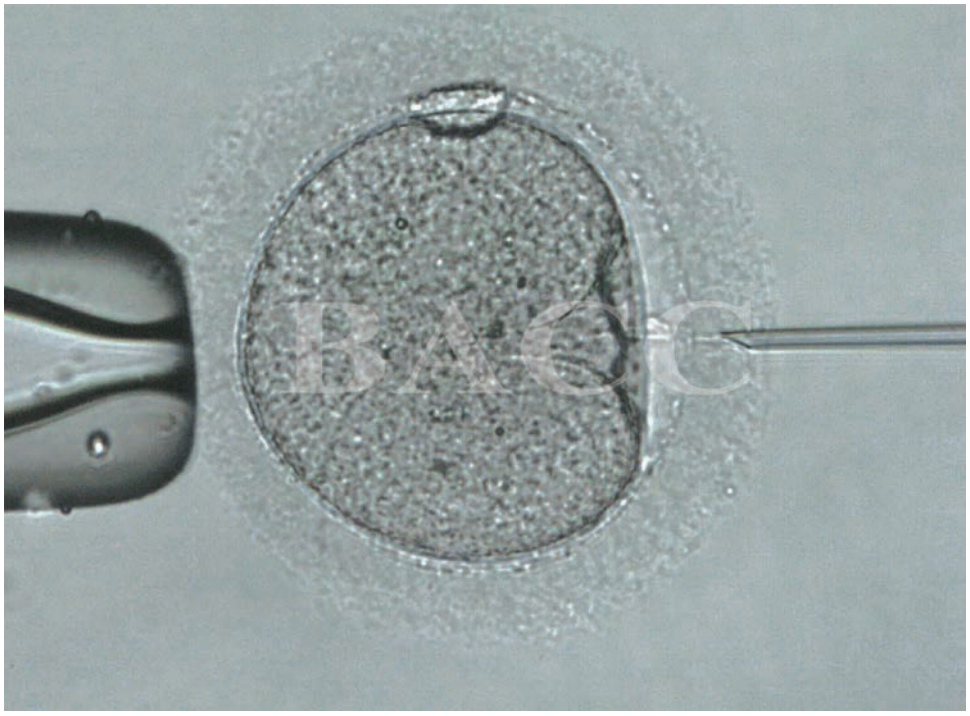

Fig. 7E: Metaphase II (MII) oocyte, immediate postintracytoplasmic sperm injection (ICSI) (note the funneling of the ooplasm).

PHYSIOLOGICAL INTRACYTOPLASMIC SPERM INJECTION

Anitha S Kumari K, Bezar Ghan VV, Divyashree PS, Mohammed Ashraf C

INTRODUCTION

Physiological intracytoplasmic sperm injection (PICSI) is an advanced method of sperm selection, before intracytoplasmic sperm injection (ICSI) **(Figs. 1A and B)**. PICSI represents a physiologic alternative for slowing sperm motility before ICSI, avoiding any potential damaging effect of synthetic polyvinylpyrrolidone (PVP).[1]

In the natural human fertilization process, hyaluronic acid (HA) seems to play a pivotal role in physiological sperm selection. Spermatozoa that are able to bind permanently to HA in vitro are mature and have completed the spermiogenetic process of plasma membrane remodeling, cytoplasmic extrusion and nuclear maturity.[2] These mature spermatozoa have a high density of HA receptors.

Sperms are added to the dot of hyaluronan and within minutes the bound sperms are attached by their acrosome to the surface of the dot **(Figs. 2A and B)**.

An ICSI microtool is used to select the HA bound sperm, which will be used for ICSI **(Fig. 3)**.

INTRACYTOPLASMIC MORPHOLOGICALLY SELECTED SPERM INJECTION

Bezar Ghan VV, Dileep Kumar R, Anitha S Kumari K, Divyashree PS

INTRODUCTION

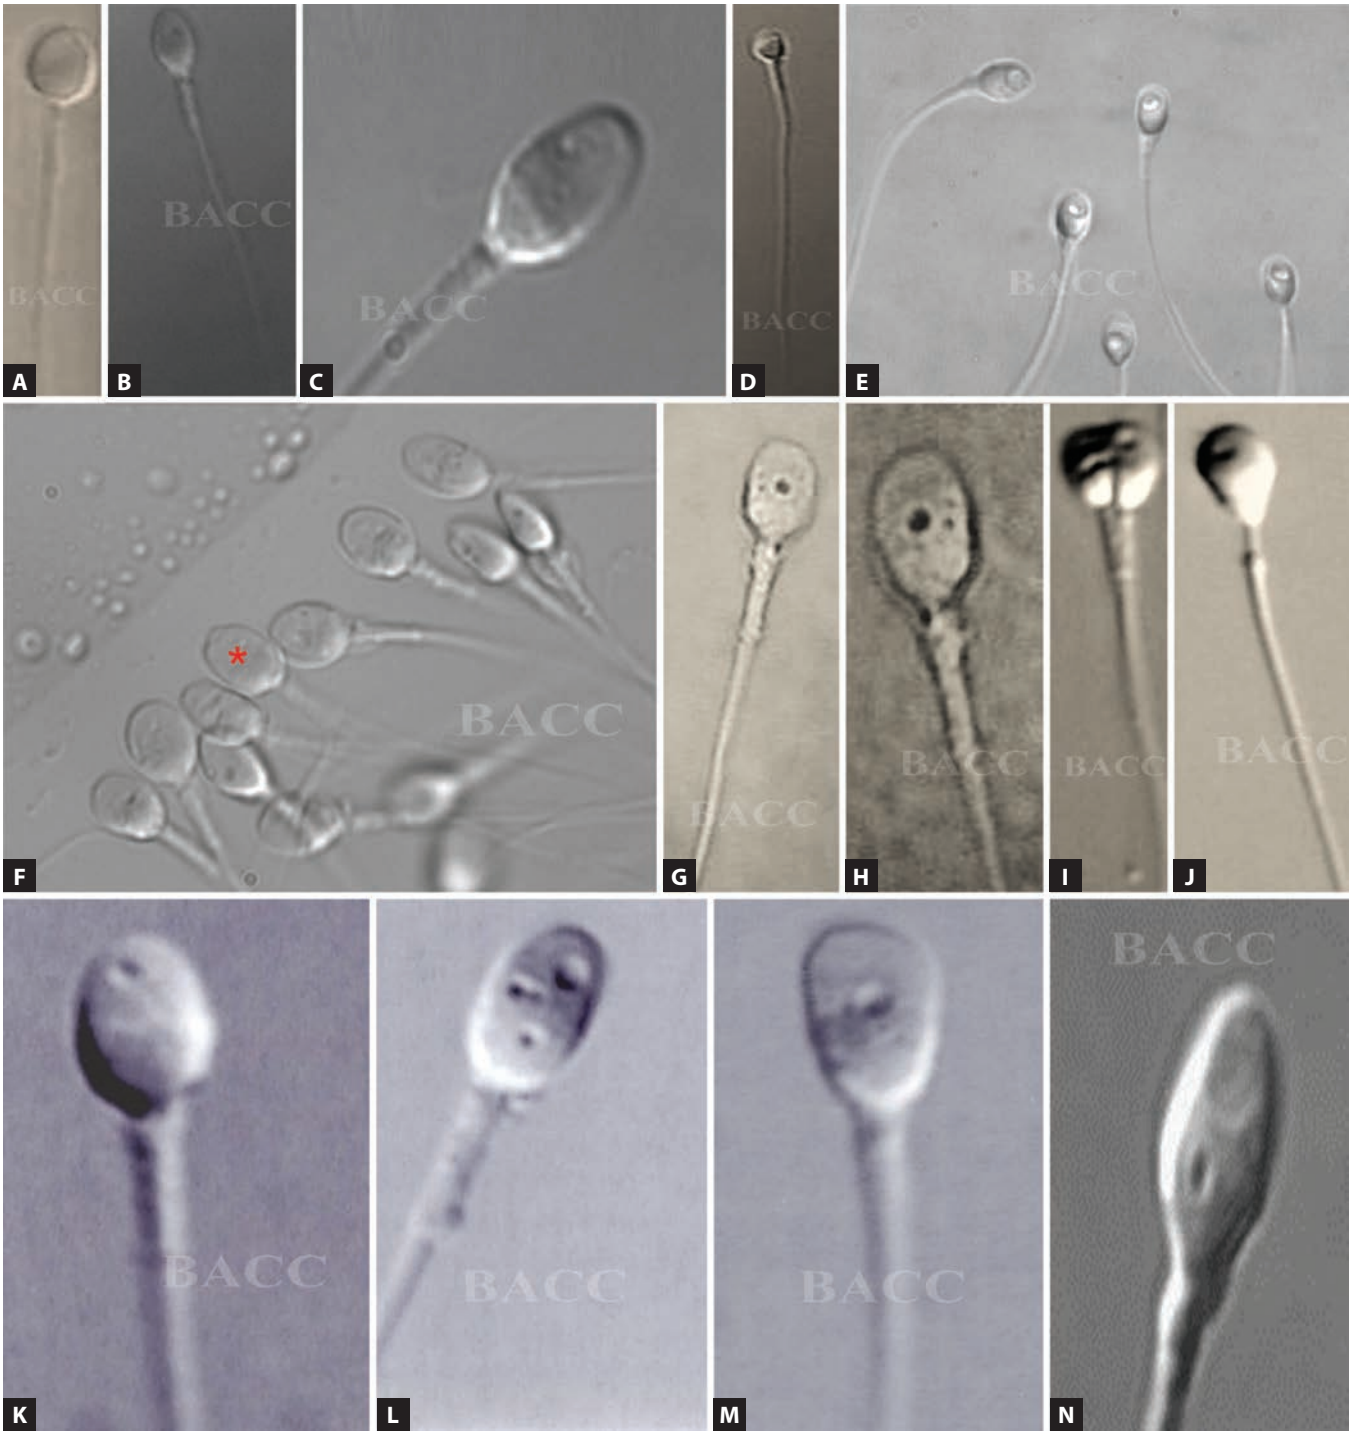
Intracytoplasmic sperm injection is usually performed at an optical magnification of 400×, since this magnification allows identification of only major morphological defects of the sperm; minor morphological defects of the sperms, which seem to be related to ICSI outcome, can be missed.[3]

Methods of advance sperm selection include motile sperm organelle morphology examination (MOSME; magnification 6,600×) and intracytoplasmic morphologically selected sperm injection (IMSI).

Motile sperm organelle morphology examination is an unstained cytological technique; its incorporation together with micromanipulation system has resulted in evolution of IMSI.

Intracytoplasmic morphologically selected sperm injection is a real-time method in which the sperm structure is visualized at a magnification of 6,600× **(Figs. 4A to N)**.

The meta-analysis by Souza Setti et al. concludes that IMSI not only significantly improves the percentage of top-quality embryos, implantation and pregnancy rates, but also significantly reduces miscarriage rates as compared with ICSI.[4]



Figs. 4A to N: (A to C) Sperms with normal morphology; (D) Sperm head showing vacuole with normal mid-piece and tail; (E) Sperms under 6,600x magnification showing vacuoles; (F) All sperms showing vacuoles except one (*) showing extrusion; (G to N) Morphologically abnormal sperms under 6,600x magnification; (G and H) Sperms with vesicles; (I) Double-headed sperm with vesicles; (J) Pear-shaped head with vesicle and beaded mid-piece; (K) Round-headed sperm with vesicle; (L) Sperm head with multiple vesicles; (M and N) Sperms with abnormal head shape, containing vesicle.

POLOSCOPY

Divyashree PS, Bezar Ghan VV, Anu Kottur

INTRODUCTION

The important role of meiotic spindle during oogenesis and fertilization need not be overemphasized. The developmental competence of a mature oocyte can be obtained by the detection and analysis of meiotic spindle.

Polarized light microscopy (poloscopy) helps to visualize the meiotic spindle noninvasively and in a dynamic fashion **(Figs. 5 to 9)**.

PRINCIPLE OF POLOSCOPY

The highly orderly structure of spindle microtubules generates the phenomenon of birefringence, which consists of the decomposition of a single incident beam of polarized light into two orthogonal rays. This creates a difference in contrast between the spindle and the rest of the cell which may be detected by imaging methods (e.g., the poloscope) that digitally amplify birefringence signals and after computational manipulations, make quantifiable the degree of microtubule orientation within living cells.

Several studies have confirmed that the absence of the spindle compromises the ability of the oocyte to fertilize and undergo normal preimplantation development.[5-7]

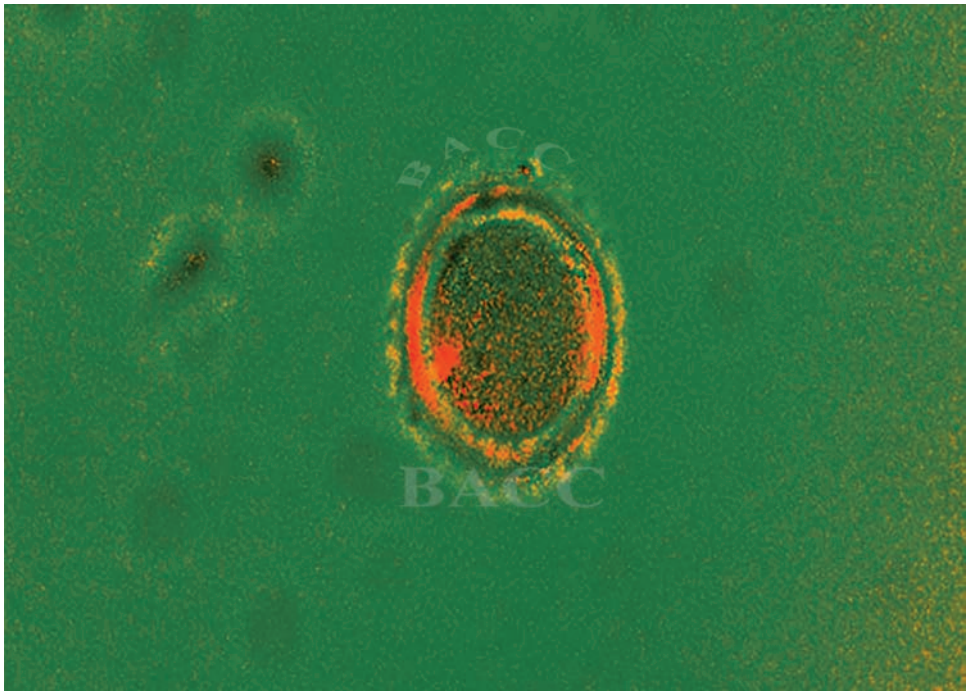


Fig. 5: Telophase I oocyte visualized using polarized light microscopy. The meiotic spindle (MS) can be seen at 8 o'clock position and first polar body (IPB) at 6 o'clock position.

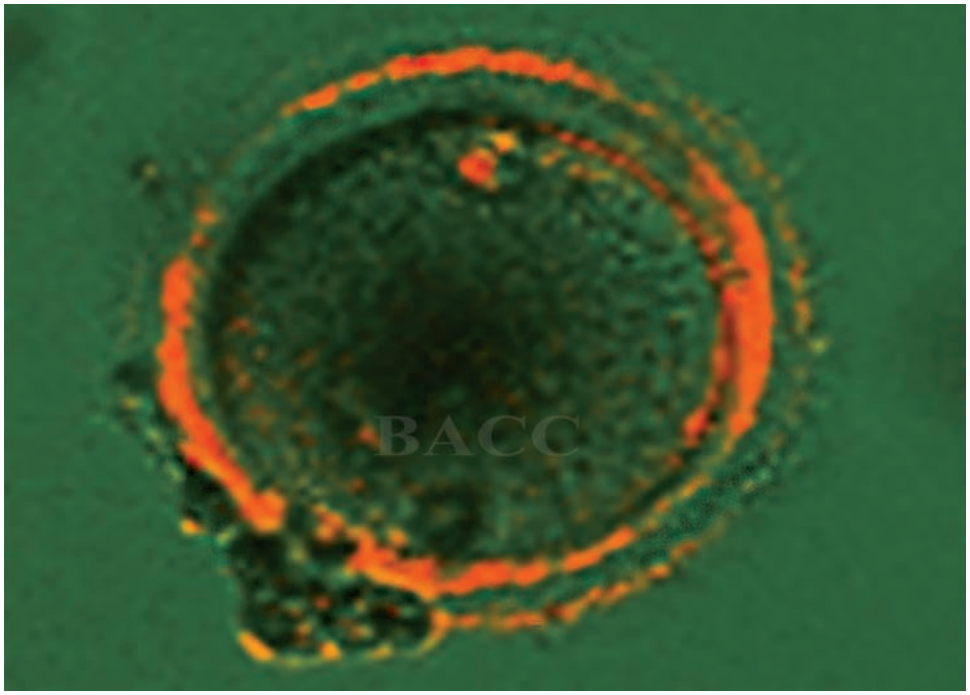

Fig. 6: Metaphase II (MII) oocyte visualized using polarized light microscopy. The meiotic is visible along with the polar body at 12 o'clock position, indicating the first meiotic division is not complete.

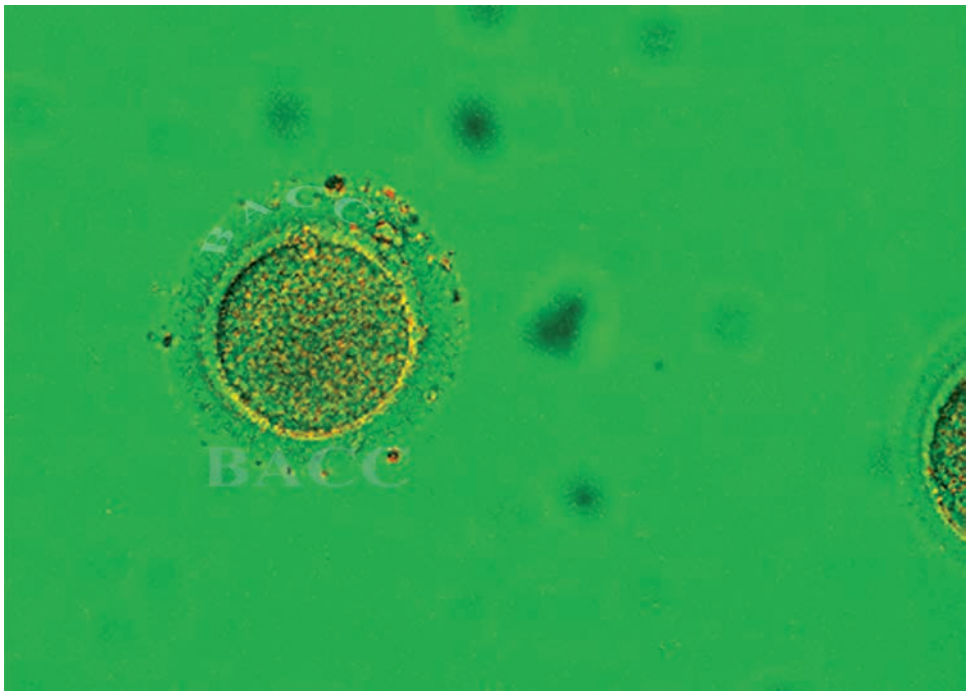

Fig. 7: Metaphase II (MII) oocyte visualized using polarized light microscopy. The meiotic spindle of the second meiotic division is absent.

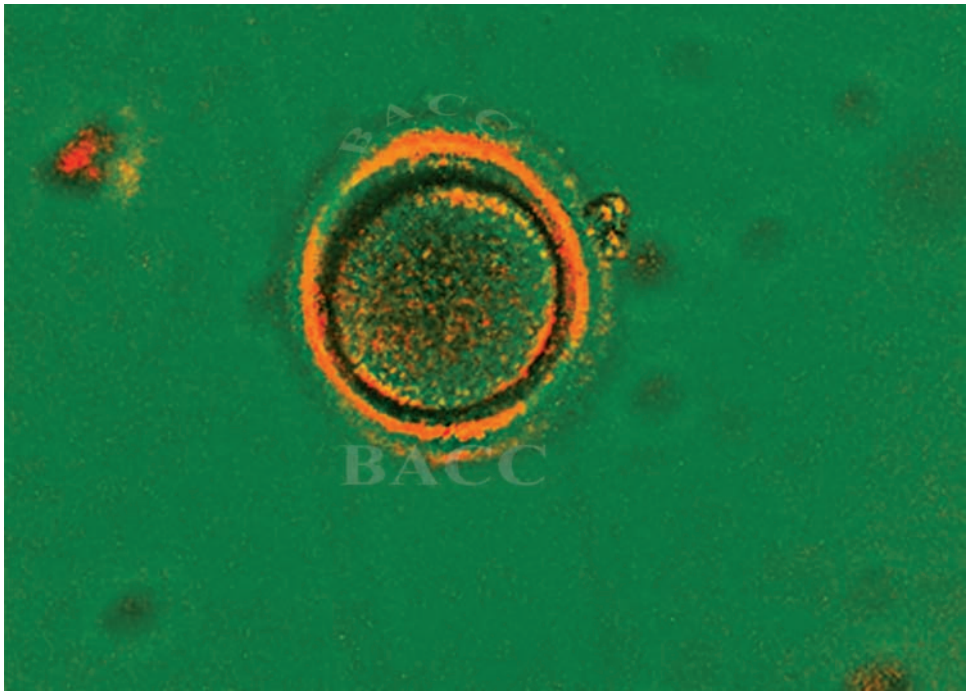

Fig. 8: Metaphase I (MI) oocyte visualized using polarized light microscopy. Note the absence of meiotic spindle and polar body.

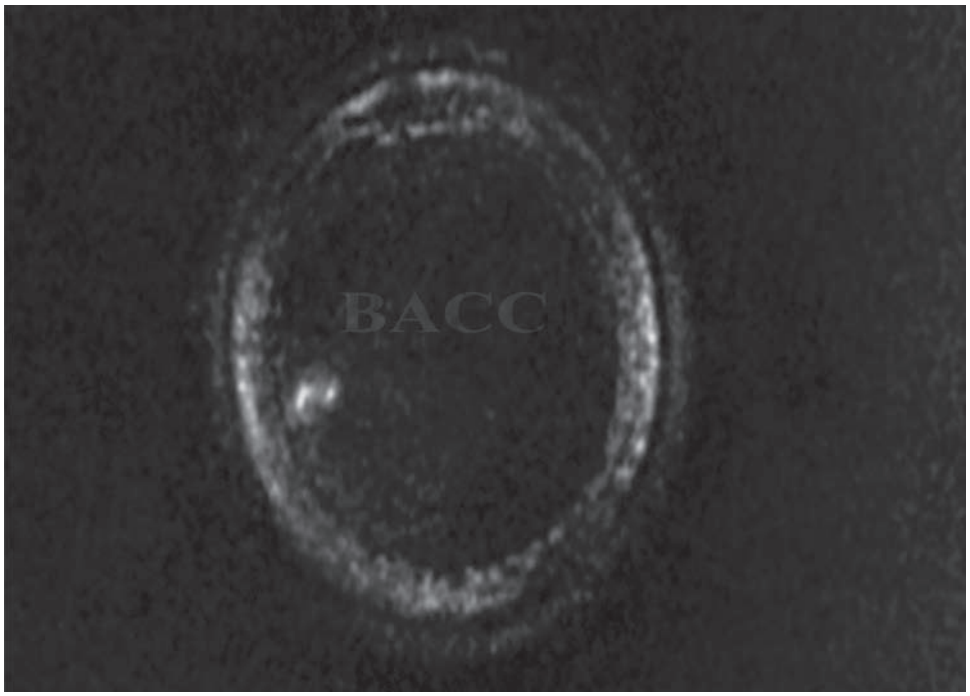

Fig. 9: Metaphase II (MII) oocyte visualized using polarized light microscopy.
Note the meiotic spindle at 9 o'clock position and polar body at 11 o'clock position.

TIME-LAPSE IMAGING

Divyashree PS, Anitha S Kumari K, Mohammed Ashraf C, Bezar Ghan VV

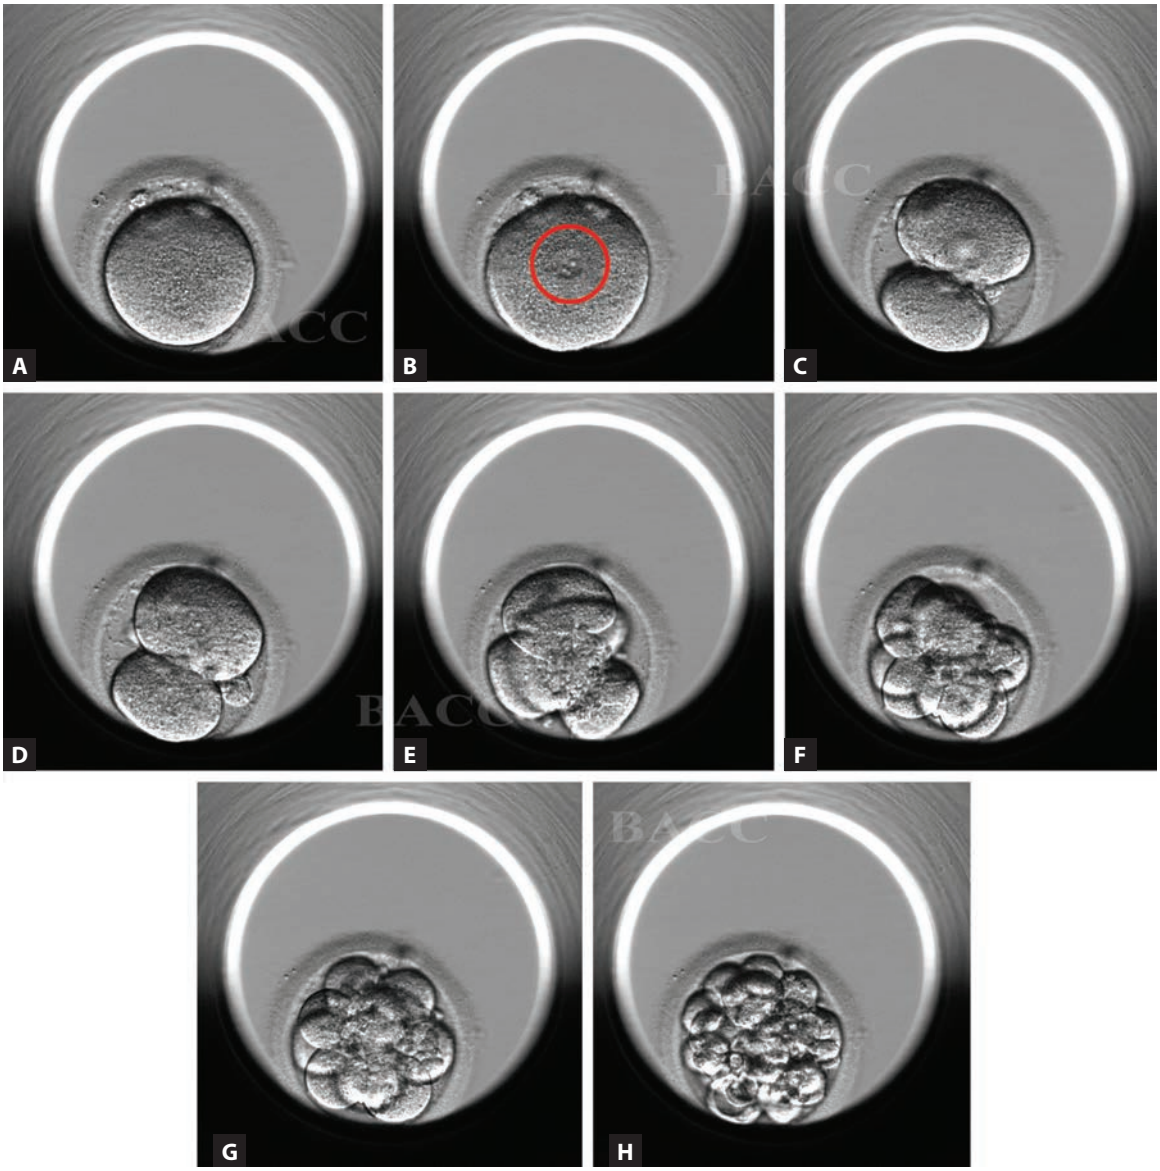
INTRODUCTION

Time-lapse imaging (TLI) is a powerful tool for the study of early embryo development. It offers many advantages over traditional time-point microscopy. Using time-lapse microscopy (TLM) **(Fig. 10)**, biological samples are cultured directly on an imaging device that captures images at defined intervals over a specific period of time. Individual captured images can then be processed into a time-lapse sequence, and from the video sequence, morphological, dynamic and quantitative data can be extracted. In contrast, traditional time-point microscopy acquires images at distinct time points. Such time points are often selected for user convenience rather than biological relevance, and they are acquired at a significantly lower frequency than TLI sequences **(Figs. 11 to 17)**. For example, in embryo grading and embryo research, images may be collected daily, while TLI enables images to be captured at 20-minute, 5-minute or even 10-s frequencies.[8,9]

Fig. 10: Embryoscope (Time lapse system).

1 PRONUCLEI

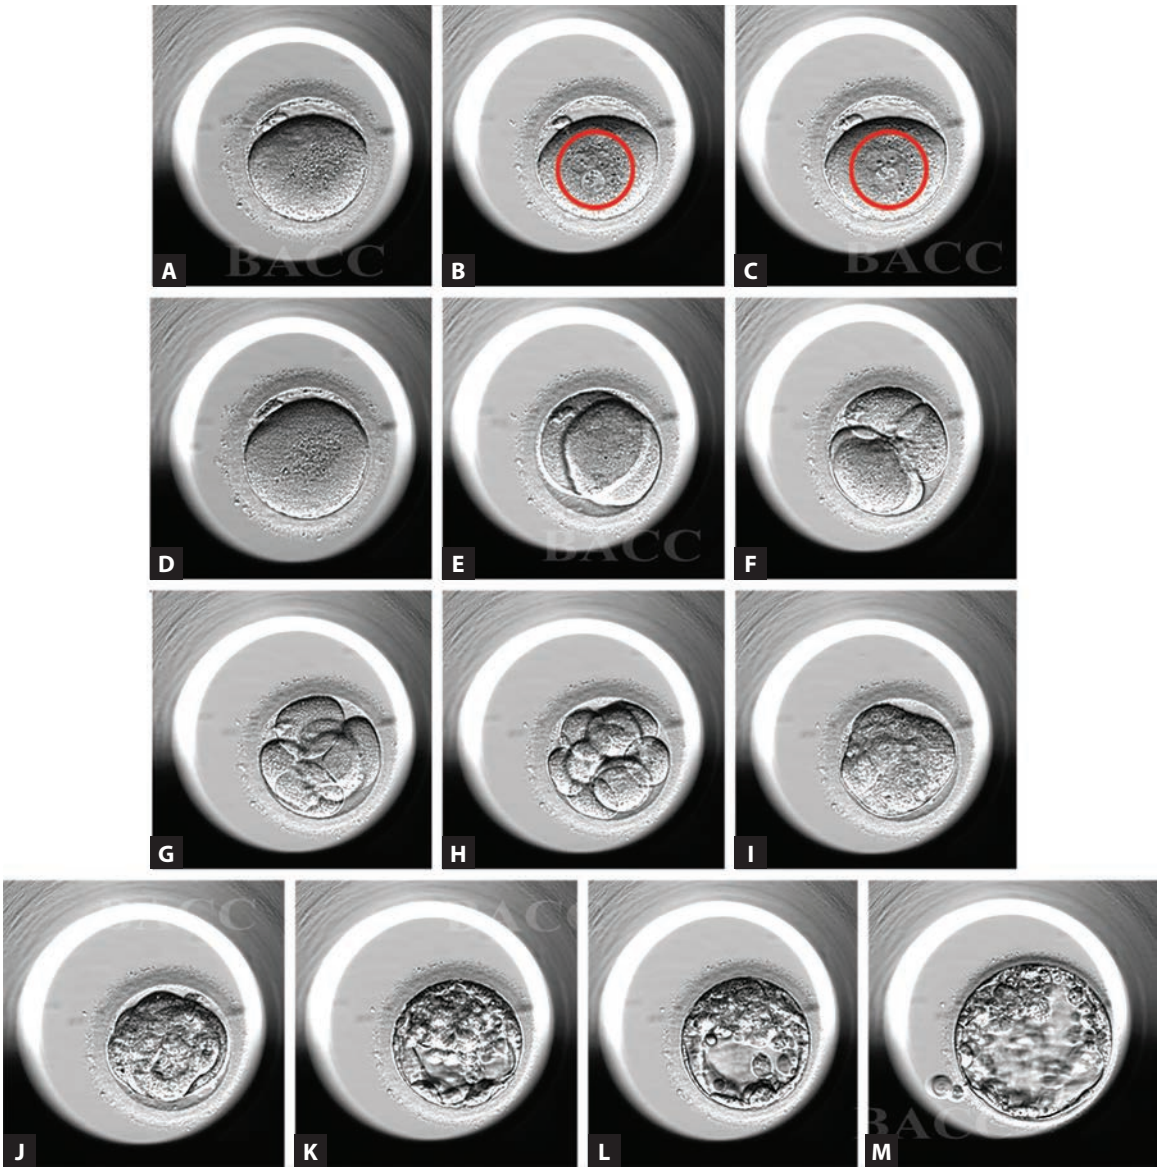
The asynchrony in Pronuclei (PN) formation or PN fusion during fertilization can lead to the presence of 1 pronuclei. This results in the possibility of oocytes having a diploid set of chromosomes and two polar bodies. Transfer of such oocytes can be considered but the possibility of aneuploidy is higher **(Figs. 11A to H)**.



Figs. 11A to H: A time-lapse imaging (TLI) showing the formation of a 1 Pronuclei (1PN) (abnormal fertilization) resulting in the development of an embryo.

3 PRONUCLEUS

The pictures depict the formation of triploid zygote with the injection of a single sperm. In this case, it is believed that the oocyte did not complete meiosis and has retained half of the female genetic material that should be discarded in the second polar body. These oocytes will have two maternal and one paternal pronuclei. An embryo is considered anomalous if it has more than two pronucleus regardless of the source of the extra nucleus **(Figs. 12A to M)**.



Figs. 12A to M: Time-lapse imaging (TLI) showing the formation of a 3PN (abnormal fertilization) resulting in the development of a blastocyst (anomalous embryo).

Fig. 13: An early cleavage embryo seen at two-cell stage, 25 hours postinsemination. Fragmentation at 12 o'clock position.

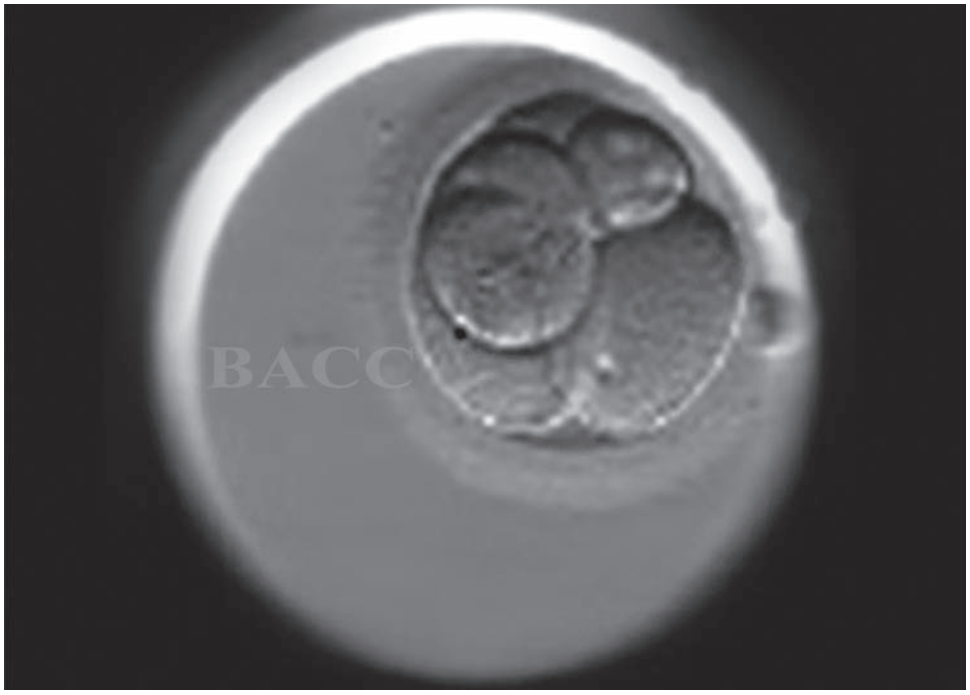


Fig. 14: Time-lapse imaging (TLI) at 44 hours postinsemination showing five-celled embryo. The division is earlier in one of the blastomeres resulting in a five-celled embryo at 34 hours.

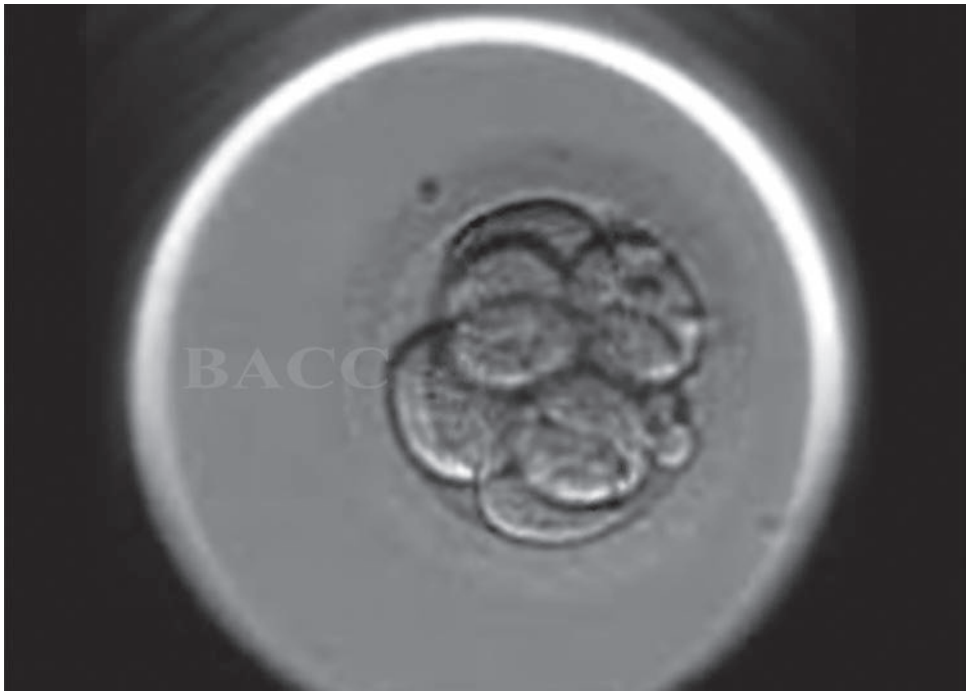

Fig. 15: Time-lapse imaging (TLI) at 68 hours postinsemination showing eight-celled embryo.

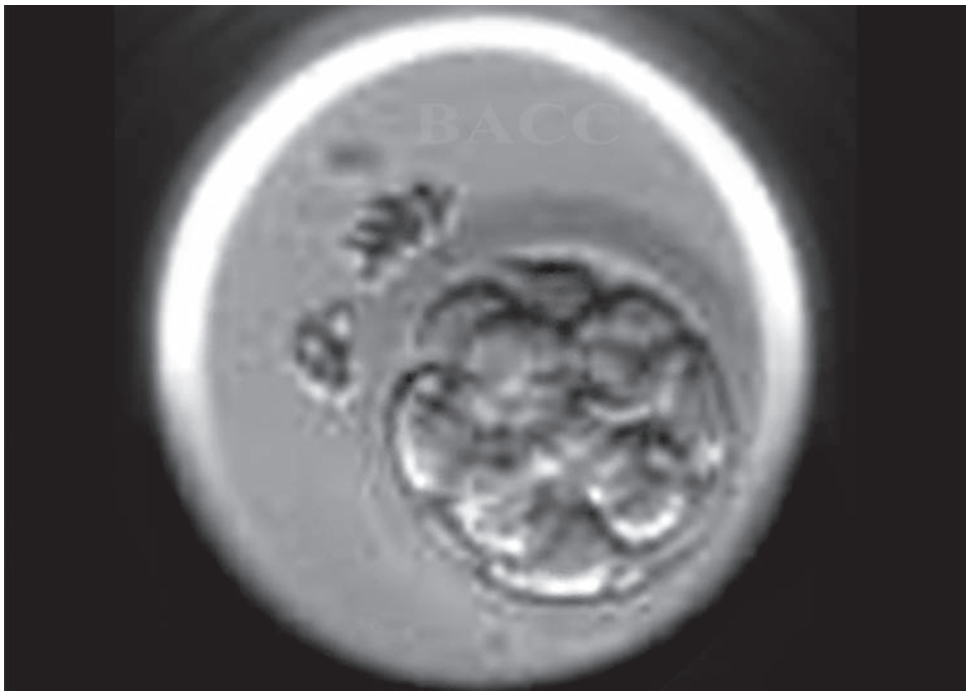

Fig. 16: Time-lapse imaging (TLI) at 95 hours postinsemination showing embryo entering into the stage of morula.
Note: Fragment formation and fragment uptake of an embryo that can occur at different stages of cell division is an example of the dynamic cellular division (note the presence of fragmentation in Figure 15 and fragmentation uptake in Figure 16).

Fig. 17: Time-lapse imaging (TLI) at 105 hours postinsemination showing embryo in the early blastocyst stage.

LASER-ASSISTED HATCHING

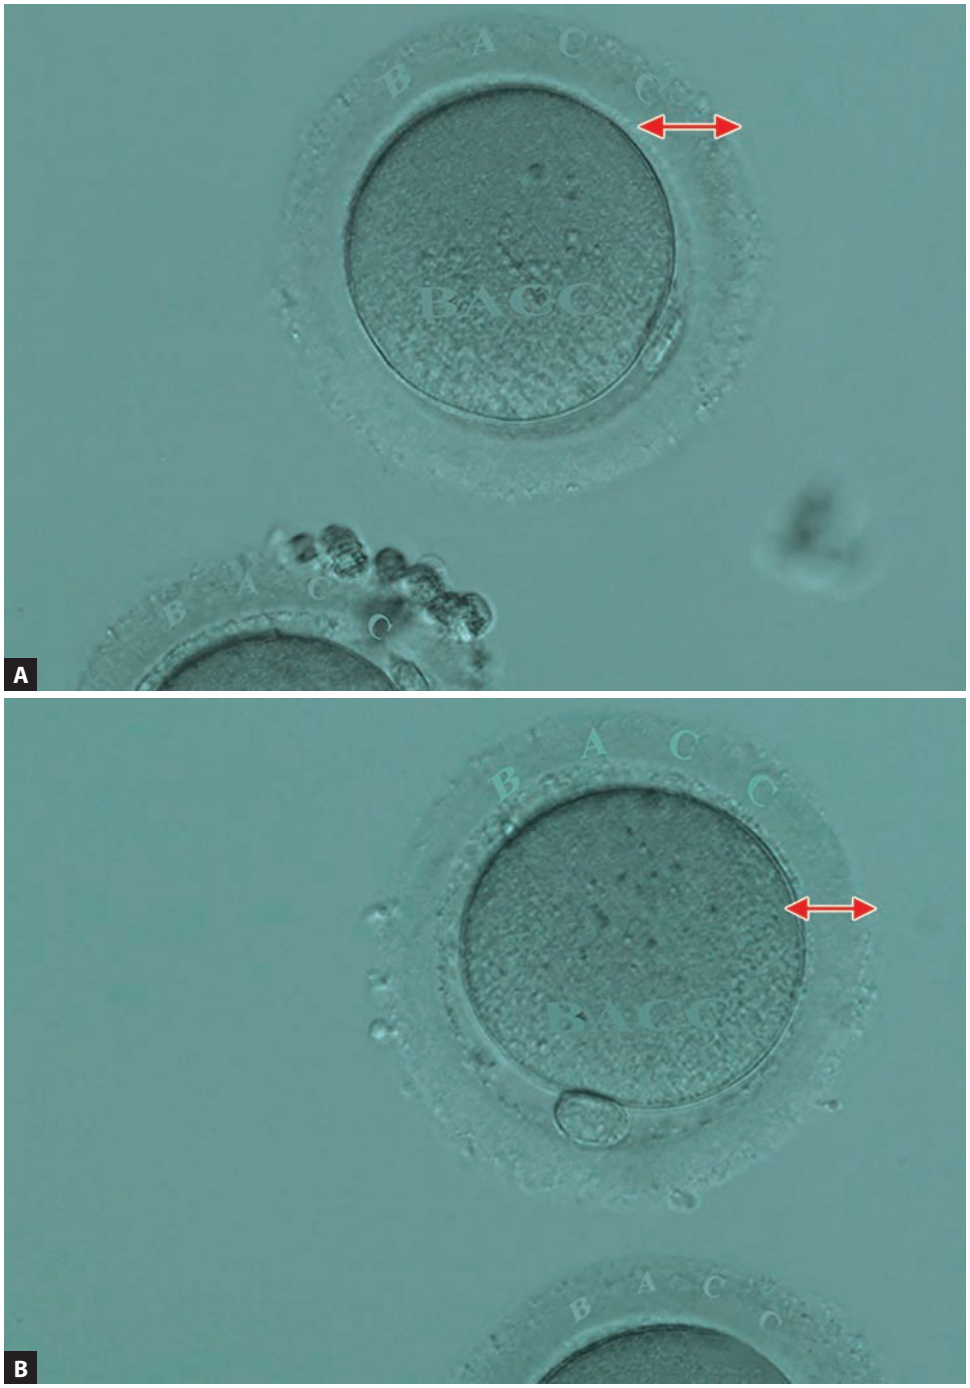
Bezar Ghan VV, Divyashree PS, Kamini A Rao

INTRODUCTION

For the trophectoderm cells to interact with endometrial cells, blastocyst should get out of the zona pellucida (ZP) (hatching). It has been postulated that during in vitro culture of human embryos, zona hardening can occur and as a consequence hatching can be inhibited.[10]

Recent systematic review and meta-analysis by Martins et al.[11] conclude that assisted hatching (AH) was related with increased clinical pregnancy and multiple pregnancy rates in women with previous repeated failure or in frozen-thawed embryo transfer.

The procedure is performed on a microscope slide, and the embryo is placed in a drop of medium covered with paraffin oil. The embryo is held with a holding pipette and the laser is delivered through a microscopic laser glass fiber, fitted to the manipulator by a pipette holder, in direct contact with the ZP. Several pulses are necessary to penetrate the ZP. Because each laser pulse removes only small portions of the ZP, the fiber tip has to be continuously readjusted to guarantee close contact with the remaining zona **(Figs. 18 to 21)**.



Figs. 18A and B: Denuded mature oocytes showing thick zona.

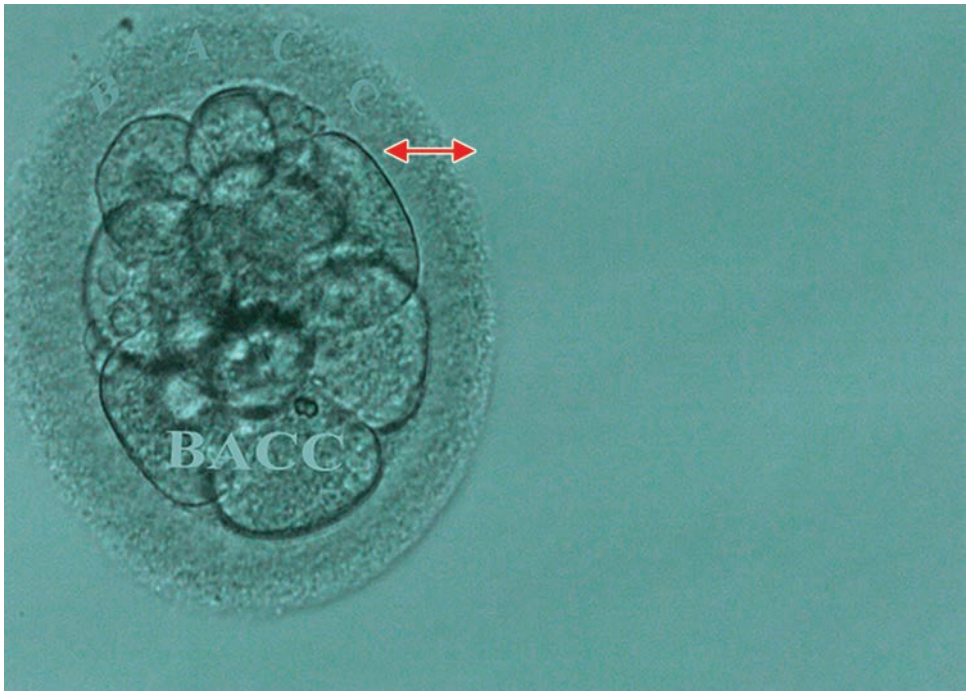


Fig. 19: Eight-celled human embryo showing thick zona before laser-assisted hatching (LAH).

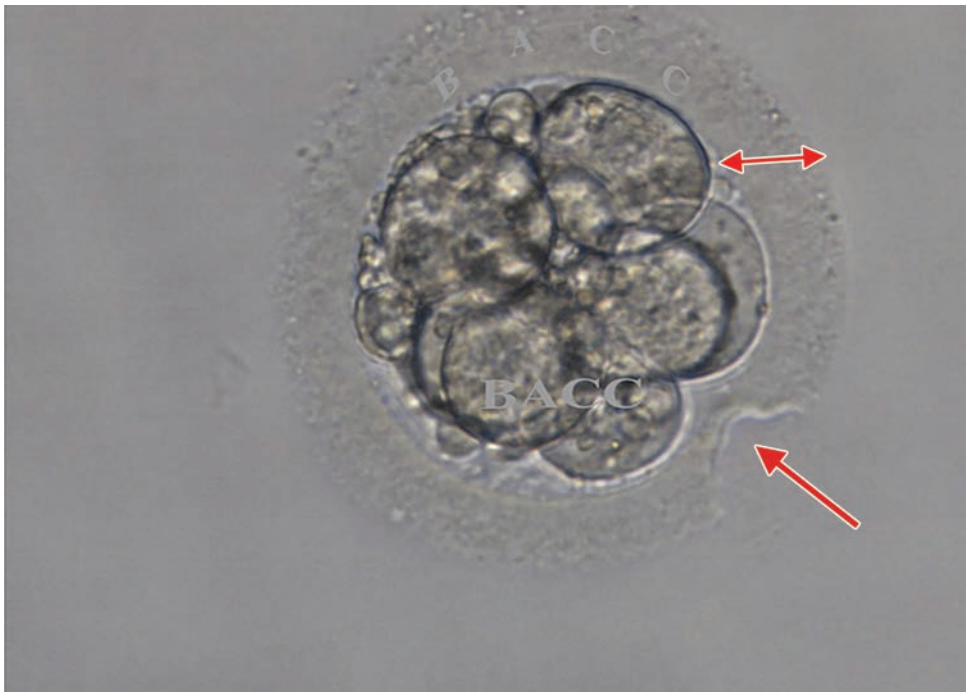

Fig. 20: Eight-celled human embryo after laser-assisted hatching (LAH) at 4 o'clock position.

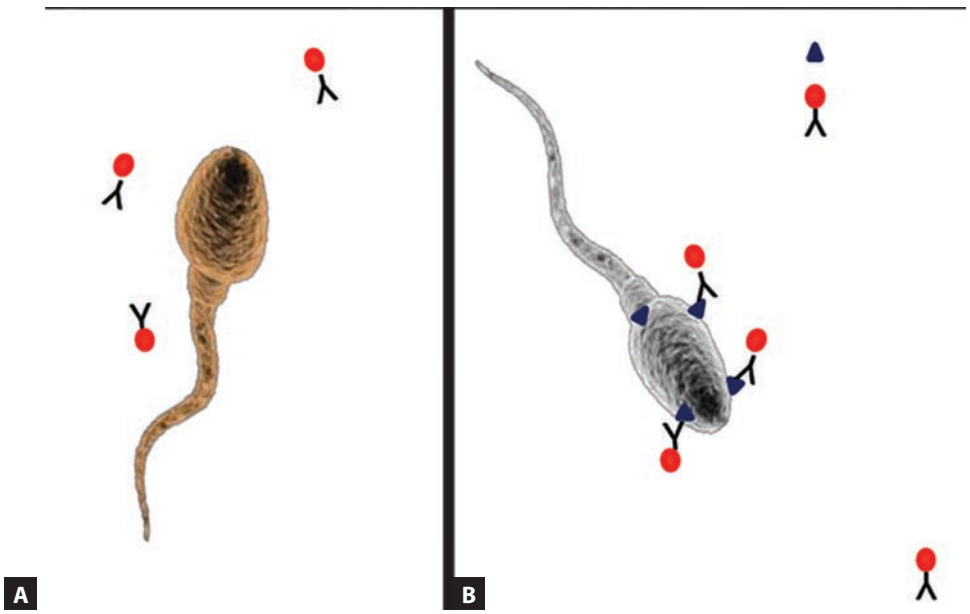
Fig. 21: Human blastocyst after laser-assisted hatching (LAH) at 11 o'clock position.

MAGNETIC-ACTIVATED CELL SORTING (MACS) OF HUMAN SPERMATOZOA

Mohammed Ashraf C

The sperm cell membrane plays a vital role in sperm survival. MACS was introduced as a technique that separates apoptotic spermatozoa from nonapoptotic ones **(Fig. 22)**. In an abnormal sperm, the phosphatidyl serine located in the inner leaflet of the lipid bilayer of the plasma membrane moves to the outer leaflet (apoptotic marker).

Fig. 22: Magnetic-activated cell sorting.



Figs. 23A and B: (A) Normal sperm (viable spermatozoa) Annexin V negative: no annexin V binding; (B) Abnormal sperm (apoptotic) Annexin V positive: annexin V binding.

Image denotes Annexin V Microbead.

The isolation of sperm cells with exposed phosphatidyl serine is performed using Annexin V-coated microbeads **(Figs. 23A and B)**.

In MACS technique, spermatozoa are incubated with a buffer containing Annexin V-conjugated microbeads and are then exposed to a magnetic field in an affinity column which separates apoptotic sperms.[12]

CHAPTER 135

Cryopreservation

Bezar Ghan VV, Anitha S Kumari K, Divyashree PS, Mohammed Ashraf C

INTRODUCTION

The main principle of cryopreservation for mammalian oocytes and embryos is to reduce damage caused by intracellular ice formation. Two basic techniques have been developed: (1) controlled slow rate freezing protocols, and (2) rapid freezing protocols such as vitrification.

There are various studies comparing the effectiveness between slow freezing and vitrification. Eventually, the overwhelming comparative evidence has made it clear to everybody that in developmental stages, vitrification produces better survival and more competent oocytes/embryos than traditional freezing.[1]

In this chapter, we summarize the basic steps of vitrification along with the morphological changes during vitrification and warming.

CRYOPRESERVATION OF OOCYTES

Materials

Vitrification of oocytes contains two solutions: (1) equilibration solution (ES), (2) vitrification solution (VS).

Equilibration solution: It is a 3-(N-morpholino) propanesulfonic acid (MOPS) buffered solution of modified human tubal fluid (HTF) containing nonessential and essential amino acids, gentamicin sulfate (10 mg/L), 7.5% (v/v) each of dimethyl sulfoxide (DMSO) and ethylene glycol and 12 mg/mL human serum albumin **(Figs. 1 to 9)**.

Vitrification solution: It is a MOPS buffered solution of modified HTF containing nonessential and essential amino acids, gentamicin sulfate (10 mg/L), 15% (v/v) each of DMSO and ethylene glycol, 12 mg/mL human serum albumin and 0.6 M sucrose **(Figs. 10 to 13)**.

Fig. 1: Oocytes in equilibration solution (ES) at 30 seconds. Oocytes beginning to shrink.

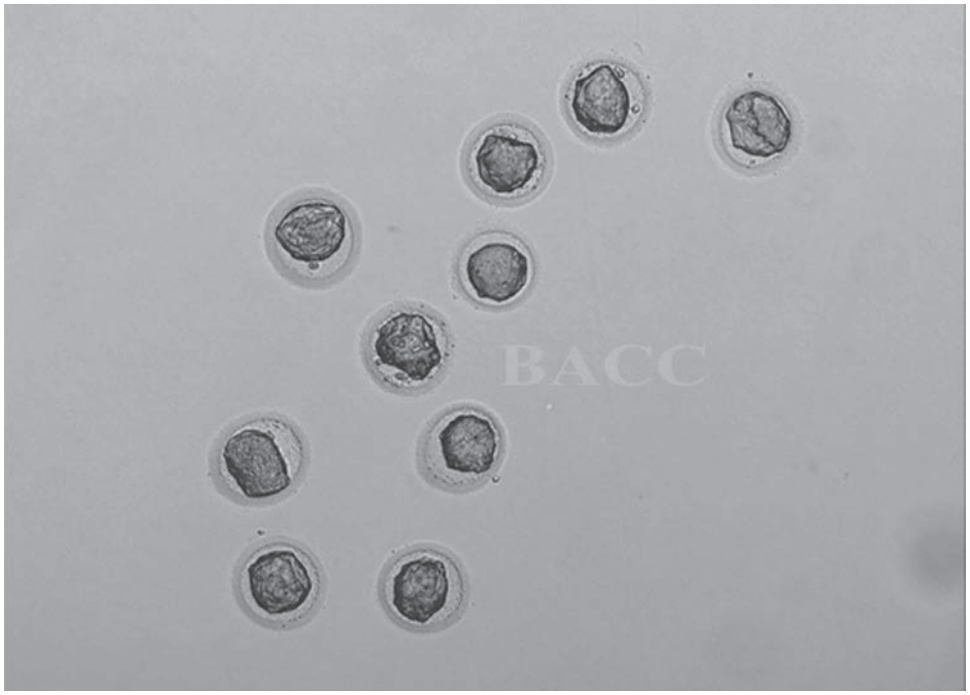

Fig. 2: Oocytes in equilibration solution (ES) at 1 minute at 10x magnification. Note further shrinkage of oocytes.

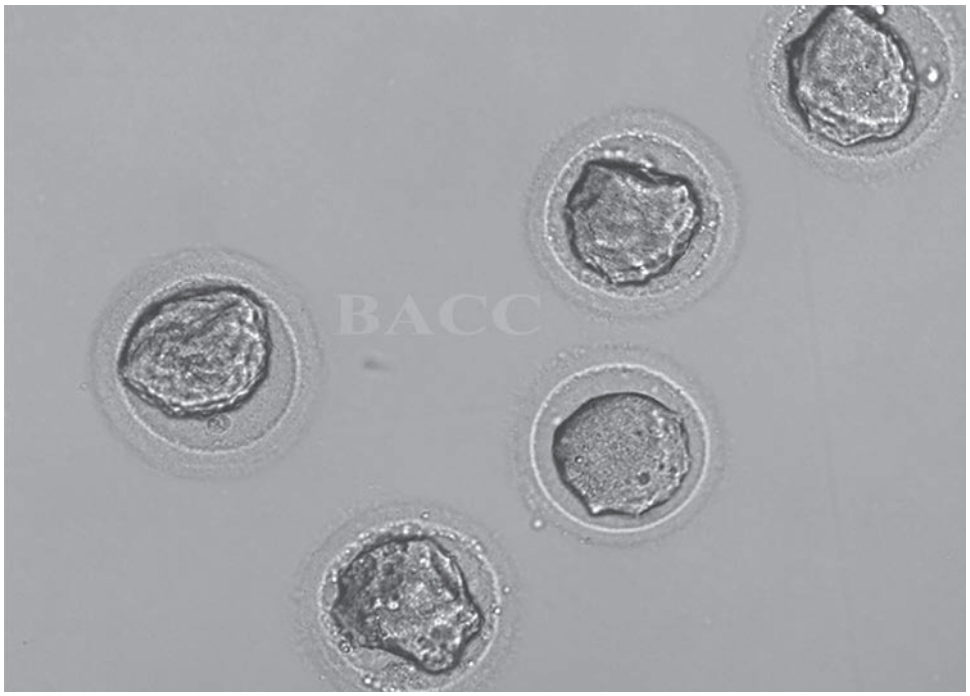

Fig. 3: Oocytes in equilibration solution (ES) at 1 minute at 200x magnification.

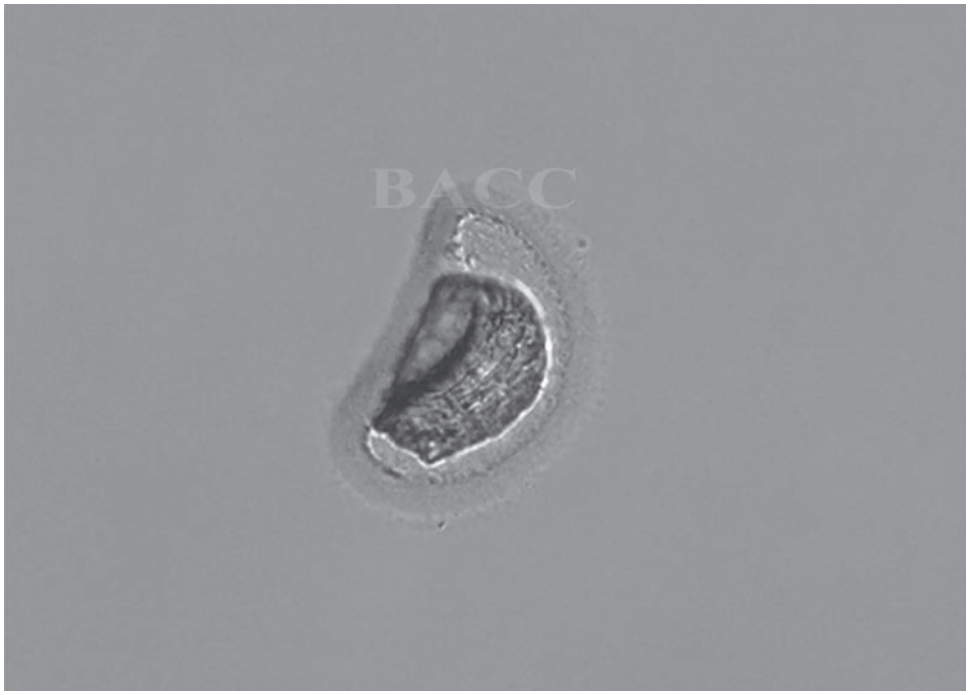

Fig. 12: Oocytes in vitrification solution (VS) at 90 seconds at 200x magnification. Note fully shrunken kidney-shaped oocyte.

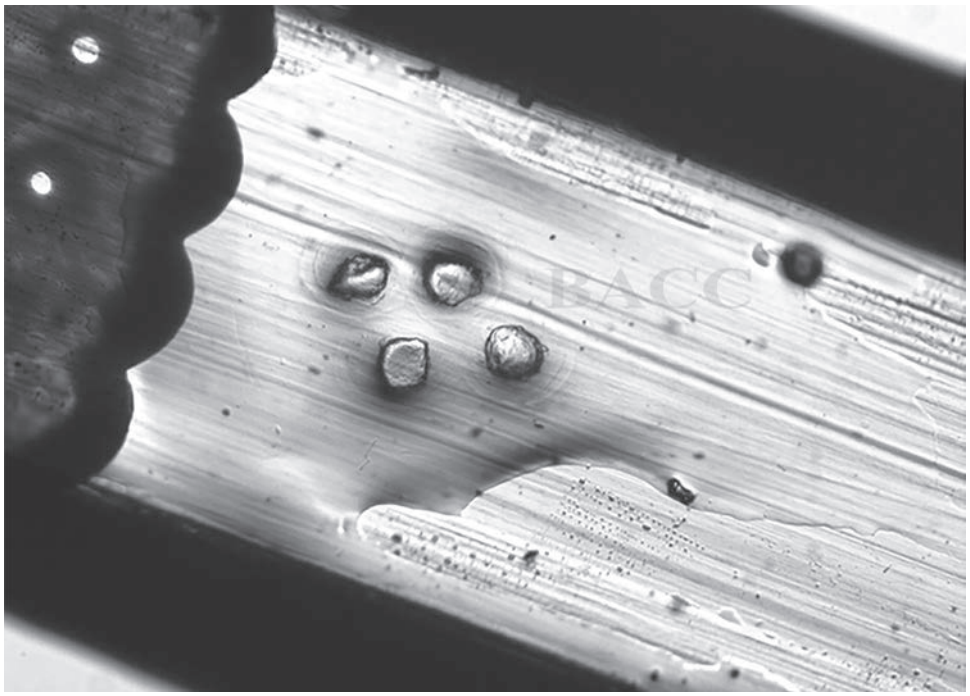

Fig. 13: Vitrified oocytes loaded on a cryodevice before immersion into liquid nitrogen.

CRYOPRESERVATION OF EMBRYOS

Vitrification

Materials

Vitrification of embryos contains three solutions: (1) equilibration solution (ES): contains no cryoprotectant, (2) vitrification solution 1 (VS1): contains ethylene glycol as cryoprotectant; (3) vitrification solution 2 (VS2): contains ethylene glycol, propanediol, ficoll and sucrose as cryoprotectants.

Equilibration solution contains no cryoprotectant. The embryos are kept in this solution for a minimum of 5 minutes to a maximum of 10 minutes **(Fig. 14)**.

Vitrification solution 1 contains ethylene glycol as a cryoprotectant. The embryos are transferred from ES to VS1. The embryos remain in this solution for 2 minutes. The embryos tend to float to the surface; if so collect them and replace them to the bottom of the dish **(Figs. 15 to 18)**.

Vitrification solution 2 contains ethylene glycol, propanediol, ficoll and sucrose as cryoprotectants.

Transfer the embryos from VS1 to VS2 and let the embryos remain in VS2 for 30 seconds.

Figures 19A to D show eight-celled embryos floating in the media containing ethylene glycol, propanediol, ficoll and sucrose as cryoprotectants at 10, 15, 20 and 25 seconds respectively.

Warming

Materials

- *Warming solution 1 (WS1):* Contains sucrose as cryoprotectant
- *Warming solution 2 (WS2):* Contains sucrose as cryoprotectant
- *Warming solution 3 (WS3):* Contains sucrose as cryoprotectant
- *Warming solution 4 (WS4):* Contains no cryoprotectant.

In a cryodewer, bring the cryodevice containing the vitrified embryos close to the prepared wells **(Figs. 20 to 22)**. Place the vitrified embryos quickly into the WS1 **(Fig. 23)**. Allow the embryos to fall from the cryodevice and sink to the bottom. Leave for 10–30 seconds **(Fig. 24)**.

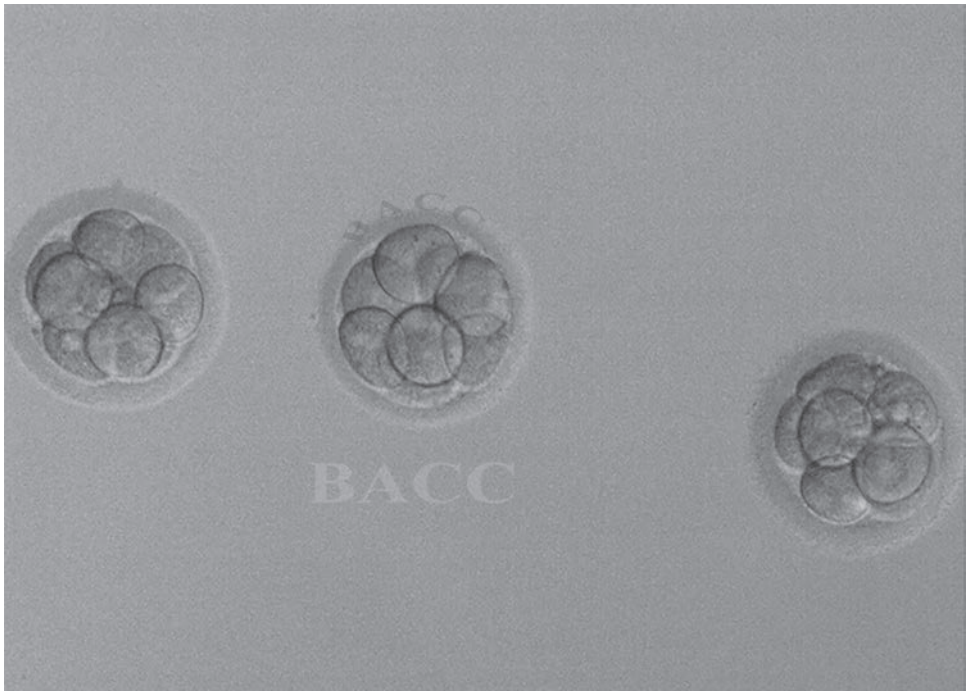

Fig. 14: Eight-celled embryos in equilibration solution kept for 5–10 minutes at 37°C.

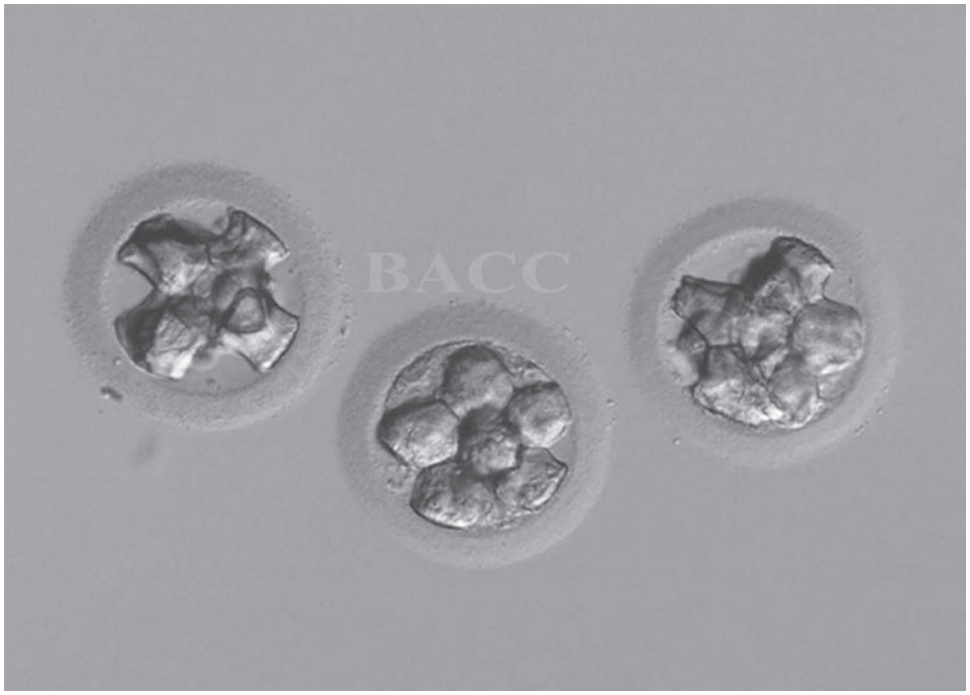

Fig. 15: Eight-celled embryos in vitrification solution 1 (VS1), containing ethylene glycol as a cryoprotectant at 15 seconds. Note the blastomere shrinkage.

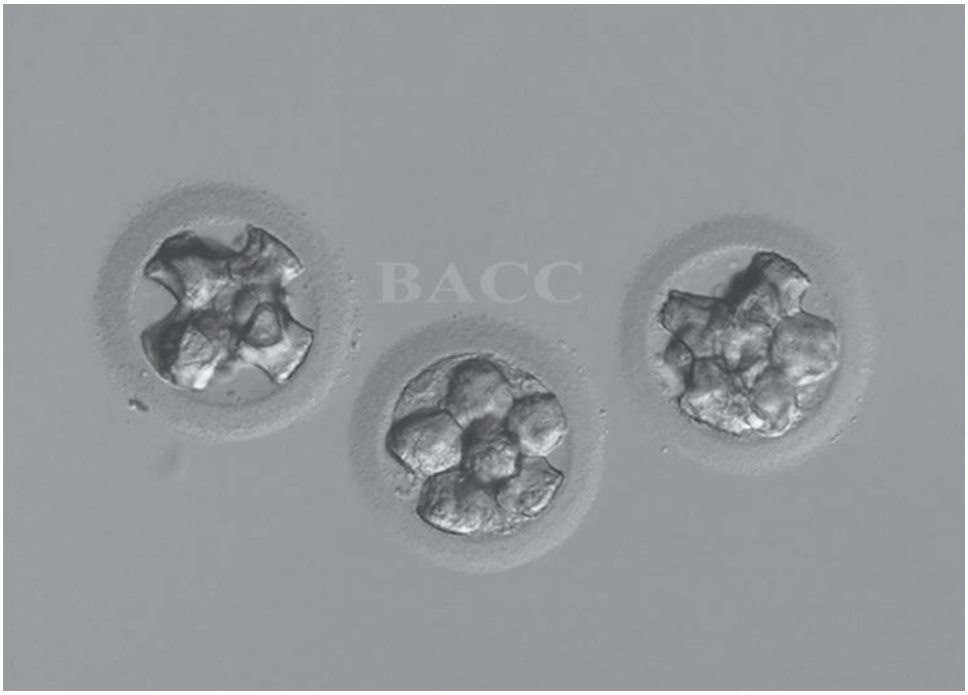

Fig. 16: Eight-celled embryos in vitrification solution 1 (VS1) containing ethylene glycol as a cryoprotectant at 30 seconds. Note the blastomere shrinkage.

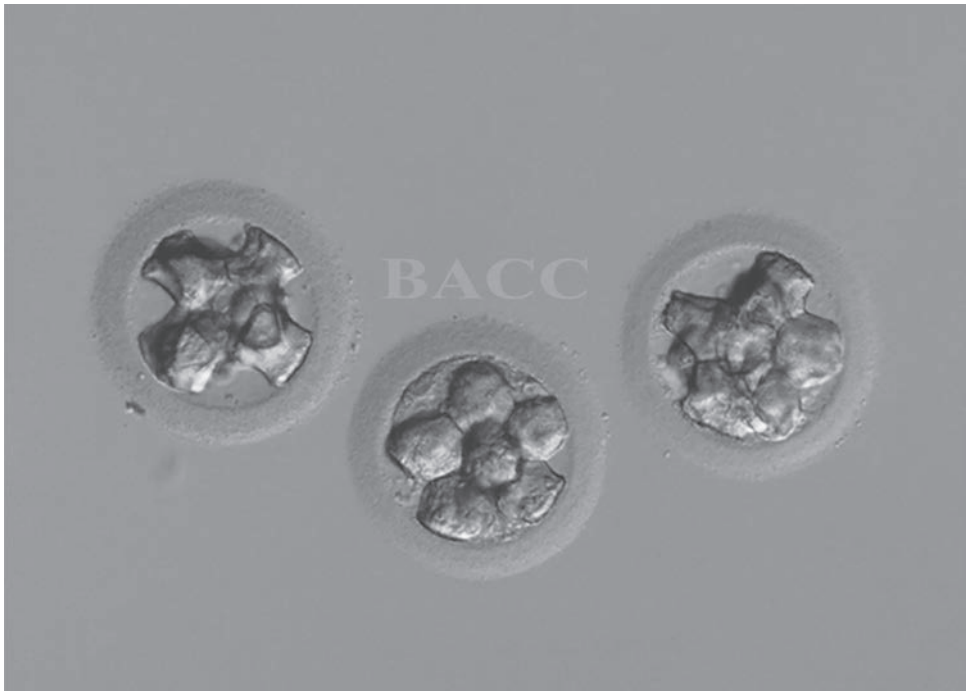

Fig. 17: Eight-celled embryos in vitrification solution 1 (VS1) containing ethylene glycol as a cryoprotectant at 60 seconds. Note the blastomere shrinkage.

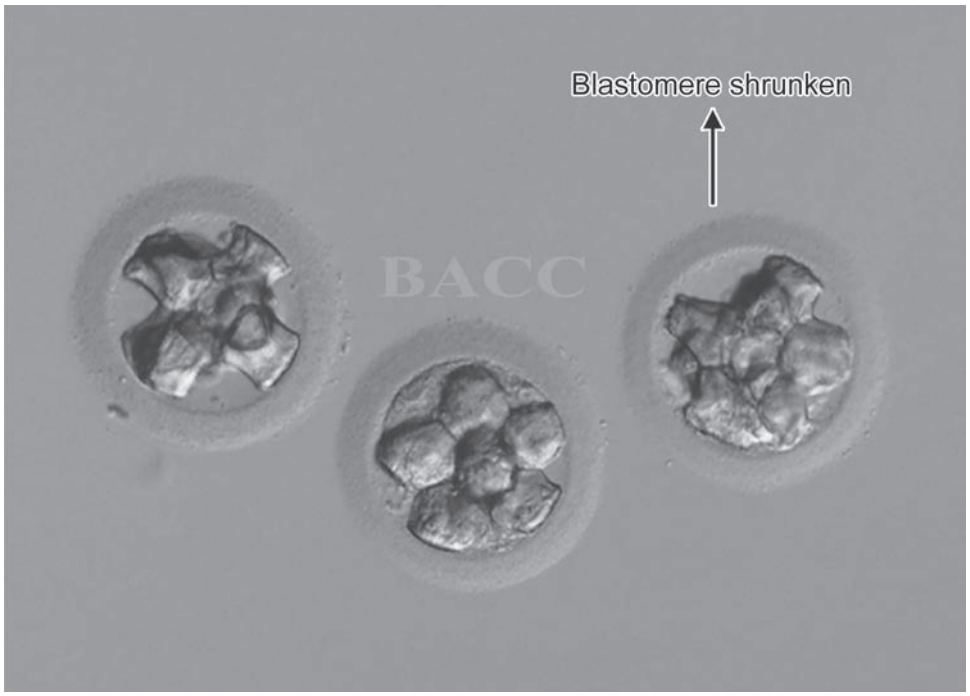

Fig. 18: Eight-celled embryos in vitrification solution 1 (VS1) containing ethylene glycol as a cryoprotectant at 90 seconds. Note the degree of blastomere shrinkage.

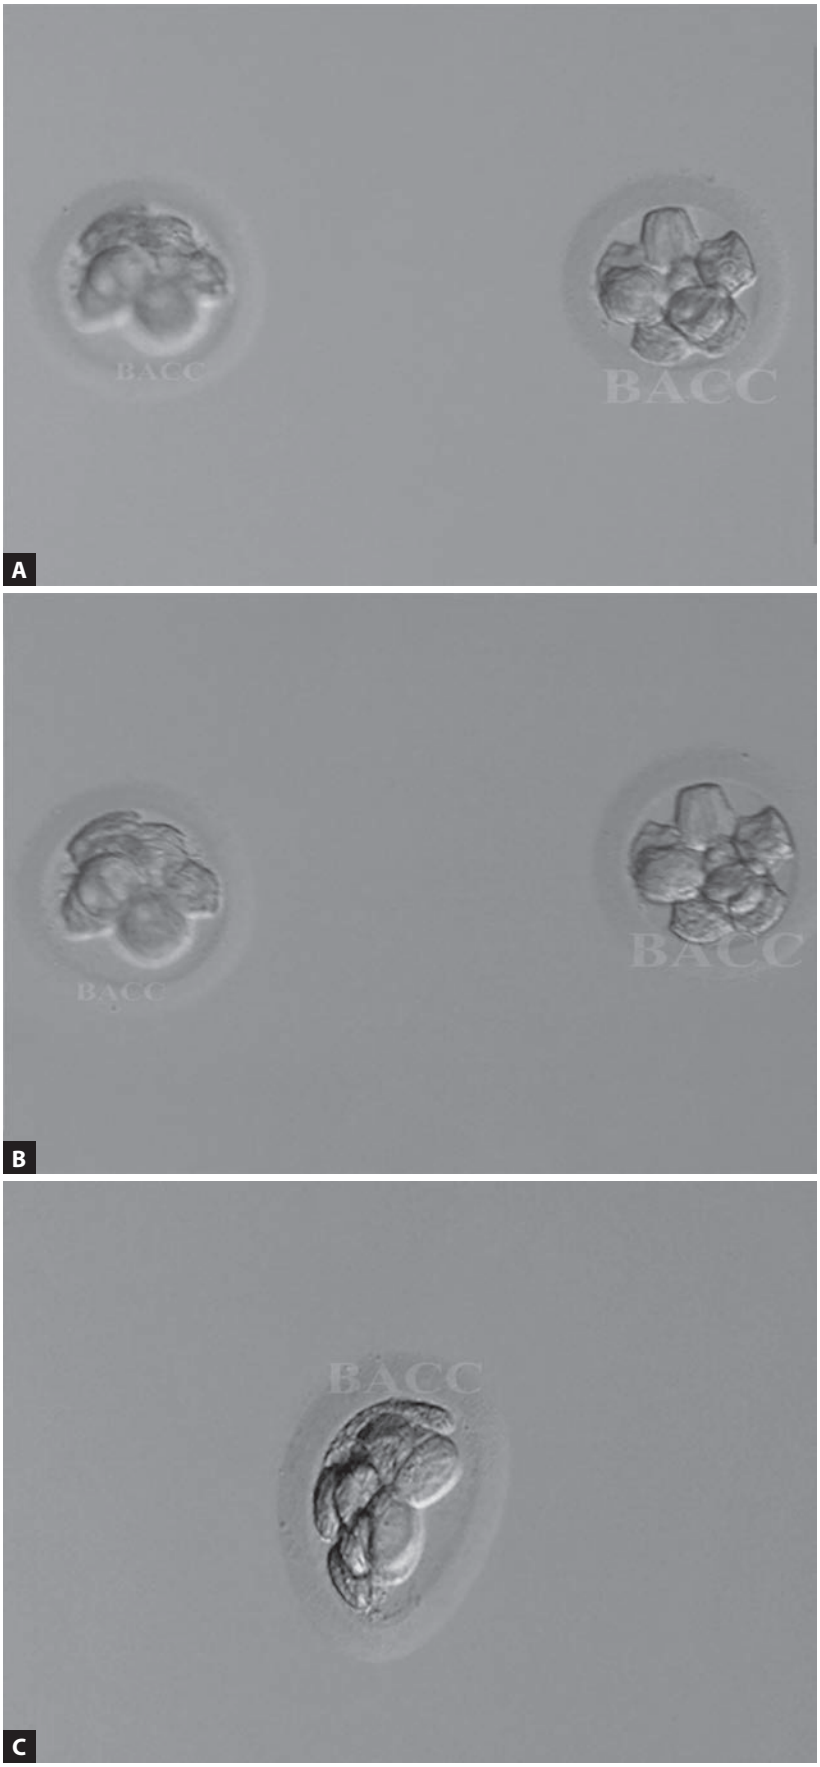

Figs. 19A to C

Fig. 21: Locking the cryolock under liquid nitrogen.

Fig. 22: The cryolock after locking under liquid nitrogen.

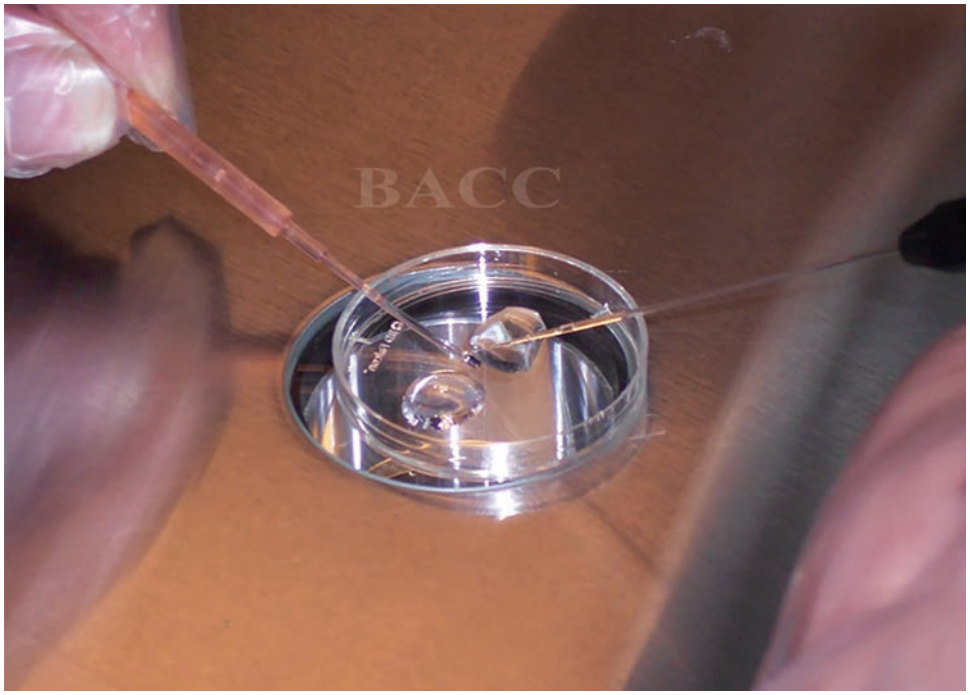

Fig. 23: The cryodevice is immersed into the warming solution 1 (WS1) for the embryos to fall in the media.

Fig. 24: The eight-celled embryos in warming solution 1 (WS1) kept for 30 seconds.

Warming solution 2: Transfer the embryos to WS2 and let the embryos remain in the solution for 1 minute **(Fig. 25)**.

Warming solution 3: Transfer the embryos to WS3 and let the embryos remain for 2 minutes **(Fig. 26)**.

Warming solution 4: Transfer the embryos into WS4 and let the embryos remain in the solution for 5 minutes **(Fig. 27)**.

Rinse the embryos in culture media several times and continue with embryo transfer or continued culture.

BLASTOCYST CRYOPRESERVATION

Materials

Vitrification of blastocysts contains three solutions: (1) *equilibration solution:* Contains no cryoprotectants **(Fig. 28)**, (2) *vitrification solution 1* **(Figs. 29 and 30)**: Contains ethylene glycol and propanediol as cryoprotectants; (3) *vitrification solution 2:* Contains ethylene glycol, propanediol and ficoll as cryoprotectants **(Fig. 31)**.

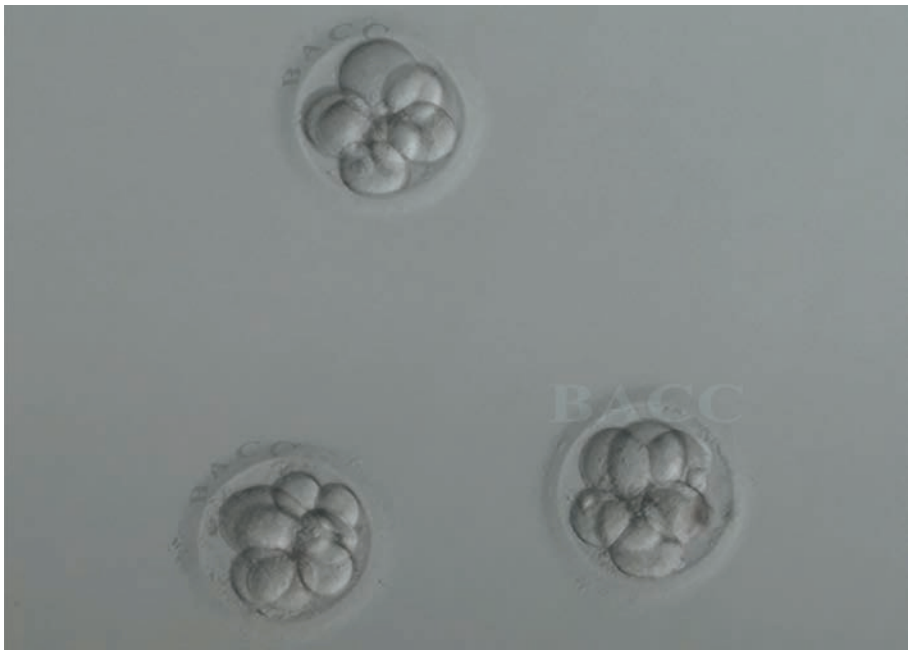

Fig. 25: Eight-celled embryos in warming solution 2 (WS2). Note the blastomere expansion.

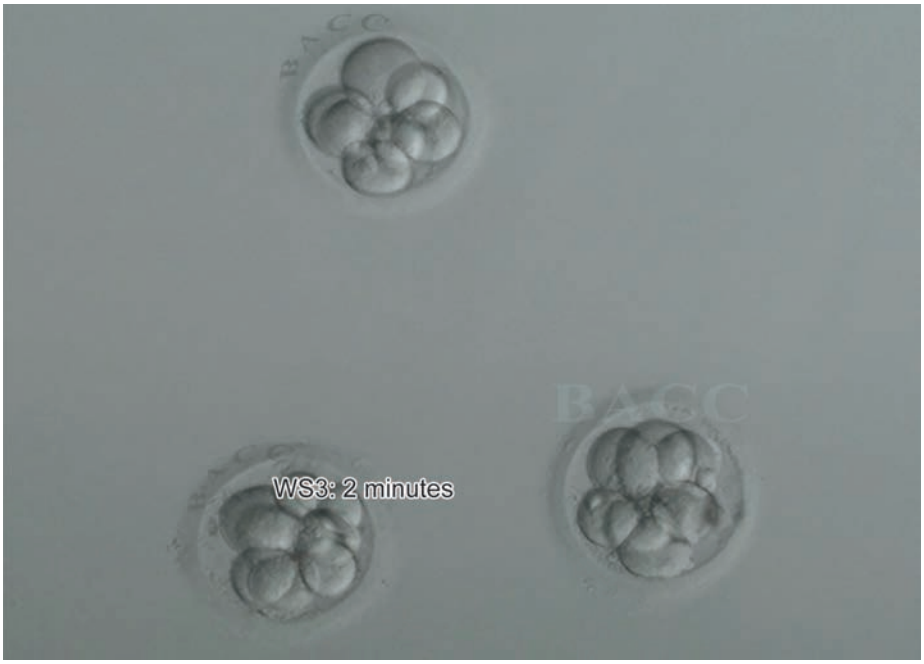

Fig. 26: Eight-celled embryos in warming solution 3 (WS3). Note the blastomere expansion.

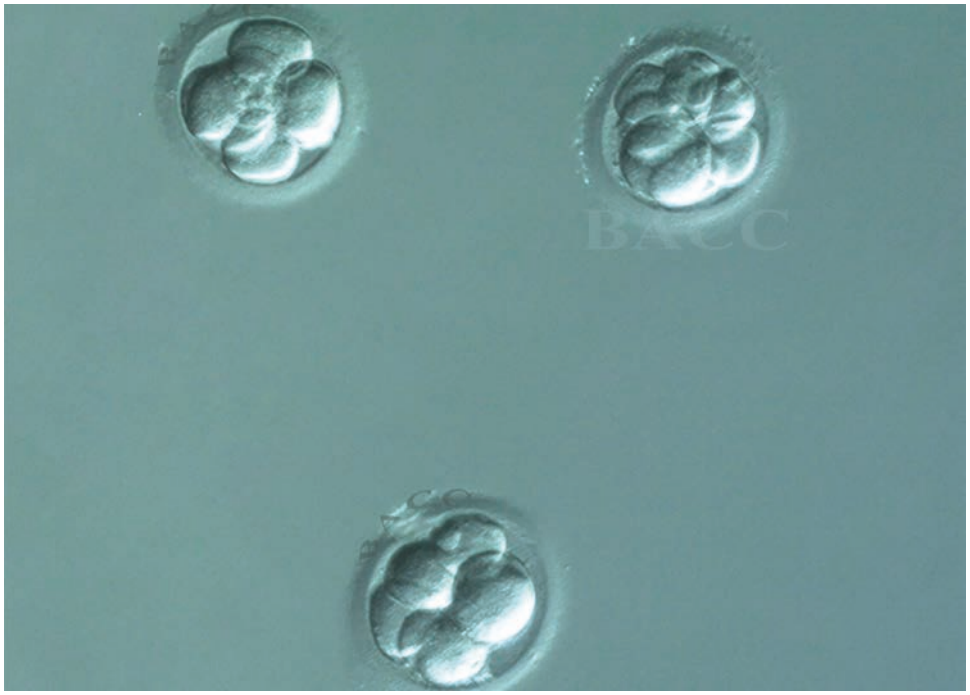

Fig. 27: Eight-celled embryos in warming solution 4 (WS4). Note the blastomeres having regained the cell contents/blastomeres are completely expanded.

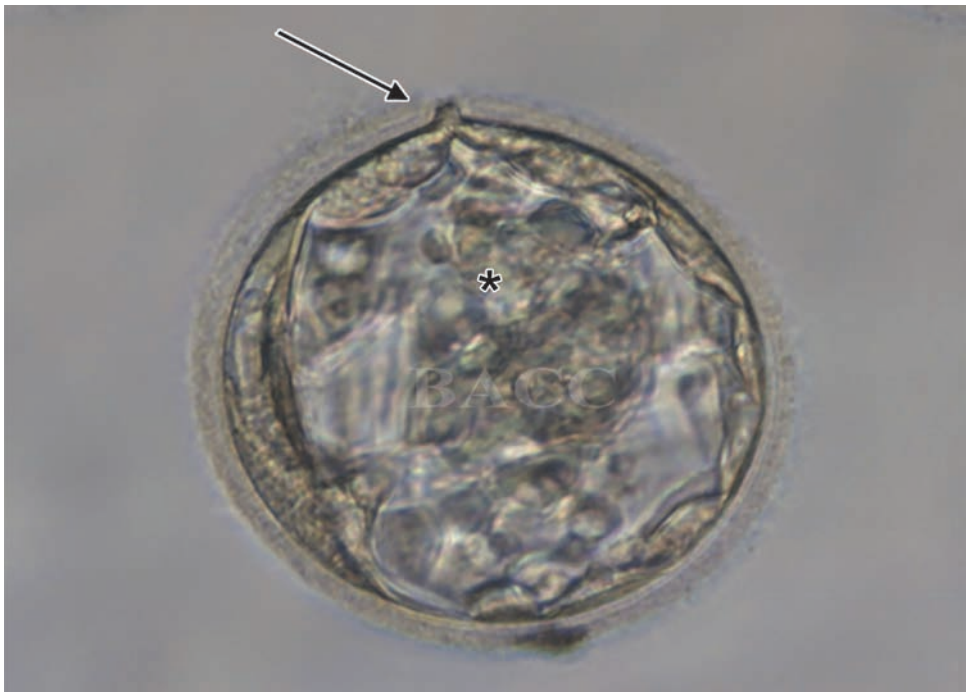

Fig. 28: Collapsed blastocyst in equilibration solution (ES). Arrow indicates the laser pulse given between two trophectoderm cells to bring about artificial shrinkage in the blastocyst and (*) indicates the collapsed inner cell mass. An octax laser was used and a single opening was created using a single laser pulse.

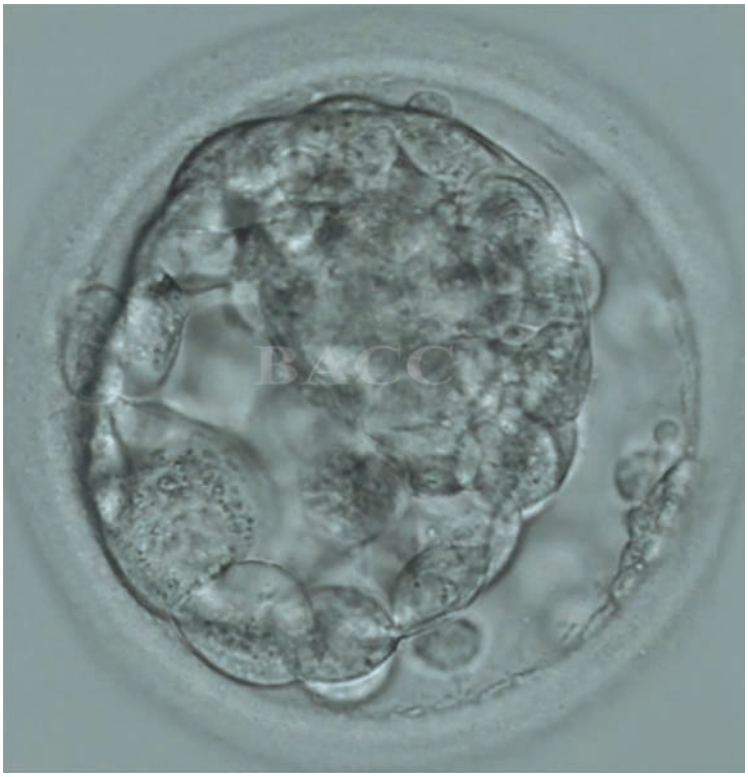

Fig. 29: Blastocyst in vitrification solution 1 (VS1) at the end of 1 minute.

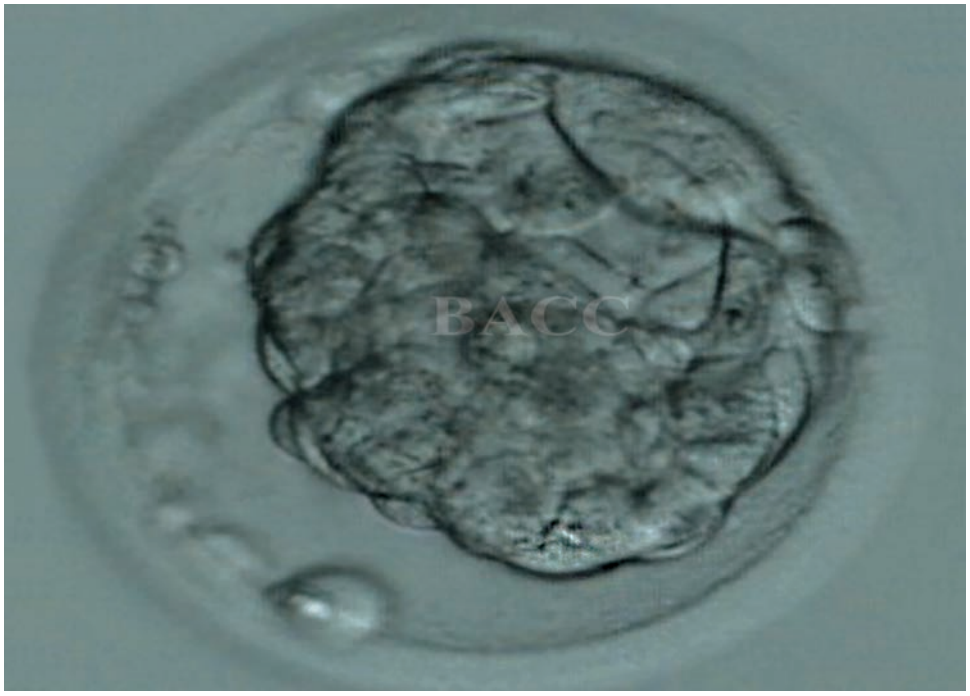

Fig. 30: Blastocyst in vitrification solution 1 (VS1) at the end of 2 minutes. Note the shrinkage of the blastocyst.

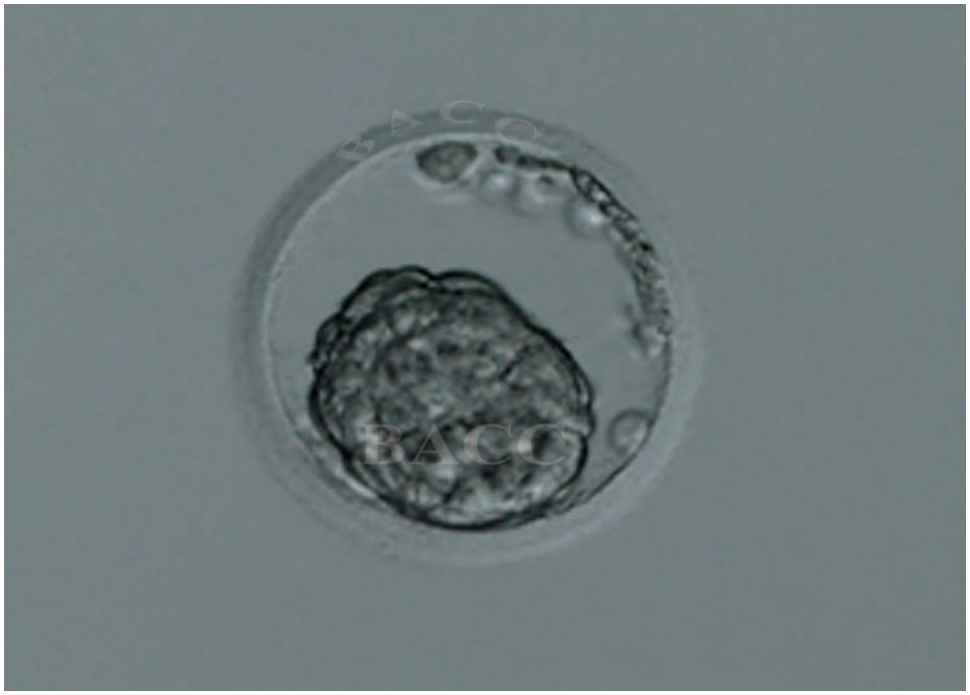

Fig. 31: Blastocyst in vitrification solution 2 (VS2) at the end of 45 seconds. Note fully shrunken blastocyst ready to be loaded on to the cryodevice.

Blastocele cavity has to be collapsed with laser-assisted hatching (LAH) shot (arrow) before placing the embryos in ES. Note the collapsed inner cell mass (ICM) (*) in this blastocyst when placed in ES at the end of 10 minutes (***see* Fig. 28**).

BLASTOCYST WARMING

Materials

- *Warming solution 1*: Contains sucrose as cryoprotectant.
- *Warming solution 2:* Contains sucrose as cryoprotectant.
- *Warming solution 3:* Contains no cryoprotectant.

Vitrified blastocysts are placed in WS1 immediately after removing from the cryodevice. Note the shrunken blastocyst within the zona **(Figs. 32 and 33)**.

Figures 34 and 35 show blastocyst in WS2 at 2 minutes and 3 minutes, respectively. Note the gradual expansion of

Fig. 32: Vitrified blastocyst in warming solution 1 (WS1) at 30 seconds.

CHAPTER 136

Assisted Reproductive Technology Laboratory Setting

Divyashree PS, Hemanth Kumar MA, Dileep Kumar R, Mohammed Ashraf C

ESSENTIAL EQUIPMENT OF ASSISTED REPRODUCTIVE TECHNOLOGY LABORATORY

INTRODUCTION

The design, equipment and supplies of an assisted reproductive technology (ART) laboratory depend on the types of treatment offered and the workload of a particular ART clinic.

This chapter covers about:

- Essential equipment of ART laboratory
- Essential equipment for clinical procedures
- Consumables required for ART laboratory.

LAMINAR FLOW CABINETS

Laminar flow cabinets with horizontal air flow to maintain sterile environment around the gametes which are handled in vitro **(Figs. 1A and B)**.

Figs. 1A and B: Laminar flow cabinets.

HEATING, VENTILATING, AND AIR-CONDITIONING

Air handling unit (AHU) should be equipped with high-efficiency particulate air (HEPA) filters for filtration of particulate matter and coda filters (activated charcoal) for the elimination of VOCs **(Figs. 2A and B)**.

Figs. 2A and B: Air handling unit.

INCUBATORS

Types of Incubators (Figs. 3A to F)

1. *Box type incubators:* Water jacketed and air jacketed.
2. *Bench top incubators:* Cook Minc, K systems, Origio (advantage-minimal disruption of temperature and pH).
3. *Others:* Mini-incubator, portable incubator.

Figs. 3A to F: (A) Box type air jacketed incubator; (B) Box type air jacketed incubator (inside view) with different shelves; (C) Bench top incubator, K systems; (D) Bench top incubator, Origio; (E) Bench top incubator, ESCO; (F) Mini-box type incubator, Eppendorf.

MICROSCOPES

Compound microscope ***(Fig. 4A)***: Eye piece: 10×, objective: 10×, 20× and 40×.

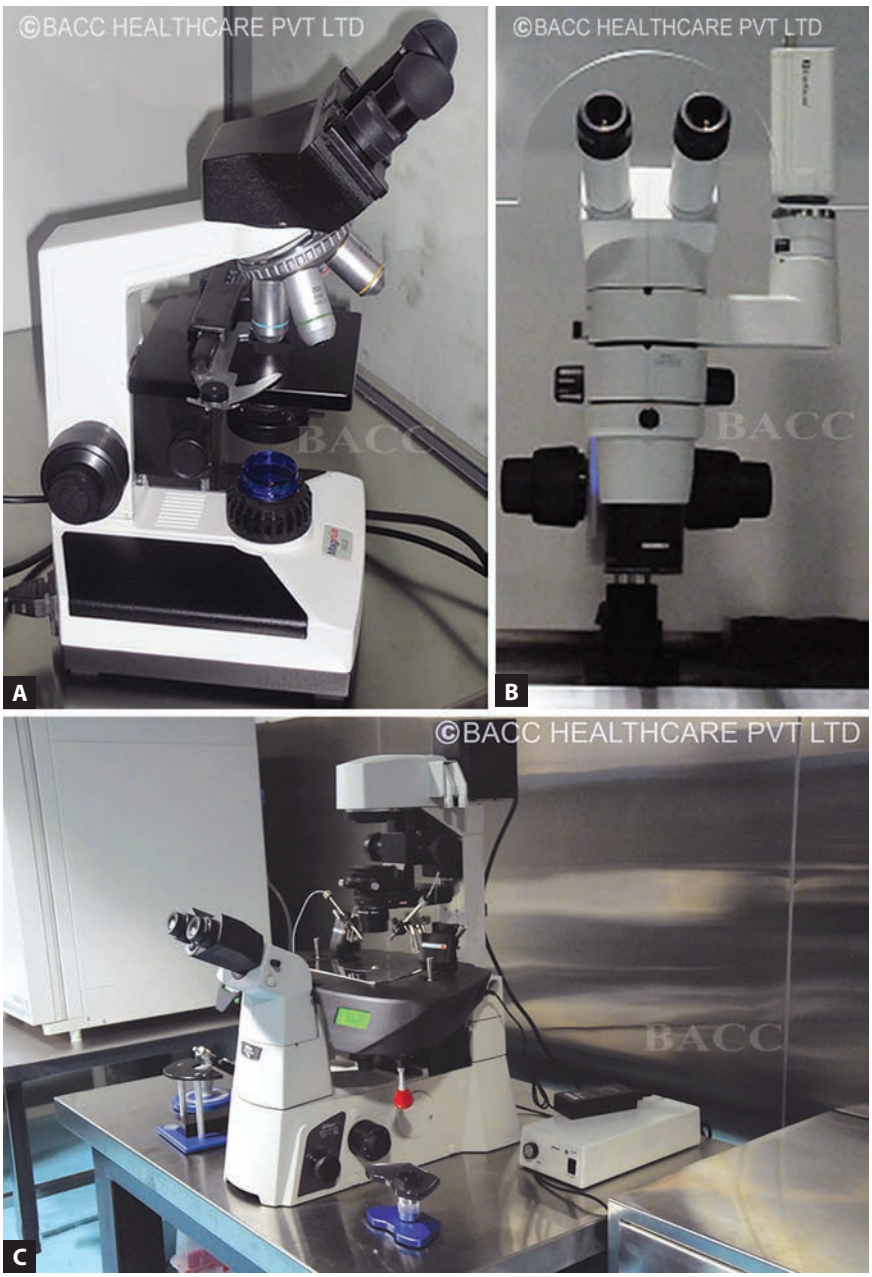
Used in andrology for semen analysis and also to see post-wash count.

Dissecting/Stereozoom microscope ***(Fig. 4B)****:* Eye piece: 10×, objective: 0.7 to 1×, total magnification—10×.

Used for follicular fluid screening, and for observation of oocytes and embryos at a lower magnification.

Inverted microscope with micromanipulator ***(Fig. 4C)****:* Inverted microscope is used for intracytoplasmic sperm injection (ICSI). Two important parts of the system include the microscope and the micromanipulator.

- Inverted microscope is equipped with an eye piece of 10× and objectives of 10×, 20× and 40×.



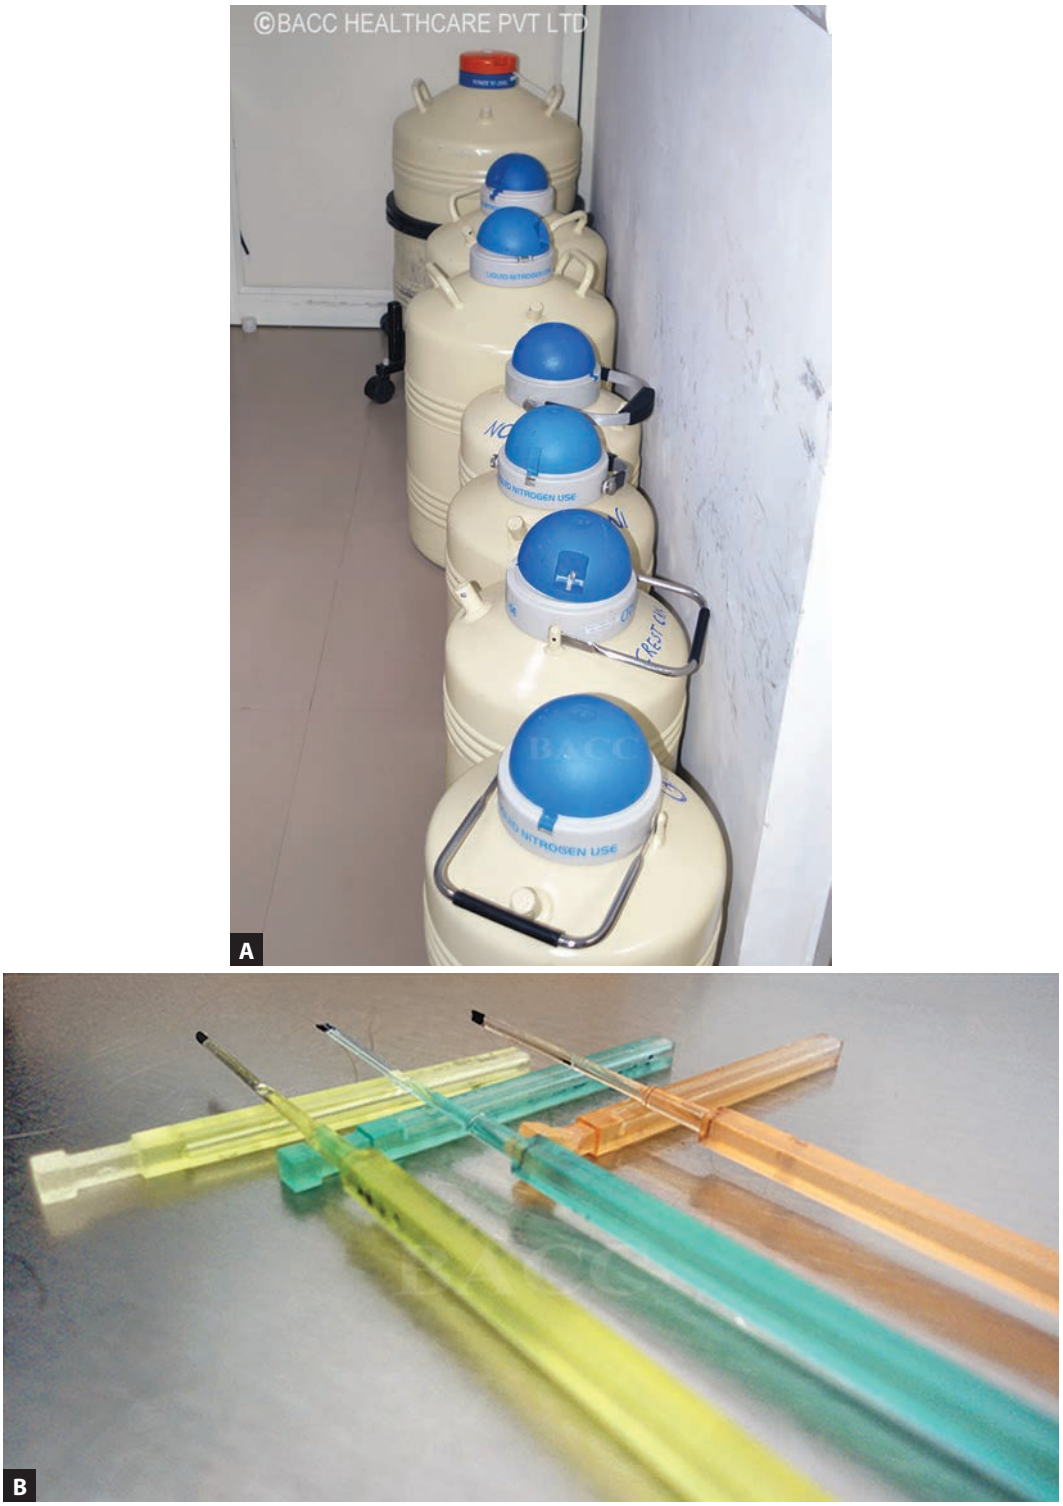
Figs. 4A to C: (A) Compound microscope; (B) Dissecting/Stereozoom microscope; (C) Inverted microscope with micromanipulator.

- Accessories used along with inverted microscope include heated stage and portal for attachment of camera.
- The micromanipulator system from research instruments (RI) is purely a mechanical system. Micromanipulator system includes microtool holders, and suction/injection device.

Cryopreservation Equipment

Storage dewars with canisters ***(Fig. 5A)***: Storage dewars contains canisters immersed in liquid nitrogen. Canisters are containers which hold the straws in an effective and accessible manner.

Straws ***(Fig. 5B)****:* Different types of straws are available for loading the embryos after vitrification.



Figs. 5A and B: (A) Storage dewars with canisters; (B) Straws for embryo loading.

Centrifuge

Centrifuge is used in Andrology laboratory for semen processing for IUI/IVF/ICSI for sperm concentration **(Fig. 6)**.

Fig. 6: Centrifuge.

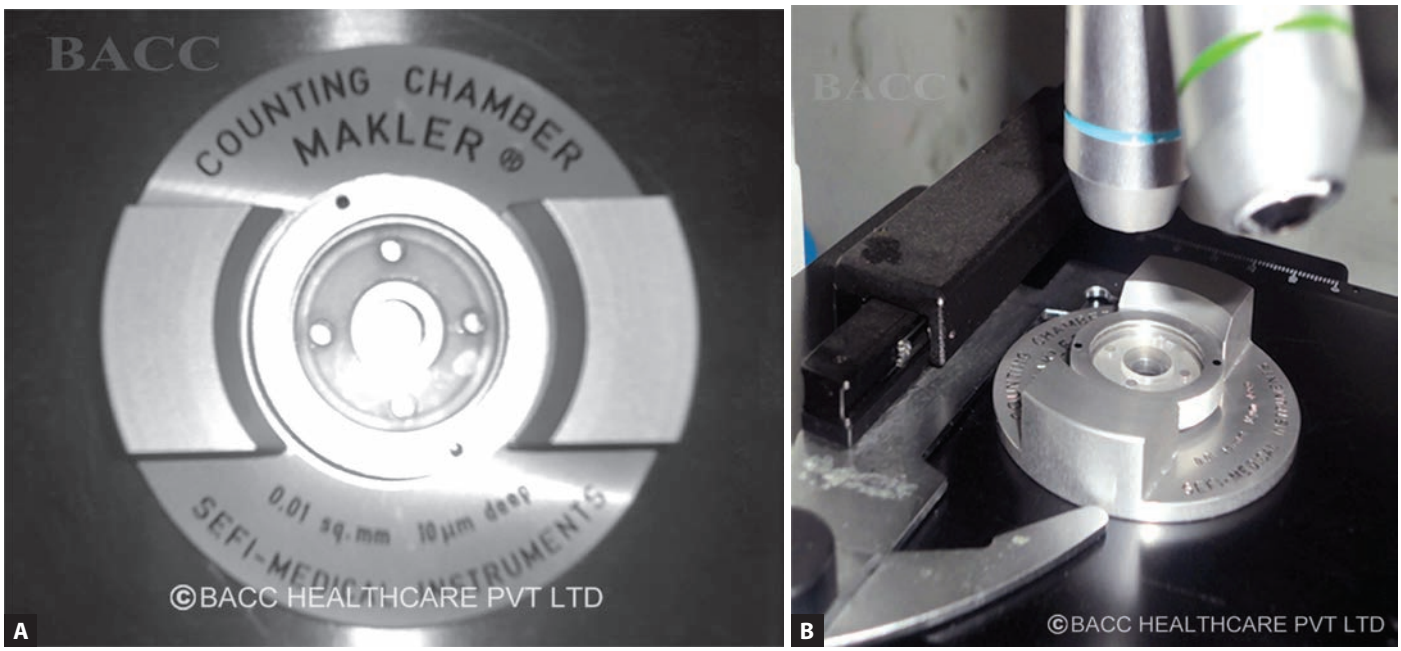
Semen Analyzer

SQA-vision is an automated high resolution visual interface for assessing all semen parameters **(Fig. 7)**.

Fig. 7: SQA-vision (Automated sperm quality analyzer).

Makler Chamber

Makler chamber is used for sperm counting **(Figs. 8A and B)**.



Figs. 8A and B: Makler chamber.

Test Tube Warmer

Test tube warmer maintains the temperature at 37°C, so that gametes and embryos are handled at a physiological temperature in vitro during the transition time when they are outside the incubator **(Figs. 9A and B)**.

Figs. 9A and B: Test tube warmer.

Coda Tower

Coda tower **(Fig. 10)** is housed in the IVF laboratory to ensure filtration of air within the IVF laboratory. It is a purifier that reduces particulates, harmful volatile organic compounds (VOCs) and chemical airborne contaminants (CACs).

Fig. 10: Coda tower.

Coda Inline Filters

These filters improve the air quality in the incubator by reducing the VOCs. It contains a mixture of activated carbon to absorb the VOCs, aldehydes and formaldehydes from all incoming gas lines **(Fig. 11)**.

Fig. 11: Coda inline filters.

ESSENTIAL EQUIPMENT FOR CLINICAL PROCEDURES

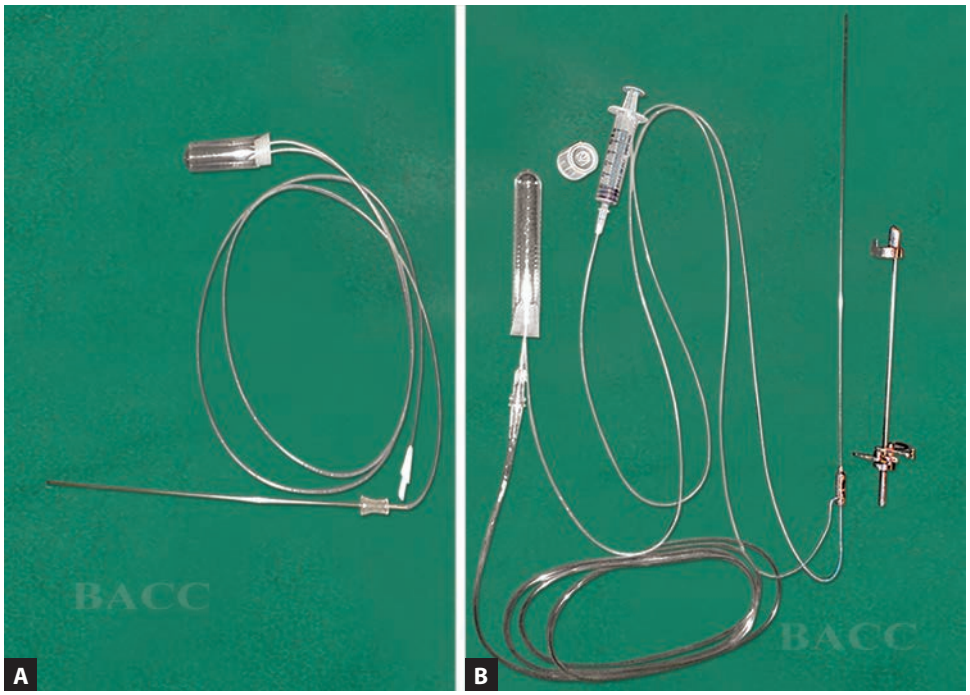
Intrauterine Insemination Catheters

Semi-rigid catheters with open end and rounded tip should fit the curvature of the uterus **(Fig. 12)**.

Fig. 12: Intrauterine insemination catheter.

Oocyte Aspiration Set

Oocyte aspiration set contains single or double lumen echo tip needle, connected to gas tubing, round bottom test tube and suction apparatus **(Figs. 13A and B)**.



Figs. 13A and B: Oocyte aspiration set.

Embryo Transfer Catheters

There are different types of embryo transfer (ET) catheters available. Common characteristics of ET catheters include softness and flexibility. Optional characteristic include echogenicity **(Fig. 14)**.

Fig. 14: Embryo transfer catheters.

Suction Pump with Foot Pedal

Suction pump with foot pedal for oocyte aspiration **(Fig. 15)**. The pressure should be set at 100 mm Hg.

Fig. 15: Suction pump with foot pedal.

Ultrasound Machine

Ultrasound machine is used for follicular monitoring and as a guide during oocyte aspiration and embryo transfer as a guide **(Fig. 16)**.

Fig. 16: Ultrasound machine.

Consumables Required for Assisted Reproductive Technology Laboratory

Plastic test tubes: Plastic tubes are of two types round bottom and conical **(Figs. 17A to C)**.

Figs. 17A to C: Plastic test tubes.

Petri Dishes

Different types of Petri dishes are as follows **(Fig. 18)**:

- *Tissue culture dish:* 60 × 15 mm, polystyrene dish used for follicular fluid screening.
- *Central well dish:* 60 × 15 mm, polystyrene, central well dish. Can be used for IVF, oocyte washing after denudation, etc.
- *Intracytoplasmic sperm injection dish:* 59× 9 mm low wall dish, with side grooves. Used for ICSI.
- *Tissue culture dish:* 35 × 10 mm, polystyrene dish used for embryo culture.

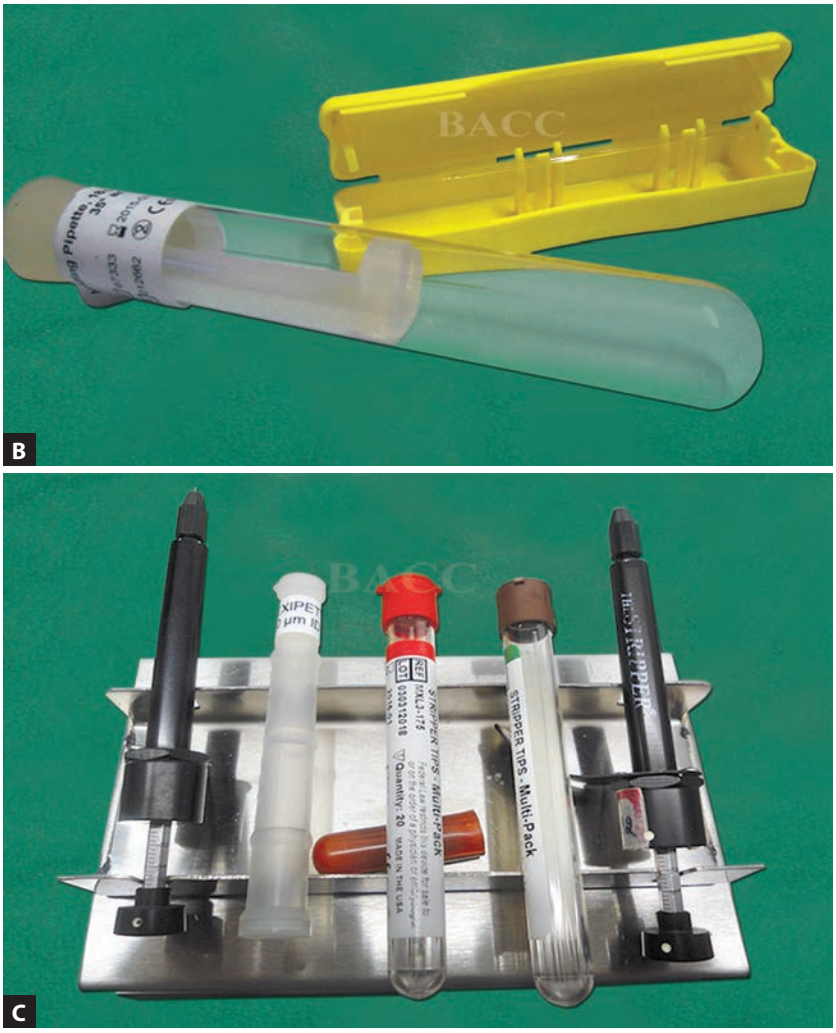
Fig. 18: Different types of Petri dishes.

Pipettes

Different types of pipettes include **(Figs. 19A to C)**:

- A 3 mL plastic pipette
- Glass pasteur pipettes
- Holding pipette to hold the oocyte. It has a diameter of 18–25 mm, and has an angulation of 35°.
- Injection pipette used for microinjection of the sperm. It has 5 µm inner diameter and 7 µm outer diameter and an angulation of 35°.
- Stripper pipettes of different diameters (140 µm, 175 µm and 275 µm) for denudation of oocyte and also for embryo handling.

Fig. 19A: Different types of pipettes. (A) Glass Pasteur pipettes and plastic pipettes.



Figs. 19B and C: Different types of pipettes. (B) Holding and injection pipette used for ICSI; (C) Different types of Stripper pipettes.

Culture Medias

Different types of culture media **(Fig. 20)** required in ART laboratory are as follows:

- Flushing media
- Fertilization media
- Cleavage media
- Blastocyst media.

Fig. 20: Different types of culture media.

Hyaluronidase

Hyaluronidase at a concentration of 80 IU/mL is used for enzymatic dilution of cumulus mass surrounding the oocyte **(Fig. 21)**. Denudation helps in identification of oocyte maturity and oocyte abnormality and also denudation is a prerequisite for ICSI.

Fig. 21: Hyaluronidase.

Polyvinylpyrrolidone

Polyvinylpyrrolidone (PVP) for suspension of sperms before ICSI **(Fig. 22)**.

Fig. 22: Polyvinylpyrrolidone.

Mineral Oil

To overlay the culture dishes. Overlaying with mineral oil prevents evaporation of culture dots and fluctuations in temperature and pH **(Fig. 23)**.

Fig. 23: Mineral oil.

CHAPTER 137

Embryo Biopsy

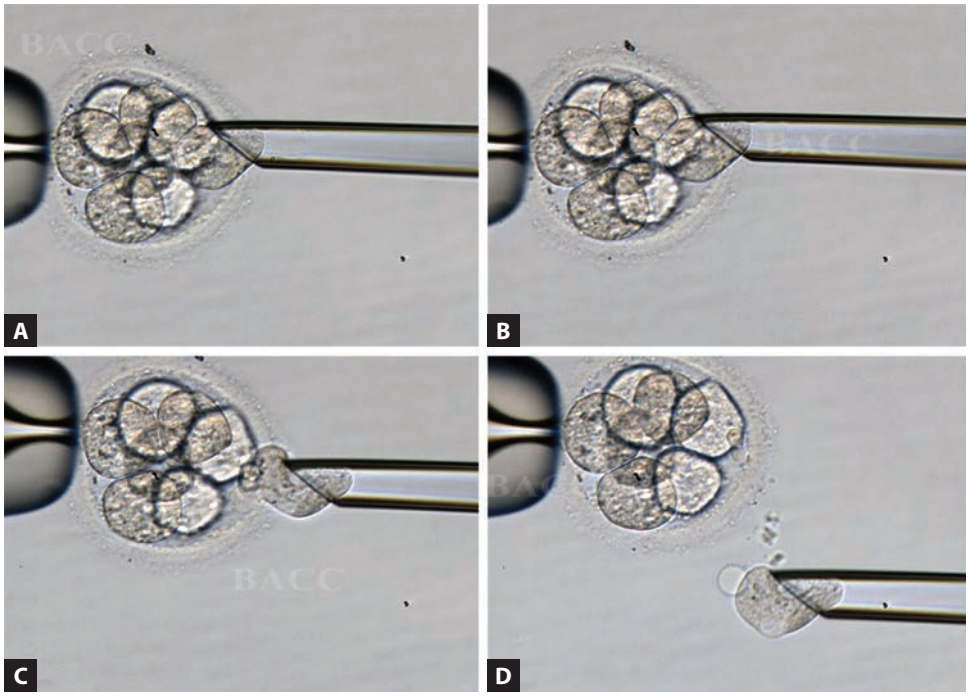
Mohammed Ashraf C, Anuja Kamath

INTRODUCTION

Preimplantation genetic screening (PGS) and preimplantation genetic diagnosis (PGD) are specialized techniques designed to screen embryos for chromosomal or genetic disorders. The PGS and PGD techniques are procedures requiring removal of several cells [blastomeres and trophectoderm (TE) cells] from the embryo. The TE cells are genetically evaluated to determine the presence or absence of specific chromosomal abnormalities and/or genetic diseases. After the genetic evaluation of embryos, they are selected for embryo transfer into the uterus, or frozen (cryopreserved) to be used later, to achieve pregnancy. The advantages of using PGS/PGD are to greatly reduce the risk of miscarriage or having a child with the chromosomal/genetic problems.[1–3]

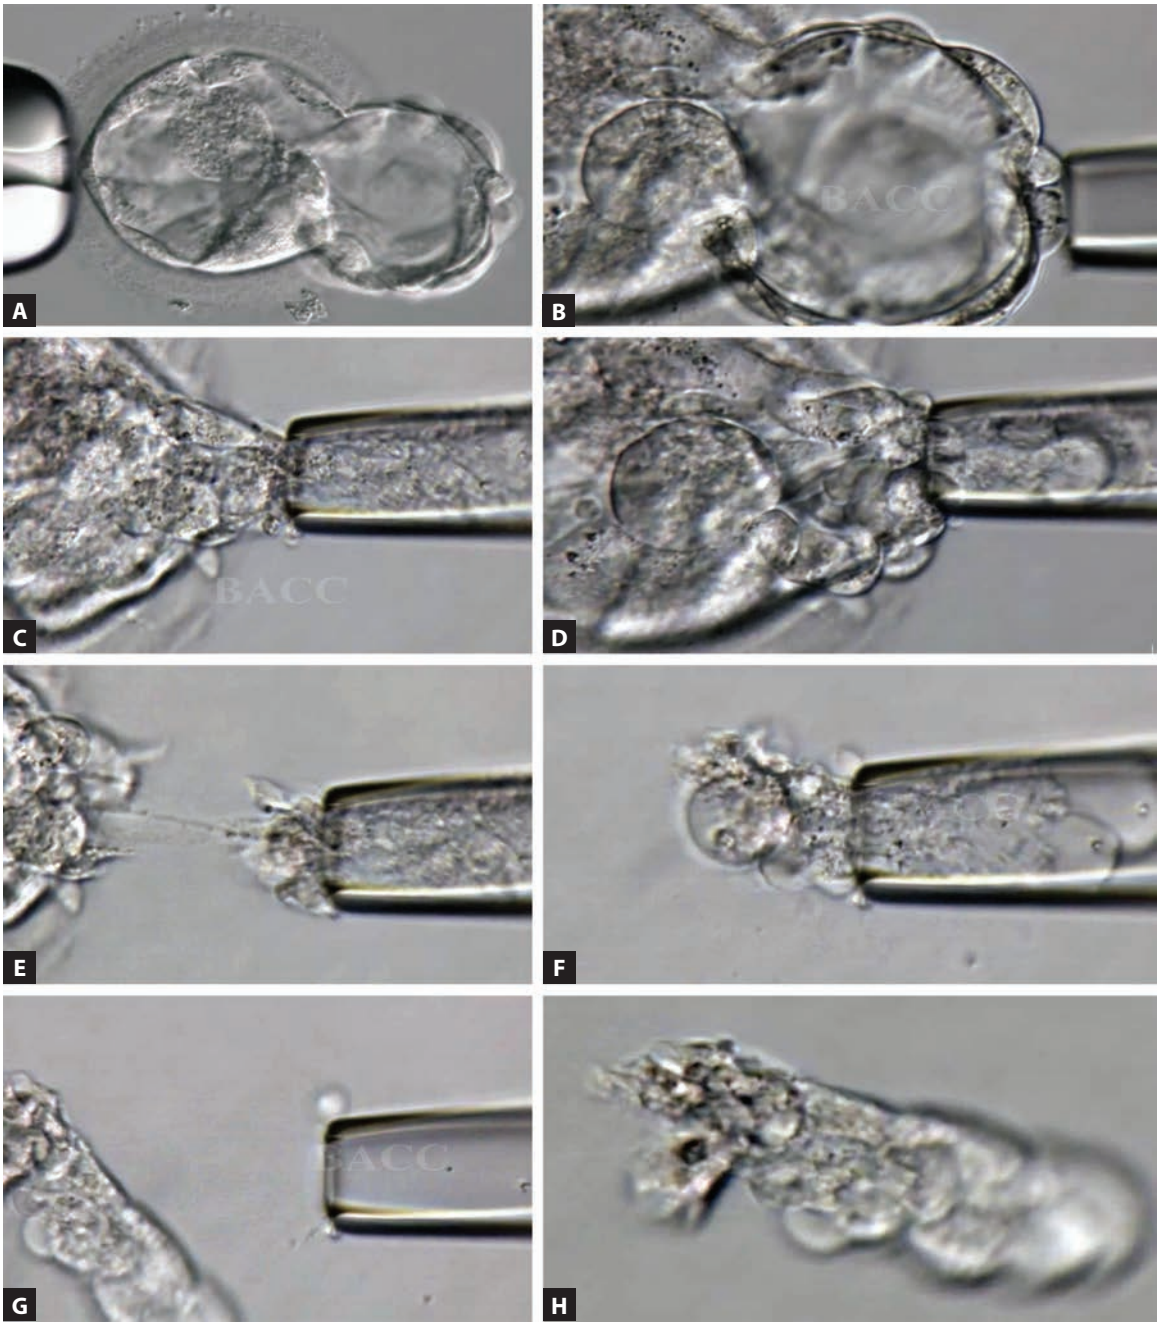
Using specially designed micromanipulation tools and microscope, an opening is created in the outer shell of the embryo (zona pellucida), and several cells are extracted. The cell(s) removed from each embryo are then subjected to PGS/PGD using various genetic analysis techniques such as polymerase chain reaction (PCR), array-comparative genetic hybridization (aCGH), or next generation sequencing (NGS).

BLASTOMERE BIOPSY (FIGS. 1A TO D)



Figs. 1A to D: Blastomere is removed by suction with a micropipette through the hole (made by laser shots) in the zona pellucida.

TROPHECTODERM BIOPSY (FIGS. 2A TO H)



Figs. 2A to H: Involves removal of a portion of the mural trophectoderm (Trophoblast cells that is located farthest from the IMC). With trophectoderm biopsy, 5–10 TE cells can be retrieved. This approach limits the effects of mosaicism.
