- Nontuberculous salpingitis can be divided into chlamydial, gonococcal and nongonococcal-nonchlamydial disease.
- Chlamydial infections are common in sexually active young adults.
- Culture is the method of diagnosis for *Neisseria gonorrhoeae*.
- Tubal damage is a very common sequela of PID (pelvic inflammatory disease).
- HIV, hepatitis B, hepatitis C are important sexually transmitted viral infections.

CHAPTER 36

Tuberculosis and Infertility

JB Sharma, Sona Dharmendra, Gowri Rapaka

INTRODUCTION

Tuberculosis (TB) is caused by *Mycobacterium tuberculosis* complex (*M. tuberculosis, M. bovis*, *M. albicans* or atypical *Mycobacterium* species with human disease in immunocompetent persons mainly caused by *M. tuberculosis*[1,2]). It remains a major public health problem worldwide.[1-5] Most cases (95%) occur in developing countries with 3.2 million cases in women and 1.4 million deaths in the year 2019.[2] India has one of the highest incidences of TB in the world.[3] Coinfection with human immunodeficiency virus (HIV) and more liberal immigration has significantly increased the risk of developing TB all over the world.[3] Multidrug-resistant (MDR) and extreme drug-resistant TB, which are caused by poor case management, are causes of serious concern throughout the world.[1-5]

HISTORY

Morgagni in 1744 reported the first case of female genital tuberculosis (FGTB).[6]

Due to the high prevalence, mortality, and morbidity due to TB globally, World Health organization (WHO) promoted a new treatment strategy based on five essential elements named—directly observed treatment, short-course (DOTS) strategy.[2] India adopted DOTS, and achieved high cure rate, and has now planned to eliminate the disease from India by 2025.[3]

Extrapulmonary TB (EPTB) is gradually becoming more common.[1,3] FGTB, an important form of EPTB, develops secondary to TB elsewhere in the body.[4-7] It causes significant morbidity and short- and long-term sequelae like menstrual dysfunction and infertility for the affected women due to damage to endometrium and fallopian tubes.[4-9] Timely diagnosis and treatment may prevent permanent damage to genital organs.[4-9]

MICROBIOLOGY OF *MYCOBACTERIUM TUBERCULOSIS*

Staining

Acid-fast bacillus (AFB) microscopy is performed on endometrial sample by staining with Ziehl–Neelsen staining culture. Mycobacterial culture from endometrial aspirate can be done by Löwenstein–Jensen medium or Middlebrook 7H9 broth.[4-10] Their major disadvantage is that the results may take up to 6 weeks. Drug susceptibility tests take another 4 weeks (total 10 weeks).[4,10]

Modern Rapid Methods

These give reports faster and are reasonably sensitive and specific. They include BACTEC 460, MGIT 960 system, MB/Bact system, and liquid-based culture for TB using Versa TREK. They have better sensitivity (80–90%) with faster results (5–10 days). Molecular diagnostic tests like polymerase chain reaction, gene Xpert, and loop-mediated isothermal amplification (LAMP) are done with gene Xpert giving results in few hours and detect Rifampicin resistance also.

Serological tests have been banned by Government of India due to their low specificity.

EPIDEMIOLOGY OF FEMALE GENITAL TUBERCULOSIS

Female genital tuberculosis can manifest with infertility, abdominal or pelvic pain, and menstrual irregularities, in autopsy series, and recently in laparoscopy series of infertility cases and pelvic pain.[11,12] It can even coexist with other diseases like endometriosis.[13] Incidence of genital TB in infertility cases varies greatly depending upon the geographical location being 1% in infertility clinics of USA,[6] 1.4% in Sweden,[14] 3.5–20% in Pakistan,[15,16] 0.8% (2% in tubal

factor) in Italy,[17] 4.2% in infertility patients in Saudi Arabia,[18] 16.7% in Nigeria,[19] 6.15–21.1% in South Africa,[20,21] and 1–19% in different areas of India.[8,9,22-24]

Incidence is more in tertiary centers like Delhi, where prevalence of FGTB in women of infertility was 26% and incidence of infertility in FGTB to be 42.5%, by referral cases from all over India, especially from states like Bihar, Jharkhand, and Uttar Pradesh with high prevalence of TB.[4,5]

Singh et al.[24] reported 48.5% prevalence in tubal factor sterility can produce many signs and findings.[25-32]

The prevalence of genital TB in infertility patients in various countries and different cultures in India is shown in **Table 1**. The incidence of infertility in genital TB patients is very high ranging from 44% to 90.6% with average being 70.6% as reported by Chaman Ara et al. **(Table 2)**.[33]

Female genital tuberculosis is encountered in younger women in developing countries with range being 20–40 years whereas in developed countries it is usually diagnosed in premenopausal women over the age of 40 years.[4,5,14] It could be due to younger age at marriage and childbearing in developing countries as compared to developed nations.[4,5]

TABLE 1: Prevalence of genital tuberculosis in infertile patients in different countries and different centers in India by different authors.

Study (Reference no.)	*Year*	*Country*	*Prevalence in infertile patients*
Malkani et al.[22]	1959	Delhi, India	10%
Schaefer et al.[6]	1976	USA	1%
Khan[15]	1985	Pakistan	23.08%
Chattopadhyay et al.[18]	1986	Saudi Arabia	4.2%
Oosthuizen et al.[21]	1990	South Africa	21%
Marana et al.[17]	1991	Italy	0.8% (2% in tubal factor)
Margolis et al.[20]	1992	South Africa	6.15%
Emembolu et al.[19]	1993	Nigeria	16.7%
Parikh et al.[8]	1997	Mumbai, India	39% (tubal factor)
Tripathy and Tripathy[23]	2002	Cuttack	3% (41% tubal factor)
Gupta et al.[9]	2007	Odisha	26%
Singh et al.[24]	2008	Delhi, India	48.6% in tubal factor
Shahzad[16]	2012	Pakistan	20%
Sharma et al.[32]	2020	India	18%

TABLE 2: Incidence of infertility in genital tuberculosis patients in different countries and different centers in India by different authors.

Study (Reference no.)	*Year*	*Country*	*Incidence in infertile patients*
Schaefer et al.[6]	1976	USA	55%
Sutherland et al.[7]	1980	UK	44%
Saracoglu et al.[25]	1992	Turkey	47.2%
Margolis et al.[20]	1992	South Africa	73.7%
Tripathy and Tripathy[23]	2002	Cuttack	53%
Zou SE et al.[28]	2014	Odisha	77.2%
Sharma et al.[31]	2008	Hyderabad, India	90.6%
Chaman Ara et al.[33]	2017	Iran	70.6%

PATHOGENESIS

The genital organs are secondarily infected from lungs through hematogenous route but can be affected through lymphatics or directly from gastrointestinal tract.[4-7] Rarely, the infection can be primary from infected semen of the male partner.[6]

Fallopian Tubes

They are infected in most (>90%) cases in genital TB and the involvement is usually bilateral. Various types of TB salpingitis can be TB endosalpingitis, exosalpingitis, interstitial TB salpingitis, and salpingitis isthmic nodosa.[4-7,14,26]

In TB endosalpingitis, the infection begins in endosalpinx, mostly hematogenously. The tube is swollen and edematous with hydrosalpinx and pyosalpinx with fibrosis and adhesions.[4-7,26]

Endosalpinx may be hyperplastic or edematous and may be totally destroyed with higher rate of sterility and ectopic gestation.[4-7,26]

In TB exosalpingitis, disease usually spreads from intestines and starts in the muscularis mucosa of the tubes with their hyperemia and tubercles on ovaries and peritoneum of the pouch of Douglas with flimsy adhesions, pyosalpinx, and pelvic adhesions.[4-7,11,26] Various grades of adhesions are formed between tubes and adjacent pelvic organs. In more severe cases, there may be multiple adhesions in peritoneal cavity with obliterated pouch of Douglas (frozen pelvis).[4-7,11,26] There may occur perihepatic adhesions (Fitz-Hugh–Curtis syndrome) in FGTB and abdominopelvic TB.[27]

Using laparoscopy and laparotomy, hydrosalpinx and tubal condition can be graded by taking into consideration the type of adhesions (peritubal, partial ovarian, extensive ovarian), patency (patent, partially patent, or blocked), morphology (soft or hydrosalpinx), morphology (soft, partially narrow in shift or hydrosalpinx, and fimbrial structure (complete, partially destroyed, and totally destroyed) which has prognostic significance.[28]

Uterus

The endometrium is involved in about 50–60% cases of FGTB.[4-7] The spread of infection from the fallopian tubes to uterus is usually hematogenous but can rarely be lymphatic or contagious.

Initially, there is no macroscopic disease but caseation and ulceration occurs and in advanced stages, distortion of the cavity occurs with adhesion formation and Asherman's syndrome causing amenorrhea and sterility.[4-7,31]

Microscopically, TB granulomas with or without caseation, granulomatous endometritis or focal collection of lymphocytes in endometrium may occur.[4-7,26]

Ovaries

Ovarian involvement occurs in 20–30% cases.[4-7] Ovarian function and reserve may also be affected in FGTB and abdominal pelvic TB.[34]

Peritoneum

Pelvic and abdominal peritoneum may be involved in widespread TB simulating ovarian neoplasm.[30]Ascitic fluid sampling for biochemical analysis and peritoneal biopsy may confirm the diagnosis of TB and thus avoiding a needless laparotomy.[4,5]

Quinsville grading of abdominal TB includes tubercular lymphadenopathy, peritoneal TB, which can be acute, chronic, visceral, and gastrointestinal TB.[35]

Cervix

The cervix may be involved in 5% cases of genital TB, usually as a downward extension of endometrial TB, but may rarely be a primary disease. It may present as polypoidal growth or ulceration and may resemble cervical cancer necessitating biopsy for confirmation of diagnosis.[6,7,26] Histopathological examination demonstrates granulomatous inflammation in cervical TB.[6,7,26]

Vagina and Vulva

They are rarely involved (1–2%) and are usually secondary to the downward extension but occasionally be primary infection from male partner.[6,7] There may be a hypertrophic lesion or a nonhealing ulcer on the vulva or vagina resembling malignancy necessitating biopsy and histopathological examination to confirm the diagnosis and to rule out malignancy and other differential diagnosis like syphilis, lymphogranuloma venereum, etc.[6,7]

PATHOGENESIS OF INFERTILITY IN GENITAL TUBERCULOSIS

Infertility is quite common in FGTB (40–80%). Pathogenesis of infertility in FGTB may be due to following factors:

- *Tubal factors causing infertility in FGTB:*
  - Blockage of one or both fallopian tubes due to their involvement in FGTB.[4,5,11]
  - Loss of tubal function due to ciliary damage in FGTB causing infertility and ectopic pregnancy.
  - Perisalpingitis causing adhesions and tubo-ovarian mass formation.
  - Unilateral or bilateral hydrosalpinx with or without obstruction occurs in 46% cases of FGTB, which adversely affects fertilization and embryonic implantation.[36] In in vitro fertilization (IVF) treatment, women with tubercular hydrosalpinx have very low pregnancy rate, which is worse with bilateral (12%) as compared to unilateral hydrosalpinx (24%). Clinical pregnancy rates can be increased with salpingectomy.[37] However, routine pre-IVF salpingectomy is not recommended with ultrasonologically visible hydrosalpinx but is performed if aspirated hydrosalpingeal fluid can be tested for toxin by Mouse Embryo Assay.[35,36]
- *Ovarian function causing infertility in FGTB:* Decreased ovarian function occurs in FGTB due to the tubo-ovarian mass formation, adhesions, anovulation, and poor ovarian reserve causing infertility by following mechanisms:[4,5,26]
  - Endocrine dysfunction can occur in FGTB.
  - Through chronic anovulation.
  - *M. tuberculosis* has antigonadotropic effect necessitating more ampoules of gonadotropins in IVF cycle.
  - Women with genital TB require higher number of gonadotropin ampoules than controls.[36]
  - Mycobacteria cause luteal phase defect, implantation failure, lower pregnancy rates, and higher abortion rates.[36]
  - In genital TB, quality of embryo tends to be poor due to "intrinsic oocyte factor" defect.[37] The harmful interleukins (ILs) induced by immune modulation or by the direct effect of toxins of mycobacteria adversely affect the oocyte development within the follicle.[37]
- *Uterine (endometrial) factors causing infertility:* Endometrial damage occurs in TB as follows—
  - Effect of genital TB on endometrial receptivity:
    - Female genital TB adversely impacts the endometrial markers which are essential to make the endometrium receptive for embryonic implantation.[31,38,39]
    - There is poor vascularization of endometrium in FGTB.
  - Through immunomodulation with production of enzyme procoagulase causing vascular thrombus formation.
  - Endometrial atrophy and synechiae formation: Involvement of endometrium by caseous or fibrocaseous lesions of FGTB causes Asherman's syndrome (uterine synechiae) which is common in endometrial TB.[31,38,39] We observed various grades of intrauterine adhesions in FGTB on hysteroscopy as—Grade-I 20.8%, Grade-II 28.5%, Grade-III 28.5%, and Grade-IV 17.5% with other findings of TB like tubercles and shaggy cavity with caseation on hysteroscopy.[39] We also observed increased difficulties and complications in hysteroscopy in women with genital TB.[40] Hysterosalpingographic findings in our study were irregular filling defect in 18.5%, and synechiae in 17.1% of women.[41]

- *Defective or failed implantation in FGTB:* It occurs by the following mechanism:[38]
  - There is release of harmful cytokines and growth factors (IL-2, IL-8, TNF-α) in the endometrium.
  - There is formation of symmetric antibodies.
  - There is production of natural killer (NK) cells.
  - There is production of lymphocyte activated killer (LAK) cells.
  - There is T helper 1 cell (Th1) response causing implantation failure as compared to Th2 response required for fertilized ovum implantation.
  - Hence, FGTB shifts Th2 response to ThI response in endometrium leading to implantation failure. In fact, Dam et al.[42] from Kolkata observed latent FGTB causing repeat IVF failure in their setting.

DIAGNOSIS

Clinical presentation of FGTB is shown in **Box 1**.[4-7,14,26] Prompt diagnosis by good history taking, thorough clinical examination, judicious testing, and timely treatment can prevent permanent damage.

BOX 1: Symptoms and signs in female genital TB.[4-7,14,26]

Symptoms:
- Asymptomatic (up to 12%)
- General symptoms:
  - Raised temperature
  - Loss of weight and anorexia
  - Poor or debilitated general condition
- Menstrual symptoms:
  - Menorrhagia (in early stages due to ulcerative lesions)
  - Dysmenorrhea
  - Oligomenorrhea (in late stage)
  - Hypomenorrhea (in late stage)
  - Amenorrhea (primary and secondary) (up to 10% cases) (in late stage due to endometrial atrophy and synechiae)
  - Opsomenorrhea
- Infertility (primary and secondary)
- Abdominal lump
- Dyspareunia
- Abdominal pain
- Chronic pelvic pain
- Acute abdomen
- Abnormal vaginal discharge

Signs:
- No physical sign
- Systemic examination:
  - Raised temperature
  - Enlarged lymph nodes (in TB lymphadenitis)
  - Rales on chest examination
  - Systemic signs as per site of extrapulmonary TB
- Abdominal examination:
  - Mass abdomen (vague or definite)
  - Doughy feel of abdomen
  - Ascites
- Vaginal examination:
  - Large uterus
  - Adnexal tenderness and fullness

INVESTIGATIONS

The investigations done in FGTB are demonstrated in **Box 2**.[4,5,10,43-47]

BOX 2: Investigations in genital tuberculosis.[4,5,10,43-47]

Blood investigations:
- Low Hb, leukocytosis, elevated lymphocytes, and ESR
- Moderate (up to 200 IU/mL) elevation of CA-125 in genital TB

Mantoux (Tuberculin) test and interferon gamma release assays; more than 10 mm

Skiagram chest:
- For pulmonary TB

Radiological methods:
- Ultrasound
- Computerized axial tomography **(Fig. 1)**.
- *Magnetic resonance imaging:*[43] Useful for tubo-ovarain masses **(Fig. 2)**.
- *Positron emission tomography (PET scan):*[44] Tubercular tubo-ovarian masses with increased FDG uptake **(Fig. 3)**.
- *Hysterosalpingography (HSG):*[41] Shrunken cavity, filling defects and lymphatic intravasation and blocked fallopian tubes **(Figs. 4 and 5)**.

Endometrial biopsy, curettage, or aspirate:
- *Histopathology:* Observation of epithelioid granuloma.
- *Mycobacterial smear and culture:* Using Löwenstein–Jensen (LJ) medium or BACTEC 460 or Mycobacteria growth inhibitor tube (MGIT)[4,5,45]
- *Polymerase chain reaction:* Rapid (1–2 days), sensitive, but less specific method for diagnosis of FGTB.[46] DNA PCR has also been used with higher specificity but is expensive and is not routinely available in most centers. Hence, ATT not be started only on PCR test.
- Gene Xpert if positive on endometrial biopsy is a reliable test for FGTB and treatment can be started on its basis.[32] It can also detect resistance to rifampicin. It has 33–50% sensitivity and 100% specificity for detection of genital TB.[32]

Endoscopy:
- *Hysteroscopy:* The endometrium is pale in color, may show tubercles or caseous nodules. The cavity is partially or completely obliterated by adhesions of varying grade (grade 1 to grade 4) often involving ostia **(Fig. 6)**. There may be a small shrunken cavity.[31,39]
- *Laparoscopy:* Useful modality for diagnosis of FGTB by direct visualization of disease like tubercles, adnexal masses **(Fig. 7)**, caseous nodules **(Fig. 8)**, fluid collect, pelvic adhesions, hydrosalpinx **(Fig. 9)**, pyosalpinx, beading of tubes, and inability to see tubes due to adhesions.[11,12] However, laparoscopy should be done by experts in FGTB as increased complications and difficulties have been observed on laparoscopy in FGTB patients.[45] Adhesions: Different adhesions are formed in FGTB causing hanging, gallbladder, and ascending colonic adhesions.[48] Being thick and vascular, adhesiolysis can cause bleeding and flare-up of the disease. There is very high prevalence (48%) of perihepatic adhesions on laparoscopy in FGTB cases.[27]

Combination of tests (algorithm): Can be useful in diagnosis[5,49] **(Flowchart 1)**.

(ATT: antitubercular treatment; DNA: deoxyribonucleic acid; ESR: erythrocyte sedimentation rate; FDG: fluorodeoxyglucose; FGTB: female genital tuberculosis; Hb: hemoglobin; PCR: polymerase chain reaction)

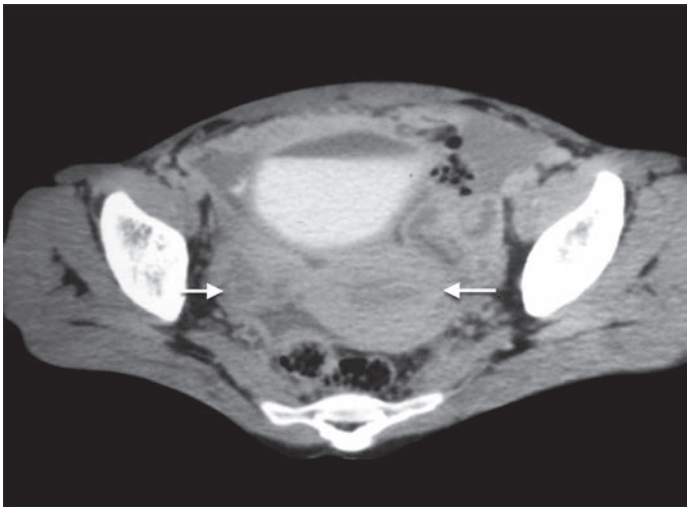

Fig. 1: CT scan findings in patient with female genital tuberculosis bilateral tubo-ovarian mass.

Fig. 2: MRI depicting adnexal masses (arrows) on both sides with enlarged lymph nodes.

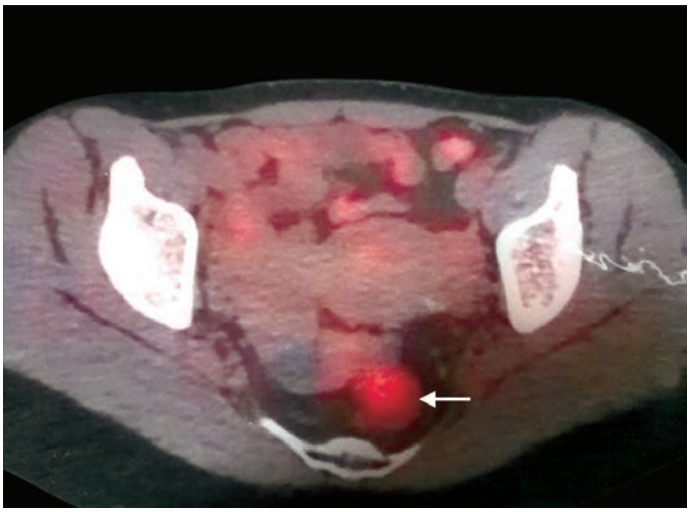

Fig. 3: Positron emission tomography CT scan showing tubercular adnexal mass (arrow) with enhanced fluorodeoxyglucose uptake.

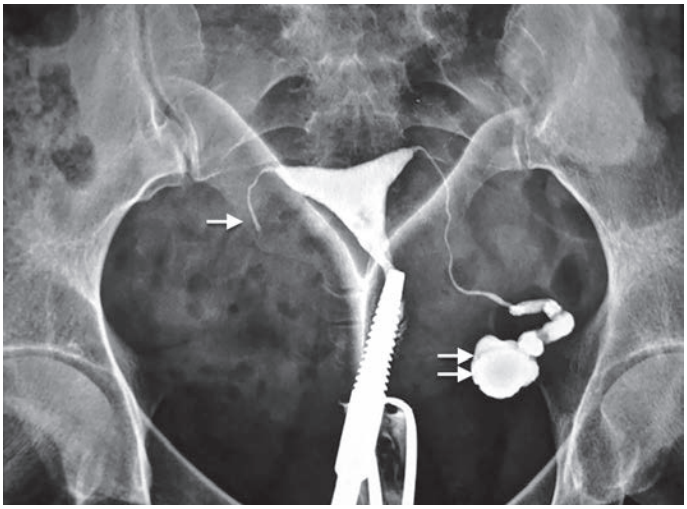

Fig. 4: Hysterosalpingography showing mid-tubal block (single arrow) on right side and fimbrial block with hydrosalpinx showing tobacco pouch appearance (double arrows) in left side in female genital tuberculosis (FGTB).

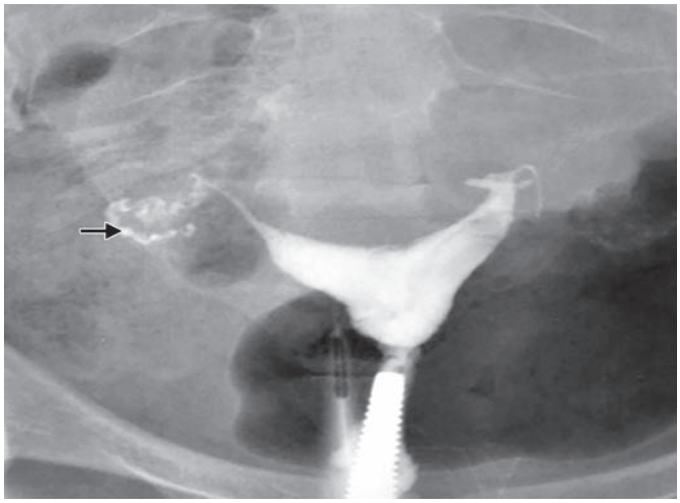

Fig. 5: Hysterosalpingograhpy depicting with "beaded" tube (arrow) on right side and left mild isthmic block in female genital tuberculosis (FGTB).

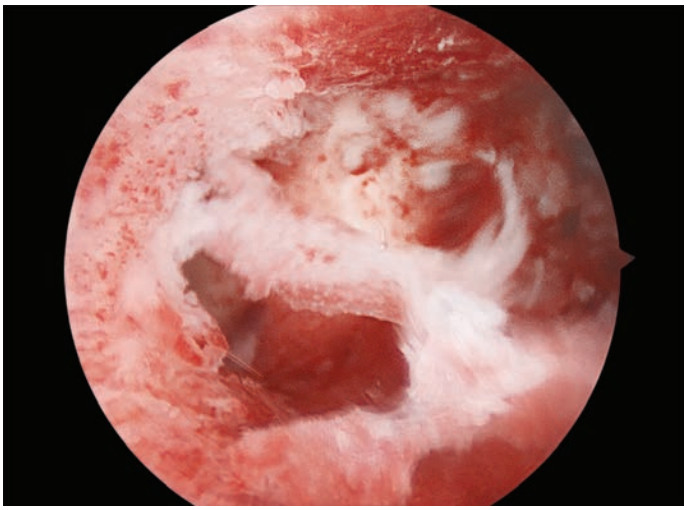

Fig. 6: Hysteroscopic picture showing Grade III adhesions in a case of female genital tuberculosis (FGTB).

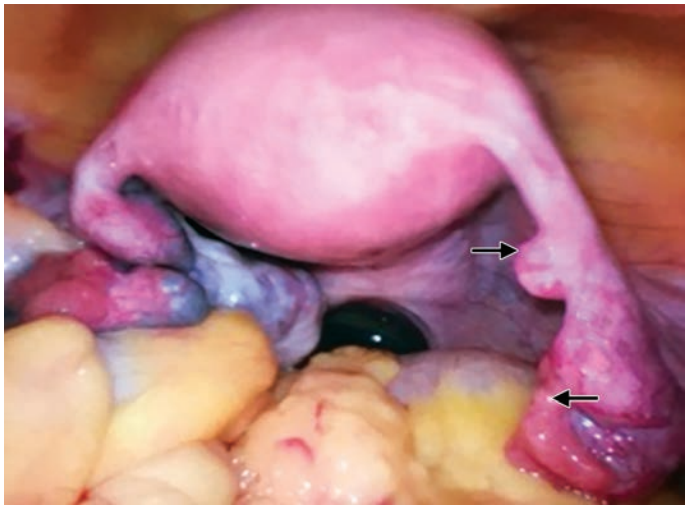

Fig. 7: Laparoscopy demonstrates congested, dilated, and inflamed fallopian tubes with tubercles (arrows) in female genital tuberculosis (FGTB).

Female genital TB is associated with increased complications in laparoscopy, hysteroscopy, and other techniques.[40,48]

Index-TB guidelines for EPTB including FGTB have been developed by Ministry of Health and Family Welfare and All India Institute of Medical Sciences in 2016 for guidance and management of FGTB.[49]

TREATMENT

Medical Treatment

Treatment of latent genital TB with positive PCR is controversial due to high false positivity. Many infertility experts routinely treat positive PCR women with higher pregnancy outcome, especially often in those women treated with antitubercular treatment (ATT) than without treatment. The logic of treating latent TB is that in early stage, it can be treated without causing permanent damage to endometrium and other genital organs with much better outcome.

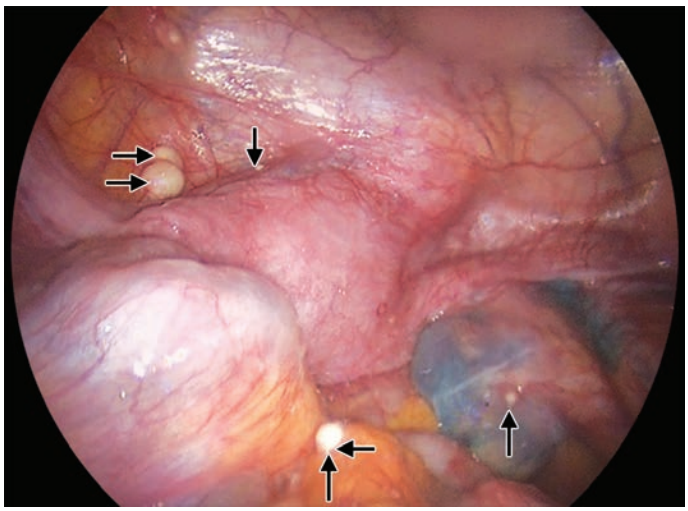

Fig. 8: Laparoscopy demonstrating caseous nodules on peritoneum fallopian tubes, and pouch of Douglas in female genital tuberculosis (FGTB).

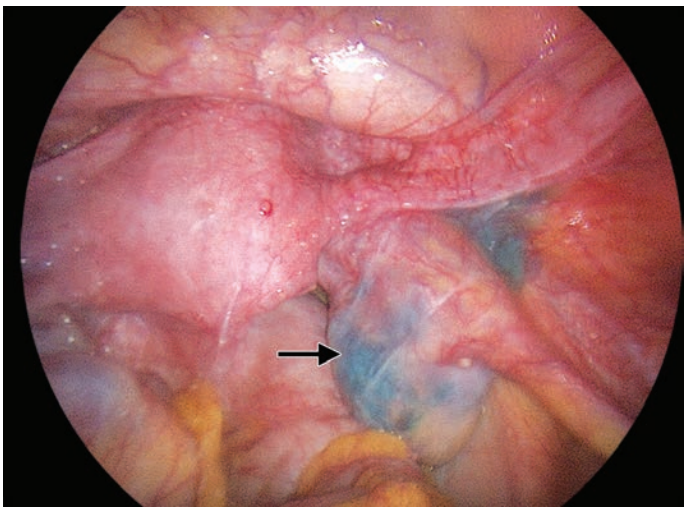

Fig. 9: Laparoscopy depicting hydrosalpinx (arrow) in female genital tuberculosis (FGTB).

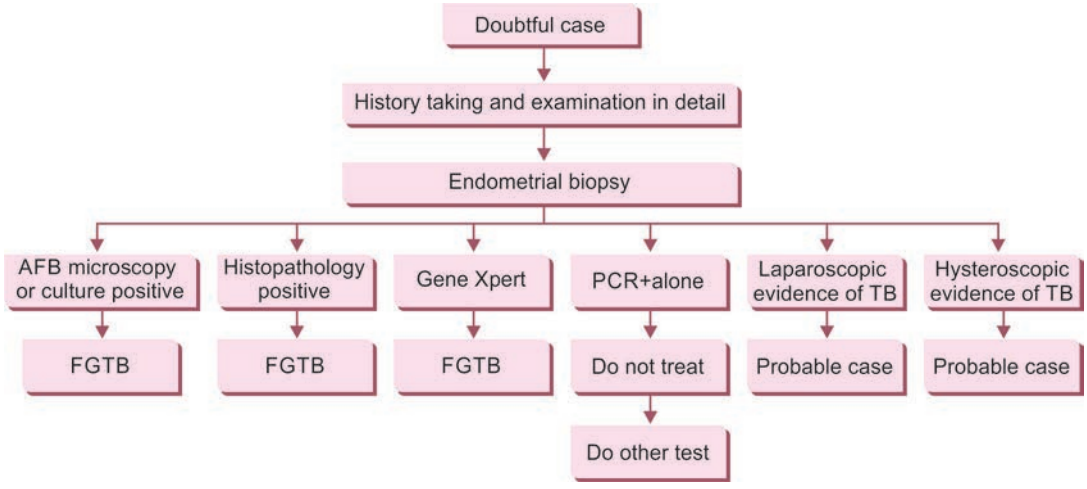
Flowchart 1: Algorithm for diagnosis of female genital tuberculosis (FGTB).



(AFB: acid-fast bacillus; PCR: polymerase chain reaction; TB: tuberculosis)

Jindal et al.[50] observed 30.8% conception rate in latent TB with ATT while Kulshrestha et al.[51] also obtained 31% pregnancy rate on ATT in TB PCR positive women. Latent genital TB has been found to be associated with recurrent IVF failure.[42] Even on migration to western countries, Indian women have poor prognosis with IVF as compared to Caucasian women despite similar embryo quality which could be due to latent FGTB in Indian women.[52] However, treating women with positive PCR is associated with risk of over treatment as many women without FGTB are then treated. ATT for 6 months is adequate effective for medical treatment of FGTB as seen in randomized controlled trial (RCT).[5,53]

DOTS Strategy Treatment

Directly observed treatment, short-course (DOTS) is favored by WHO and National Tuberculosis Elimination Program (NTEP) of India to prevent MDR and for better results. There have been recent changes in medical treatment of all types of TB including FGTB. Categories are not used anymore. All drug sensitive TB cases (both pulmonary and FGTB) including defaulters are given 2 months of 4 drugs orally daily (rifampicin [R], isoniazid [H], pyrizinamide [Z] and ethambutol [E]-intensive phase) followed by three drugs (RHE) orally daily for next 4 months (continuation phase).

DRUG TREATMENT OF DRUG SENSITIVE FGTB

Daily oral rifampicin (R), isoniazid (H), pyrazinamide (Z), and ethambutol (E) for 2 months. Then oral RHE for next 4 months orally daily as per DOTS. On an averege a 50 kg woman will require 450 mg rifampicin, 600 mg isoniazid, 1,500 mg pyrazinamid, and 1,200 mg ethambutol.

Treatment of Chronic Cases, Drug-resistant, and Multidrug-resistant FGTB

Although rare MDR FGTB is being observed in clinical practice. It is usually secondary to MDR TB in lungs or elsewhere but can be primary also if the initial infection occurs with MDR stains.[54] Treatment is same as for pulmonary MDR with second-line drugs in consultation with TB experts. Patients with HIV and TB should be treated with both ART and ATT in consultation with experts in the area. The MDR treatment is given either longer oral regimen for 18–24 months or shorter regimen for 9–12 months in consultation with experts. TB notification should be done to Government of India through Nikshay (TB notification portal).

Monitoring

Patients are regularly followed and monitored for compliance and side effects of drugs.

Surgical Treatment

Surgery is usually avoided in FGTB as modern short-course treatment is very effective. However, abscess should be drained surgically. Besides, there are difficulties increased chances of complications in various surgeries like hysteroscopy, laparoscopy, and laparotomy in women with genital TB with risk of injury to bowel necessitating a very difficult laparotomy and resection of injured bowel.[48,55] It is better to just take biopsies and avoid difficult surgery done for suspected pelvic tumors but found to be tubercular at laparotomy followed by full medical treatment. Laparoscopy and hysteroscopy can be done after ATT.

It is also useful to prognosticate and plan for further treatment. Outcome for fertility in FGTB is only good when ATT is started in early disease. However, cases of advanced TB with extensive adhesions in pelvis and uterus are usually not amenable to treatment with poor prognosis for fertility. Tuboplasty is avoided much as it runs the risk of flare-up of the disease and ectopic gestation.[56,57]

IN VITRO FERTILIZATION AND EMBRYO TRANSFER IN FGTB[23,58]

Most women with genital TB present with infertility and have poor prognosis for fertility in spite of ATT. The conception rate is low (19.2%) with live birth rate being still low (7%).[23] IVF with embryo transfer (ET) appears to be the only hope for some of these women whose endometrium is not damaged with pregnancy rate of 16.6% per transfer.[58-66] Jindal et al.[50] observed favorable infertility outcomes following ATT prescribed on sole basis of positive PCR test for endometrial TB. Singh et al.[67] observed poor endometrial blood flow in women with FGTB undergoing IVF–ET. We also observed decreased blood flow to endometrium and ovaries in FGTB patients which got improved on repeat examination after ATT.[34,68]

Malhotra et al.[69] studied perifollicular Doppler blood flow before oocyte recovery in patients with or without genital TB. They observed a trend of poor ovarian blood flow in FGTB women undergoing IVF or intracytoplasmic sperm injection (ICSI) in their center. IVF–ET has 17.3% conception rate in contrast to only 4.3% with tubal surgery in FGTB.[60] The pregnancy rate and take-home baby rate could be improved by early detection and timely treatment. The result of IVF and ET are poorer in FGTB than in other indications. The results of IVF–ET in FGTB by various authors are shown in **Table 3** and pregnancy rate vary from 9.1% to 38.3% with increased chances of miscarriage and ectopic gestation. Studies have shown poor result with IVF in FGTB due to following reasons:

- Most patients are poor responders.
- They require higher quantity of drugs.

TABLE 3: Fertility outcome in FGTB with IVF and ET by various authors.

Author (Reference) (Year)	*Frydman et al.*[66]	*Parikh et al.*[8]	*Marcus et al.*[61]	*Soussis et al.*[62]	*Gurgan et al.*[58]	*Bapna et al.*[65]	*Malik et al.*[60]	*Dai et al.*[63]
No. of patients	20	30	10	13	24	49	120	155
Pregnancy rate; No (%)	8 (25%)	5 (16%)	6 (60%)	6 (28.6%)	4 (9.1%)	17 (19.1%)	46 (38.3%)	94 (60.6%)
Implantation rate					5.8%			
Delivered No (%)	NA	16.2%	22.2%	37.5%	1 (25%)	–	45%	40.2%
Abortion No (%)	6 (30%)	5 (16%)	4 (40%)	4 (31%)	3 (75%)	37 (30.3%) 11/94 (11.7%)	37 (30.3%)	(24.5%)
Ectopic pregnancy; No (%)	1 (5%) (5%)	– 1 (3%)	1 (10%) 1 (10%)	2 (15%) –	5 (10.2%) 2 (1.6%)	9 (7.5%)	3/94 (3.2%)	

(ET: embryo transfer; FGTB: female genital tuberculosis; IVF: in vitro fertilization)

- Endometrium is invariably poorly developed.
- Quality of egg and fertilized ovum is suboptimal and pregnancy rate is poor.

Malik[60] observed a conception rate of 38.2% in FGTB patients with IVF–ET. ATT was given to the patients till the endometrial biopsy was negative and this varied from 6 to 18 months. IVF was done only after the biopsy was negative. No difference in pregnancy rate was noticed when patients were kept on or were taken off the ATT during the IVF cycle.

Hence, IVF–ET is an optimum treatment for tubal blockage but receptive endometrium in FGTB.

Gestational Surrogacy in Genital TB

It is recommended for blocked tube and Asherman's syndrome.

In gestational surrogacy another woman's uterus is used for implantation while ovum belongs to this woman and sperm belongs to her husband. She is thus the genetic mother of the fetus.

Samantha et al. recommended surrogacy for following case:

- Asherman's syndrome not amenable to hysteroscopic adhesiolysis
- Atrophic endometrium not responding to hormonal therapy
- Grossly reduced endometrial thickness (<7 mm) in spite of estrogen supplementation with high resistance subendometrial blood flow in the proliferative phase in repeated cycles
- Dense pelvic adhesions causing repeated IVF failure
- Unexplained repeated IVF failure with endometrium showing persistence of TB granuloma or PCR positivity despite adequate antitubercular chemotherapy
- MDR genital TB.

Surrogate host can be a family member or stranger but a forced friendship, must be established between host and the commissioning couple in surrogacy.

Samantha et al.[70] could achieve a viable delivery rate of 50% by surrogacy in FGTB patients with uterine synechiae, poor endometrial development, or repeated IVF failure.

Adoption: It is indicated for blocked tube, defective endometrium, and failed ovaries.

NEW TUBERCULOSIS RESEARCH

More research is being done in FGTB including immune markers, molecular tests, newer vaccines, newer and shorter drug regimen, and stem cell therapy. IVF–ET if performed on time has good success rate. There is need to improve pregnancy outcome by IVF–ET in FGTB. Gestational surrogacy has a role in some women. More research is needed on changing trends in prevalence and on better methods of diagnosis of FGTB as genital TB impacts both male and female infertility.[71-74]

CONCLUSION

Female genital tuberculosis is a common cause of sterility in India and requires early diagnosis and timely treatment with 6 months ATT followed by IVF–ET for most patients and surrogacy and adoption for some patients.

KEY POINTS

- Female genital tuberculosis is a common cause of sterility through tubal, endometrial, and ovarian factors.
- Early diagnosis by detailed history examination and selected tests including endoscopy is needed.
- Surrogacy and adoption may be needed in some women.
- Stem cell regeneration may be helpful in Asherman's syndrome.

CHAPTER 37

Sonoendocrinology and Cycle Monitoring-Assisted Reproduction Technology

Sonal Panchal, Chaitanya Nagori

INTRODUCTION

Human reproductive system is a finely balanced highly dynamic orchestra involving several hormones. The hormones as they change their concentration and their role at different phases of the cycle lead to changes in ovarian and uterine morphology and vascularity that can be effectively studied by B-mode ultrasound, Doppler, and to some extent by three-dimensional (3D) ultrasound, and 3D power Doppler also. These morphological and vascular changes can be best studied by transvaginal ultrasound and Doppler. Correlating the morphological and vascular changes with their physiological and hormonal basis can interpret the hormonal changes occurring during the menstrual cycle whether natural or stimulated. These changes can be monitored by different imaging modalities.

IMAGING MODALITIES FOR ASSESSMENT OF REPRODUCTIVE SYSTEM

Transabdominal ultrasound was the approach used earlier but this approach has certain inherent disadvantages. It uses a low-frequency probe that has a low resolution. Moreover, the probe is placed far from the pelvic organs, and further reduces the precision of information available on scan. Apart from this, the patient requires to tolerate the discomfort of full bladder.

With the development of endocavity probes, transvaginal route became very popular for scanning the pelvic organs, uterus, ovaries, and fallopian tubes. It uses a high-frequency probe and the probe is placed very close to the uterus and ovaries—both help to achieve high-resolution images of uterus and ovaries. The resolution was further improved in high-end scanners by advanced features that are used to improve the B-mode image. These are harmonics, speckle reduction imaging (SRI), and compound resolution imaging (CRI). All these together made it possible to assess morphology of uterus and ovaries more precisely. Improvement in the Doppler sensitivity with advancing technology has made it possible to assess the blood flow changes in small blood vessels of ovarian stroma, follicle, and endometrium. Volume ultrasound further leads to assessment of global vascularity of ovary, follicle, and endometrium. Moreover, these volume studies are also used to assess the volumes of the organs or structures instead of just diameters. We shall now discuss the role of ultrasound for understanding the physiology in assessment and monitoring of natural and stimulated menstrual cycles, respectively, and correlate the hormonal changes with the ultrasound findings of ovaries and uterus in different phases of menstrual cycle. The discussion here is divided into three phases of the menstrual cycle—the baseline scan (day 2–3 scan), preovulatory scan, and luteal phase scan.

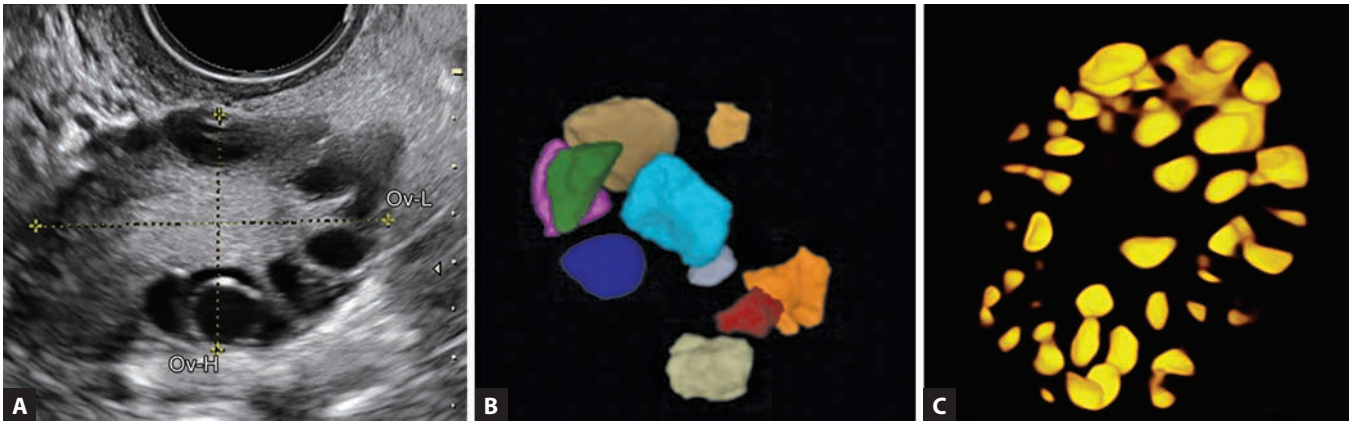
The hormones of major interest on the baseline scan are:

- Androgen
- Anti-Müllerian hormone (AMH)
- Follicle-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Estrogen
- Progesterone.

Of course other hormones like thyroid and prolactin also have an impact on fertility and it is insulin resistance (IR) that may also be of concern.

Androgen

The menstrual cycle starts on first day of the menstruation. But, actually, the recruitment of the follicles from preantral to primary antral and then secondary antral follicles start in the luteal phase of the previous cycle. The antral follicles are 2–9 mm in size and are then recognizable by ultrasound. Recruitment of these follicles is a function of androgen, and antral follicle count (AFC) represents the functional ovarian reserve. Higher androgen level would lead to more follicles being converted from preantral to antral and so higher AFC.[1] It is for this reason that patients with polycystic ovarian syndrome (PCOS), who have hyperandrogenemia, show higher AFC as compared to controls **(Figs. 1A to C)**.



Figs. 1A to C: (A) Antral follicles seen in the ovary on B-mode; (B) Low-antral follicle count on sonography-based automated volume count (Sono-AVC); (C) High-antral follicle count (on inversion mode 3D-rendered image).

What Happens in PCOS Patients?

High-basal androgen levels in the PCOS patients lead to recruitment of more antral follicles. But androgen also leads to sensitizing of the follicles to FSH. As follicles get sensitized to FSH, these cannot grow further beyond a certain size (6–7 mm) without FSH. But due to increasing estrogen levels as a result of multiple follicular recruitment and conversion of the excess androgen to estrogen in PCOS patients, the FSH rise is dampened or may also be stopped in cases. This prevents follicular growth but also stimulates LH secretion, which leads to follicular atresia, increase in the theca cell population, and thus increased stroma. Thus, more androgen levels in PCOS patients are indicated by more antral follicles. Obesity and IR may enhance follicular excess by dysregulation of AMH through pathway of hyperandrogenemia.[2] AFC and ovarian volume showed significant correlation with AMH, total testosterone, and free androgen index.[2] The ovarian stroma/total ovarian volume ratio was the most accurate predictor of both hyperandrogenemia (area under the curve, 0.915; P <0.0001) and hirsutism (area under the curve, 0.891; P <0.0001).[3]

Moreover, androgen is responsible for smooth muscle tone. Uterine arteries have thick muscularis layer to allow the flexibility and dynamicity in its caliber during different phases of menstruation and also during pregnancy and labor. This layer consists of smooth muscle fibers and therefore androgen leads to increased tone in these muscles and therefore high-resistance flow in uterine arteries in PCOS patients during the whole cycle **(Fig. 2)**.[4]

High androgen is reflected as:

- More antral follicles
- Increased uterine artery resistance
- Stromal predominance.

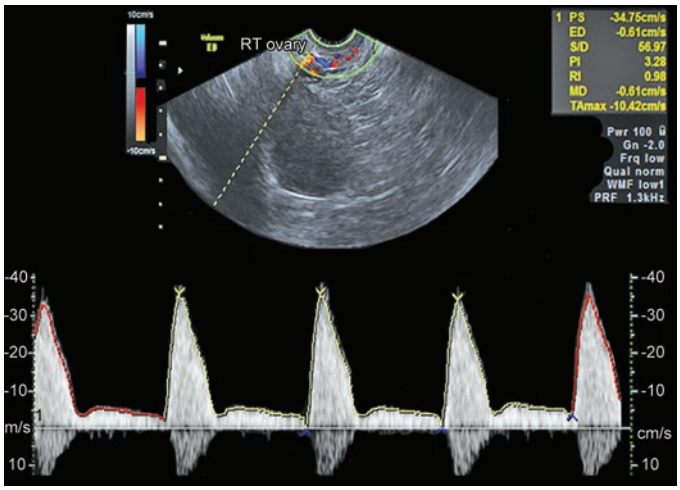


Fig. 2: High-uterine artery resistance.

Anti-Müllerian Hormone

Biochemically ovarian reserve can be assessed by AMH, FSH, and inhibin B.

The AMH is produced by granulosa cells of preantral and small antral follicles of between 2 and 6 mm, before they become sensitive to FSH. It is a regulator of recruitment of follicles. AMH has an advantage that it can be tested in any phase of cycle, though threshold in late luteal phase may be different.

Antral follicle count can be correlated to AMH. AFC and ovarian volume showed significant correlation with AMH. The number of small antral follicles (2–6 mm) is significantly related to age and also, independent of age, to all endocrine ovarian reserve tests, and suggesting that the number of small antral follicles represents the functional ovarian reserve.[5]

Serum AMH levels have been shown to strongly correlate with the number of antral follicles[6,7] and have appeared to be cycle independent.[8,9] AFC and ovarian volume provide direct measurements of ovarian reserve, while AMH, inhibin B, and estradiol are released from growing follicles and so their levels reflect the size of developing follicle cohort.[10]

The receiver operating characteristic (ROC) curves do not suggest a clearly better predictive ability for AMH than

for AFC, and the difference was not statistically significant (P¼.73). This implies that the best poor response predictor to date, AFC,[11] has obtained company from a test that may have some crucial advantages.

Sensitivity and specificity for AMH were 82% and 76%, respectively, and 82% and 80%, respectively, for AFC. Comparison of the summary estimates and ROC curves for AMH and AFC showed no statistical difference in this study, which shows that both AMH and AFC are accurate predictors of excessive response to ovarian hyperstimulation. Moreover, both tests appear to have clinical value.[12] Small AFC and AMH have similar predictive accuracy for high-ovarian response with area under curve of 0.961 and 0.922, respectively. The sensitivity and specificity for prediction of high-ovarian response were 89% and 92% for small AFC and 93% and 78% for AMH at the cutoff values of ≥16 and ≥34.5 pmol/L, respectively.[13] In our study, we compared the efficacy of AFC and AMH in PCO and non-PCO group. The results show that correlation of AFC and follicles >12 mm on day of human chorionic gonadotropin (hCG) in PCO group is 0.56 and non-PCO group is 0.63; and for AMH and follicles >12 mm on day of hCG in PCO group is 0.42 and non-PCO group is 0.47. A correlation of AFC was found with number ova retrieved on oocyte pick-up (OPU) in PCO group is 0.44 and for non-PCO group is 0.50. The value for AMH is 0.39 in PCO and 0.43 for non-PCO group (significance of correlation at 0.01 level is required to be higher than 0.283).[14] In a meta-analysis by Broer et al., it has been shown that AMH has at least the same level of accuracy and clinical value for the prediction of poor response and nonpregnancy as AFC.[15]

The AMH can be closely correlated with AFC **(Fig. 3)** and can also be used as a test of ovarian reserve instead of AMH without compromising the accuracy and efficacy. It will be worth mentioning here that androgen is the cause and AMH is the effect of recruited antral follicles.

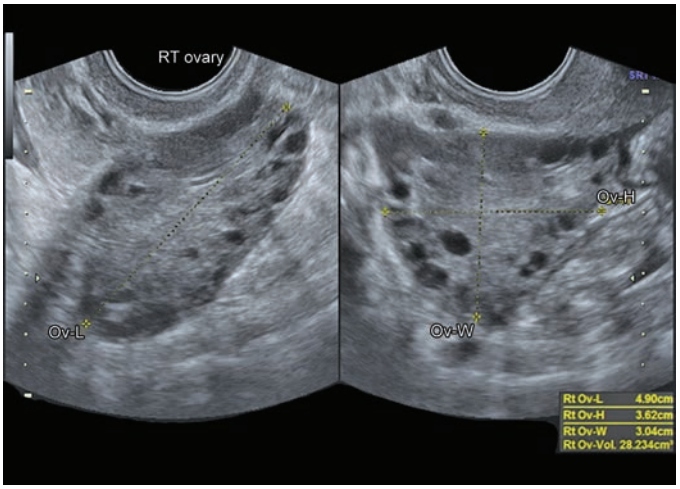

Fig. 3: Small antral follicles.

Correlation of AFC with Hyperinsulinemia and AMH in PCOS Patients

Hyperinsulinemic PCOS patients had an increased vascularity of the ovarian stroma.[16] Increased ovarian stromal blood flow in PCOS may be because of overexpression of vascular endothelial growth factor (VEGF), which modulates the permeability of theca cells and increases insulin-like growth factor 1 (IGF-1).[17,18] This in turn enhances gonadotropin-stimulated steroid production in granulosa cells and theca cells resulting in increased ovarian androgen production and subsequently increased AMH.[19]

Follicle-stimulating Hormone

Follicle-stimulating hormone is produced by pituitary and its secretion is controlled gonadotropin-releasing hormone (GnRH) from the hypothalamus and by the negative feedback of estrogen **(Fig. 4)**. It acts on granulosa cells to produce estrogen. In the initial phases of the menstrual cycle, the estrogen level is low and the FSH level is raised. When the follicle size is <6 mm, these follicles are FSH independent. By the sensitizing effect of androgen, these follicles become FSH sensitive at 6–9 mm and beyond 9–10 mm these follicles become FSH dependent. AMH, produced by the granulosa cells of preantral and small antral follicles, inhibits factors affecting FSH sensitivity of the follicle. As AMH levels decrease with follicle growth, this inhibition would be removed.[20] This means that the follicular growth beyond 6-mm size suggests FSH action. Therefore, faster growth of the follicles indicates high FSH. Early follicular recruitment, fast growth of the follicle in early follicular phase, and follicle of >10 mm on the baseline scan indicate high-basal FSH levels. But it is important to remember that the follicle that is recruited early may grow fast on stimulation, but is less likely to produce good-quality follicle due to its shorter duration to maturity.

Whereas, a slow follicular growth rate indicates that the FSH level is lower than optimum. This is the situation in PCOS patients. Because of multiple follicular development and aromatization of excess androgen to estrogen, there is rise in estrogen level leading to negative feedback to FSH and therefore slow rise in FSH and therefore slow growth of follicles.

High-basal FSH—early recruitment of follicle is shown in **Figure 5)**.

Luteinizing Hormone

The LH is also produced by pituitary. Its secretion is controlled by GnRH from hypothalamus and by positive feedback of estrogen and acts on theca cells to produce androgen and progesterone from cholesterol. LH is also responsible for proliferation of theca cells.

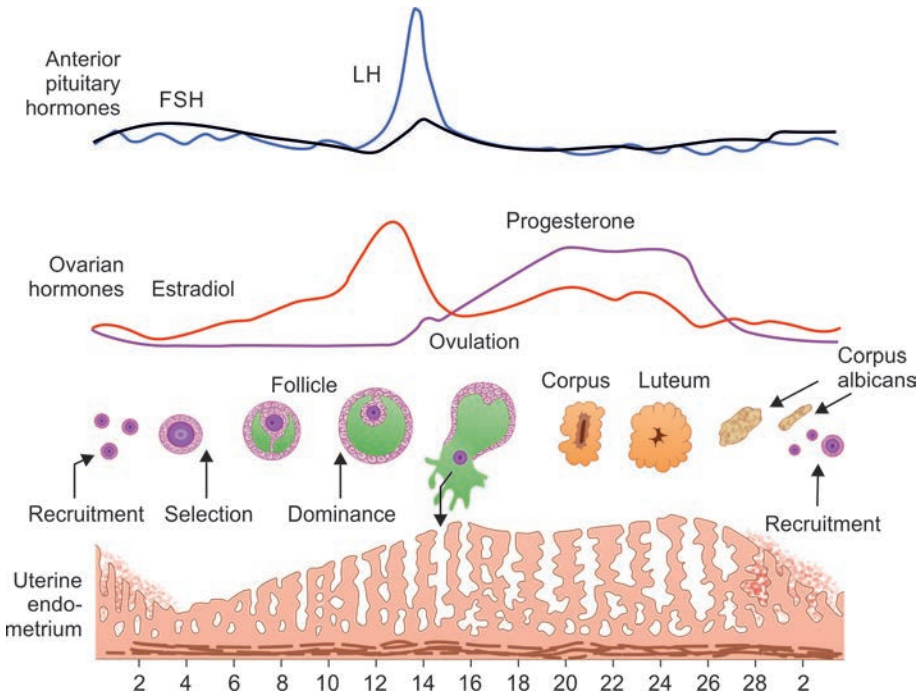

Fig. 4: Diagrammatic representation of hormonal and morphological changes occurring during the menstrual cycle. (FSH: follicle-stimulating hormone; LH: luteinizing hormone)

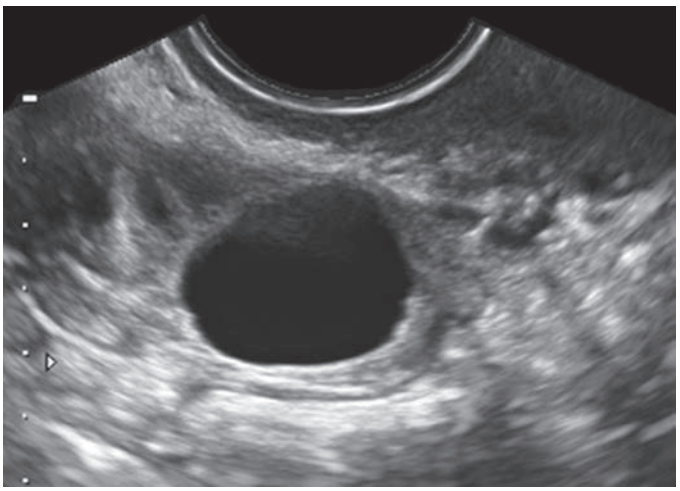

Fig. 5: Day 3 scan showing dominant follicle—early follicular recruitment.

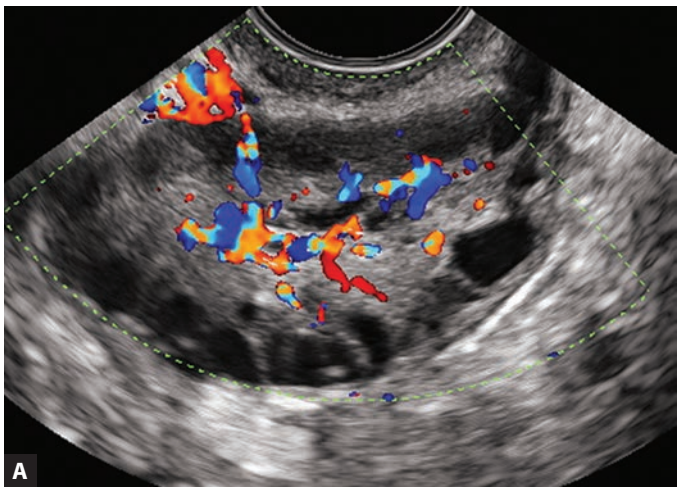
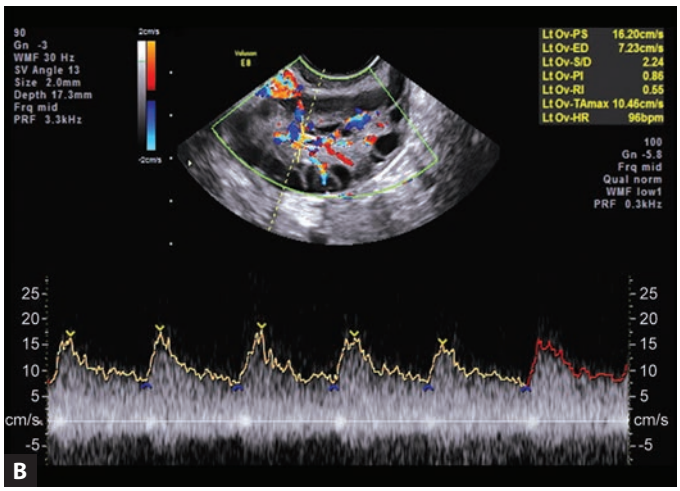




Figs. 6A and B: Stromal vascularity in polycystic ovary on color Doppler and pulsed wave Doppler.

Elevated LH levels may be responsible for increased stromal vascularization due to neoangiogenesis, catecholaminergic stimulation, and leukocyte and cytokine activation. This means LH is responsible for stromal vascularity.[21] This is the reason why PCOS patients have increased stromal vascularity as compared to the normal controls.

The vascular parameters of the ovarian stromal vessels **(Figs. 6A and B)** in PCOS and normal patients are given in **Table 1**.[22]

When assessed by 3D power Doppler, compared to the normal control women, PCOS women had higher AFC (median 16.3 vs. 5.5 per ovary), ovarian volume

(12.56 vs. 5.6 mL), stromal volume (10.79 vs. 4.69 mL), and stromal vascularization [vascularization index (VI) 3.85 vs. 2.79%, vascularization flow index (VFI) 1.27 vs. 0.85]. Though this study quotes that 2D power Doppler indices were not higher in PCOS than in controls.[23]

What is the Effect of High LH in PCOS?

It is known that PCOS is not a cause but a result of chronic anovulation. It is a process of evolution from adolescent-aged multicystic ovaries to polycystic ovaries. As a result of marginally high-androgen levels in early follicular phase in polycystic ovarian disease patients, there is recruitment of multiple antral follicles. But these follicles grow only up to 6–7 mm under the effect of androgen. These small follicles do secrete estrogen, and therefore, cumulative higher estrogen causes a negative feedback for FSH. Low FSH is not enough for follicular maturation and leads to chronic anovulation. But all these follicles do not become dominant due to high LH and/or AMH levels. These follicles, which were recruited but not matured, undergo atresia under the effect of LH and in the course of time become theca cells and contribute to stroma. This stroma tries to accommodate itself in the ovarian capsule and therefore starts becoming dense initially and then increases the ovarian volume. Polycystic ovarian morphology (PCOM) has been found to be a better discriminator than ovarian volume between PCOS and control women.[24] Patients having long-standing PCOS and long-standing anovulation have more dense stroma and this is a cardinal feature that has been shown as bright and highly echogenic stroma on transvaginal ultrasound.[25] In a study by Franks et al., it is also shown that PCOM in normal women is not a morphological variant of normal ovaries but rather represents a functional entity.[26] Lam et al. have concluded in their study that the current criteria of 10-cc ovarian volume will fail to identify a group of ovulatory, and normoandrogenic women still at risk of complications classically associated with PCOS such as ovarian hyperstimulation syndrome (OHSS), failed implantation, miscarriage, and hyperinsulinemia. To identify these women, further information, particularly about the ovarian stroma and the degree of vascularization, is required.[27]

This means that high LH in PCOS patients can be identified by increased stromal vascularity and stromal abundance in the form of increased stromal echogenicity or increased stromal volume **(Figs. 7A and B)**.

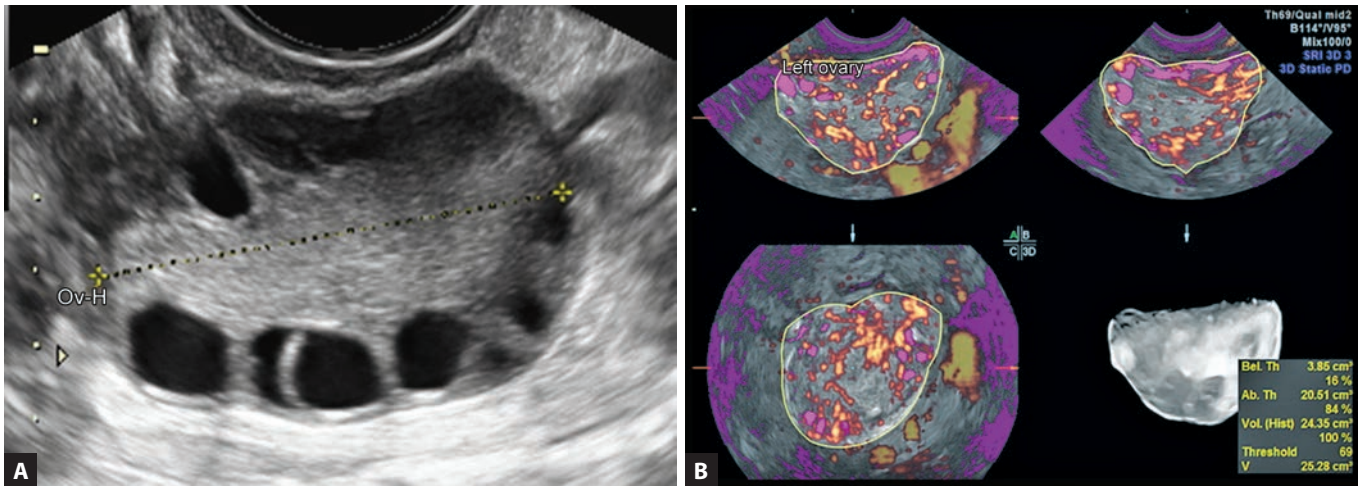
It has been observed that the poor responders have poor ovarian stromal flows. Measurement of ovarian stromal flow in early follicular phase is related to subsequent ovarian response in in vitro fertilization (IVF) treatment. Those who had low-stromal peak systolic velocity (PSV) in the early follicular phase were poor responders.[28] VI, FI, and VFI of the ovary were significantly related to ovarian response to stimulation.[29] Total ovarian VI and VFI were significantly lower in women aged ≥41 years.[30] And according to the Poseidon criteria, it is the group of patients in whom LH needs to be added.[31] The explanation here may be that these patients have less flow and therefore may have less bioactive LH and the supplementation of LH therefore can be helpful for better response.

Less ovarian stromal flow indicates poor response to stimulation and needs for LH supplementation.

TABLE 1: The vascular parameters of the ovarian stromal vessels in polycystic ovarian syndrome (PCOS) and normal patients.

Parameter	*PCOS*	*Normal*
RI	0.54 ± 0.04	0.78 ± 0.06
PI	0.89 ± 0.04	1.87 ± 0.38
PSV	11.9 ± 3.2	9.6 ± 2.1

(PI: pulsatility index; PSV: peak systolic velocity; RI: resistance index)



Figs. 7A and B: (A) Hyperechoic stroma seen on B-mode scan as an ultrasound feature for stromal abundance; (B) 3D ultrasound assessment of the stromal volume done by vocal software.

Estrogen

It is known that the granulosa cells of follicle are responsible for estrogen secretion and therefore increasing follicular size is associated with rising estrogen levels. Therefore, the simplest evidence that the estrogen level is rising is the follicular growth. It is worthwhile mentioning here that FSH is the cause and estrogen is the result of follicular growth.

This endometrial thickness can be used as a guide to estrogen levels on the baseline scan also. Thin linear endometrium on baseline scan suggests adequate downregulation and low-basal estrogen levels. For the patients on downregulation for IVF, if the baseline scan shows an endometrial thickness of >3 mm, it is an indicator of inadequate downregulation.[32] This endometrial thickness usually correlates with 30–50 pg/mL of estrogen.

Progesterone

In some cases, thick endometrium on baseline scan may be because of continuing activity of corpus luteum that may be confirmed by the corpus luteum with pericorpus luteal low-resistance flow in either ovary.

PREOVULATORY PERIOD

The hormonal assessments that may be indicated in this phase are estrogen, progesterone, and LH. These are to assess follicular maturity, endometrial receptivity, and possibility of premature LH surge.

Follicular maturity biochemically is assessed by estrogen level, and on ultrasound by B-mode and Doppler assessment of the follicle. Estrogen is responsible for perifollicular vascularity. It is known that the estrogen level gradually starts rising after fifth day of the menstrual cycle, when the dominant follicle is selected. Increase in perifollicular vascularity of dominant follicle in theca layer starts developing as early as eighth day of a normal length cycle. Fall in perifollicular resistance index (RI) starts 2 days before ovulation.[33] This is the time when the shoot up is seen in the estrogen level. At ovulation, when estrogen level has just passed the peak, the RI is the lowest. This means that the RI of the perifollicular vessels can be inversely correlated with the estrogen levels. Increase in PSV starts 29 hours before ovulation and continues for at least 72 hours after ovulation.[34,35] This can be explained by the fact that LH is responsible for the influx of blood in the ovary and neoangiogenesis that is essential for the follicular and in turn ovum oxygenation. The increase in perifollicular PSV can be correlated with the increase in the LH levels at the time of surge. It is the combined action of estrogen and LH surge that leads to these final circulatory changes before ovulation. Vascular changes at the time of impending ovulation include increased vascularity of the inner wall of the follicle and a coincident surge in blood velocity just prior to eruption.[36] A marked increase in the PSV around the follicle, in the presence of a relatively constant pulsatility index (PI), could be a sign of follicle maturity and impending ovulation.[37] In stimulated cycles, the surge is surrogate and that is by hCG. The influx of blood flow surrounding the follicle therefore follows hCG.

Thus, the increasing perifollicular blood flow and lowering resistance can be correlated with the rising estrogen levels. Whereas, increasing LH level correlates with the rising perifollicular PSV.

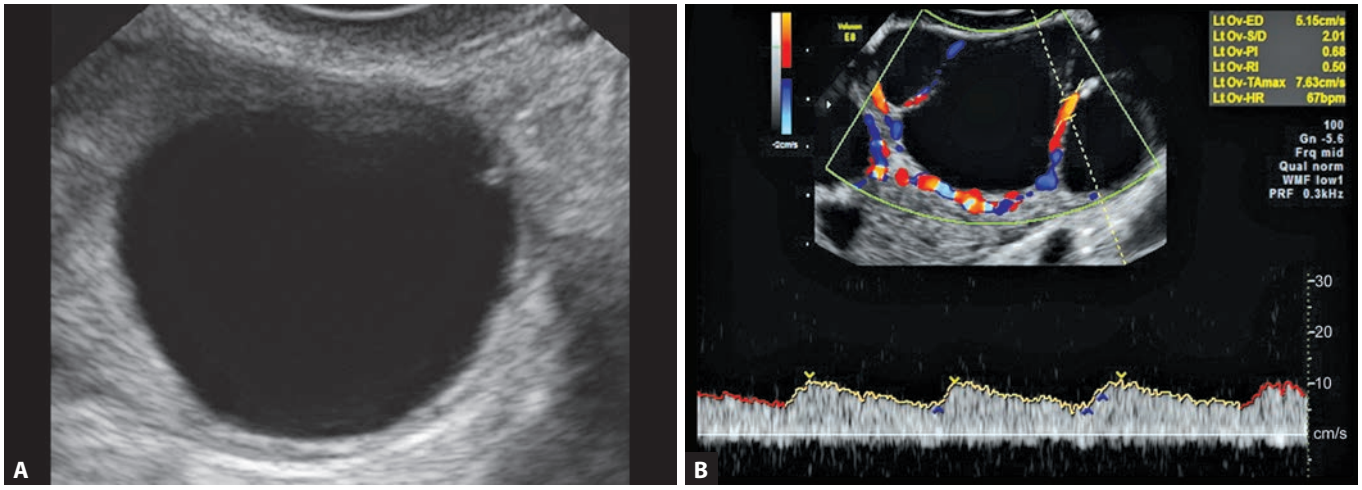
But, it is known that after the peak of LH surge, either natural or surrogate, there is a sudden downfall in the estrogen level, but the rise in the progesterone level is slow and reaches peak only in the mid-luteal phase. It is because of this that the uterine artery resistance increases after the LH surge[38,39] and the endometrial flow also decreases for 3–4 days, which then increases to reach the low-resistance flow in the mid-luteal phase. Histological and embryological data suggest that relatively low partial pressure of oxygen (pO_2) environment may be necessary for successful implantation of human blastocyst.[40] Low-endometrial VI and VFI are seen in pregnant group on the day of oocyte retrieval are considered a positive sign for endometrial receptivity. A nonsignificant trend of higher implantation and pregnancy rates is observed in patients with absent subendometrial and endometrial flow.[41]

It is known, according to two-cell–two-hormones theory,[42,43] that LH is responsible for conversion of granulosa cells to theca cells. In the preovulatory phase, this action of LH is seen whenever any follicle is exposed to LH. This means that if a mature follicle is exposed to LH, it leads to conversion of the granulosa cells of this follicle into theca cells and progresses it toward rupture leading corpus luteal formation. Instead, if an immature follicle that is dominant is exposed to LH, the granulosa cells of this follicle are converted into theca cells, and the follicle is converted into a luteinized unruptured follicle (LUF), which produces progesterone but not as much as corpus luteum; and if a follicle, which is still not dominant, may be only an antral follicle, the follicle undergoes atresia and the theca cells of this follicle also contribute to stroma.

This means a correct time to use the surrogate LH surge (hCG or GnRH agonist) is of utmost importance. And the ultrasound features, which would decide the follicular maturity on the pre-hCG scan, are as follows **(Figs. 8A and B)**:

- Follicular size of at least 18 mm
- Perifollicular vascularity covering three-fourths of the follicular circumference[44]
- Perifollicular RI 0.4–0.48[21] and PSV >10 c/s.[45]

Follicular RI and PSV are more important in decision making than the size of the follicle.[46] Ovarian flow correlates well with oocyte recovery rates and hence may be useful in determining the most appropriate time to administer hCG



Figs. 8A and B: B-mode and Doppler ultrasound parameters of a mature follicle.

to optimize recovery rate. Oocytes from severely hypoxic follicles are associated with high frequency of abnormalities of organization of chromosomes on metaphase spindle and may lead to segregation disorders and catastrophic mosaics in embryo.[47]

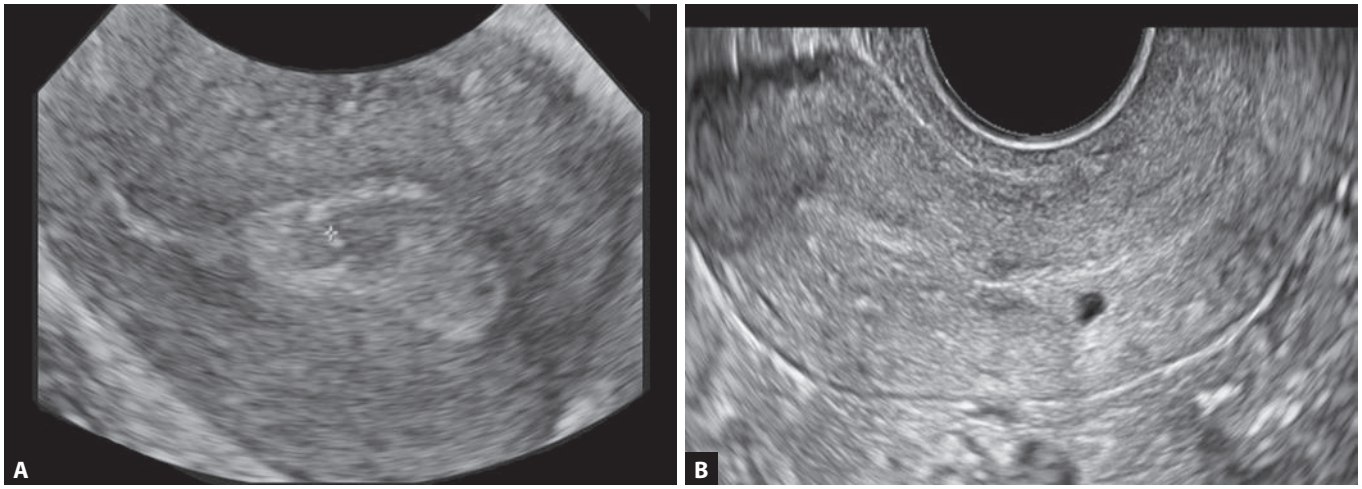
Variation in these parameters may be of help in deciding the time of intrauterine inseminations (IUIs). At the LH surge, the perifollicular PSV is 10 cm/s. According to certain studies, perifollicular PSV goes as high as 45 cm/s before an hour of ovulation[36] under the effect of rising LH. This means that if the follicle is said to be functionally mature when PSV is 10 cm/s, that is the time when the LH surge starts and under the effect of that LH, the perifollicular PSV keeps on rising constantly. Rising PSV with steady low RI suggests that LH surge has already established and the follicle is close to rupture.[37] Steady or decreasing PSV with rising RI suggests that LH surge is either inadequate or has started before the follicle was mature and the follicle is proceeding toward LUF. Therefore, in patients with high pre-hCG perifollicular PSV, early IUI would improve the conception rates.

Preovulatory Findings and Luteinizing Hormone

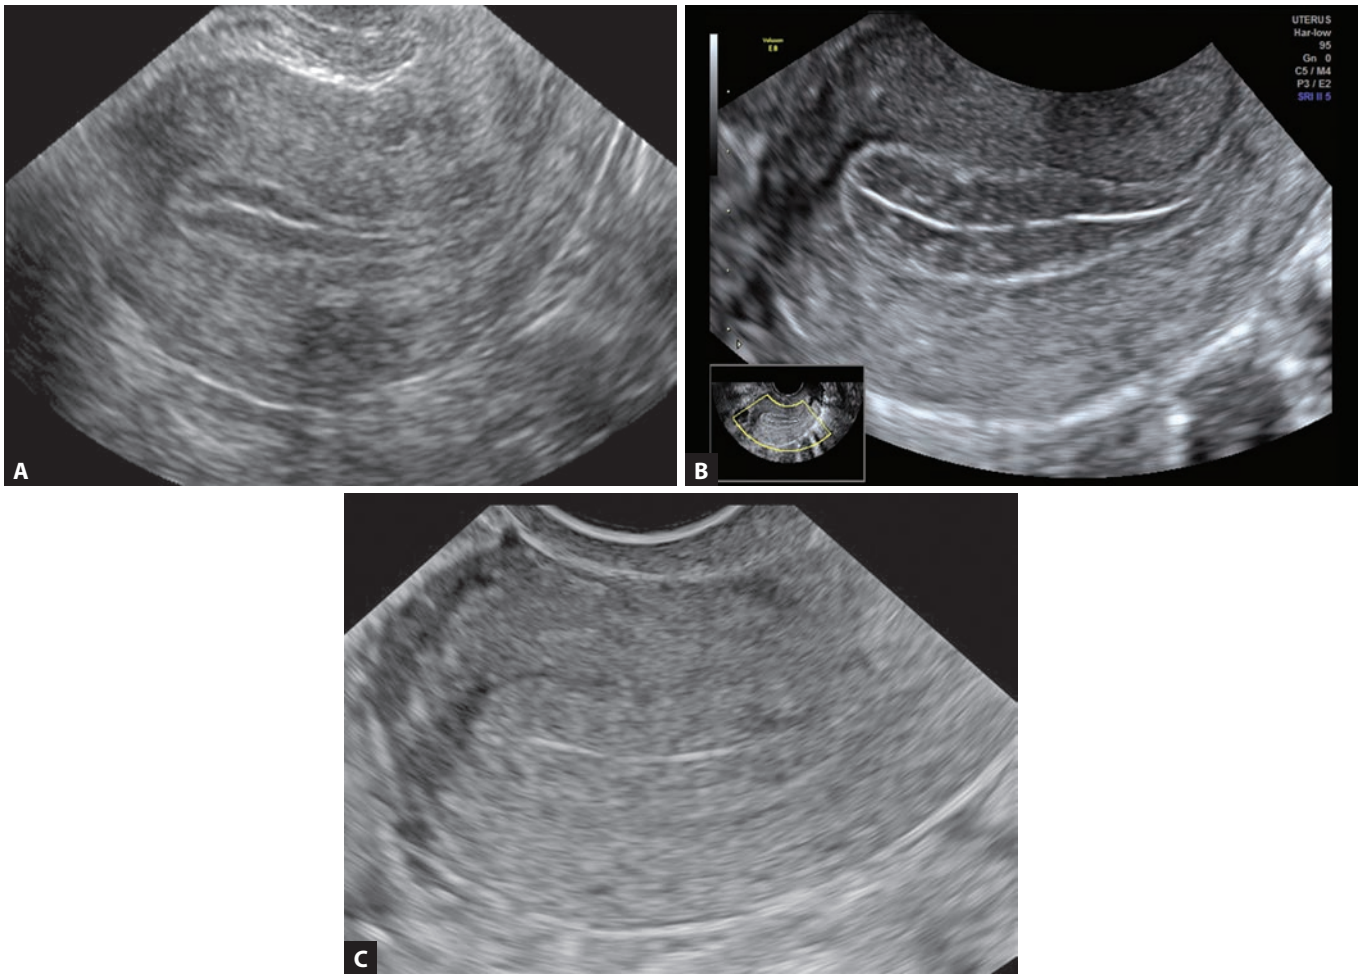
- Fall in perifollicular RI suggests start of LH surge
- Rise in perifollicular PSV suggests fast-rising LH level and impending rupture
- Rising RI with steady or falling PSV suggests falling or inadequate LH levels and therefore is an indicator of follicle proceeding towards LUF.
- Fluffy outer margins of the endometrium.

ESTROGEN AFFECTS ENDOMETRIUM

The pre-hCG perifollicular ultrasound parameters mentioned earlier in this chapter are the parameters of a follicle that is producing sufficient estrogen. Estrogen is produced by the granulosa cells of the follicle, but uterus is the receptor organ for estrogen. Evidently therefore, assessment of the uterus and endometrium should give the clue to adequacy of estrogen levels and in turn of the functional maturity of the follicle. Increasing endometrial thickness and changing endometrial morphology to multilayered correlate with follicular growth and increasing estrogen levels.[48] Endometrium is the receptor organ for both estrogen and progesterone. Following the endometrium can also be a guide to predict estrogen and progesterone dominance. At the baseline scan, the endometrium is thin or the cavity contains blood **(Figs. 9A and B)**, but as the estrogen level starts rising with the growth of the follicle, the endometrium becomes multilayered and starts increasing in thickness. This means that when the patient is on ovulation induction treatment, if the endometrium is growing even when follicle size is not increasing, it means that the estrogen level is increasing that means the stimulation is working. As the estrogen level rises and the multilayered endometrium grows, it changes in morphology. Initially it is grade B (**Fig. 10A**),[48] when it is multilayered with sharp outer margin and hypoanechoic intervening area, then it becomes multilayered with sharp outer margin and the intervening area grade A **(Fig. 10B)**, isoechoic to the myometrium and when the estrogen level rises to supraphysiological levels, the endometrium becomes homogeneous and isoechoic to the myometrium[48]—grade C **(Fig. 10C)**. If the LH surge starts, there is a minimal rise in progesterone even before ovulation. LH rise leads to fluffiness of the outer margin of the endometrium **(Fig. 11)** and when the progesterone exposure starts, the outer margin starts becoming hyperechoic **(Fig. 12)**. This hyperechogenicity progresses from periphery to the central line of the endometrium, to make it completely hyperechoic in the mid-luteal phase **(Fig. 12)**. This means that the fluffy endometrium should normally be found only close to ovulation normally. If it is seen when the follicle is not seen, check for a corpus



Figs. 9A and B: Endometrium during menstruation: (A) Blood in endometrial cavity; (B) Thin endometrium.



Figs. 10A to C: A, B, and C, respectively, are grade B, A, and C endometrium.

luteum in one of the ovaries, and if it is present, this scenario represents a very recent rupture of the follicle.

Cervical mucus **(Fig. 13)** was earlier assessed on postcoital test can now be seen on ultrasound as fluid in cervical canal and this again is the indicator of estrogen levels comparable to a mature follicle.

The vascularity of the endometrium also correlates with the estrogen levels also. There are several reports by different groups[35,39,49] that agree on the fact that implantation rates can be more correlated to the vascularity of the endometrium rather than the thickness and morphology of the endometrium. Endometrial and subendometrial flow increase in the

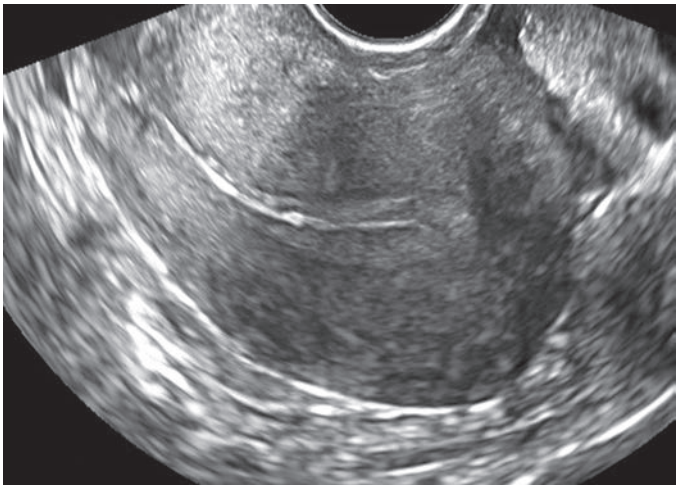


Fig. 11: Fluffy outer margin of the endometrium.

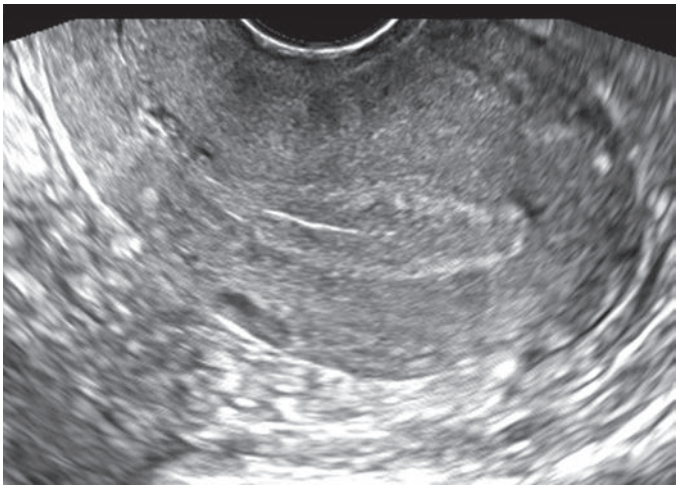

Fig. 12: Hyperechogenicity starting from the outer margin of the endometrium.

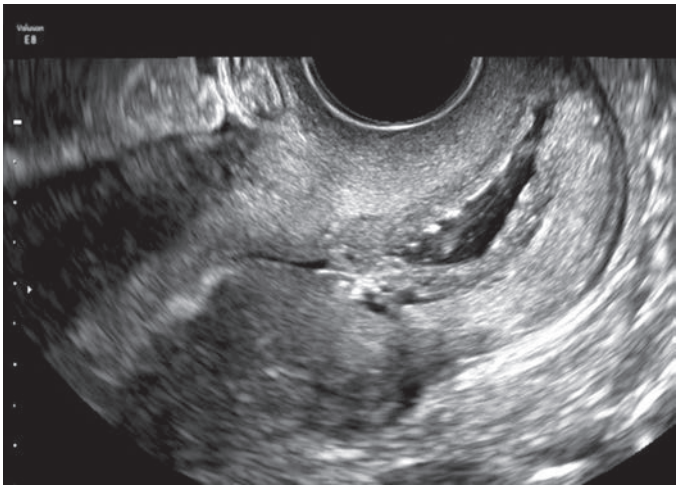

Fig. 13: Cervical mucus.

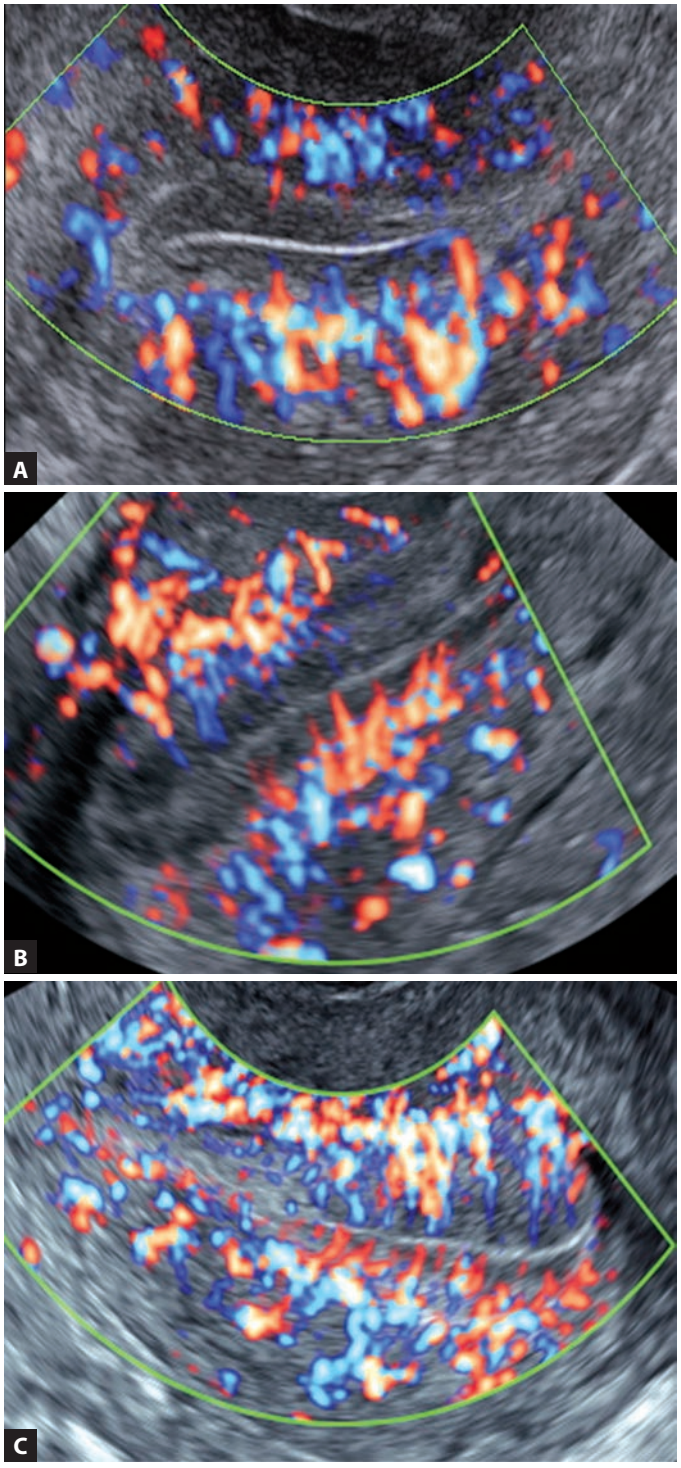

Figs. 14A to C: Endometrial vascularity growing toward the inner layers of endometrium as estrogen increases and the endometrial receptivity improves.

follicular phase and reach its maximum approximately 3 days prior to ovulation **(Figs. 14A to C)**. This is the time when estrogen level starts rising fast for the final peak. The spiral vessels grow toward the endometrium and penetrate the endometrium. Vascularization of the endometrium is very important for pre-hCG evaluation of the endometrium and implantation. Endometrial thickness and vascularity are indicators of estrogen receptors in endometrium.

Spiral arteries are branches of uterine arteries and therefore if the resistance in uterine artery is high, evidently, resistance in spiral arteries is also high, so assessment of the uterine artery resistance may also be a clue to implantation

potential of the endometrium. Just before ovulation, the uterine artery resistance rises due to fall in estrogen. Uterine artery resistance is affected by androgen levels also as discussed earlier, and so in patients with hyperandrogenemia (PCOS), uterine artery resistance remains higher throughout the cycle. This may be one of the reasons for implantation failure or early abortions in patients with PCOS. It has been shown in several studies that when uterine artery PI >3.2, implantation rates are extremely low and ET or IUI should be withheld.[50-52] If the upper limit of cut for uterine artery PI is established at 3–3.3, prediction of nonreceptive uterus has specificity of 96–100%, positive predictive value (PPV) of 88–100%, sensitivity of 13–35%, and negative predictive value (NPV) of 44–56%.[53] As has been discussed earlier, if with the start of the surge, there is increase in perifollicular PSV beyond 10 cm/s and this start of the surge also leads to increased resistance in uterine artery. Both together means that the surge has started but when the follicular PSV is low and the uterine artery resistance is high, it means that the follicle is not yet mature.

SECRETORY PHASE ASSESSMENT

Rupture of the follicle leads to formation of corpus luteum. Corpus luteum is responsible for progesterone production. The functional efficacy of the corpus luteum can be assessed by Doppler by assessing the pericorpus luteal vascularity.

Segmental uterine and ovarian artery perfusion demonstrates a significant correlation with histological and hormonal markers of uterine receptivity and may aid assessment of luteal phase defect.[54] A clear correlation between RI of corpus luteum and plasma progesterone levels has been seen in natural cycle. RI of the corpus luteum can therefore be used as an adjunct to plasma progesterone assay as an index of luteal function.[55] A corpus luteum that is functionally normal and produces adequate amount of progesterone shows corpus luteal flow—RI 0.35–0.50 and PSV 10–15 **(Fig. 15)**.

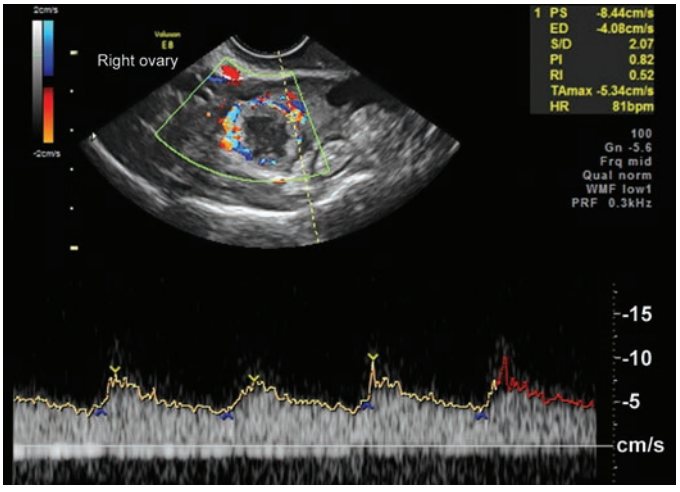

Fig. 15: Normal corpus luteal flow.

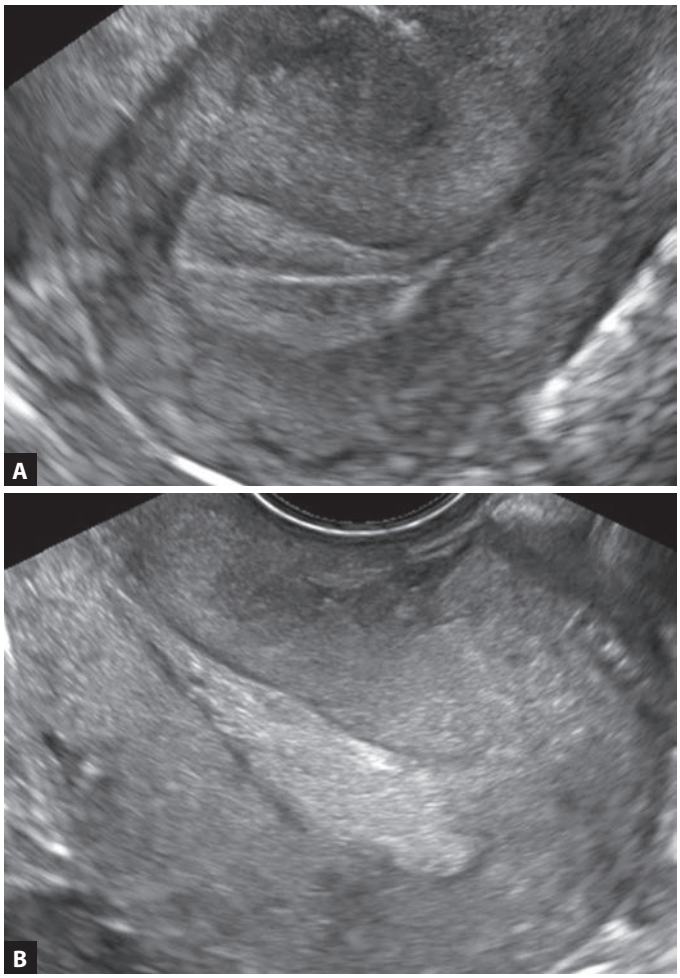
The receptor organ for progesterone also (like estrogen) is endometrium and its vascular studies can be a reliable clue to adequate progesterone production. Endometrial also becomes hyperechoic in the mid-luteal phase **(Figs. 16A and B)** as a result of progesterone exposure. With adequate progesterone levels that are achieved in the mid-luteal phase, the spiral arteries show RI 0.48–0.52 (low-resistance flow) **(Fig. 17)** and uterine artery shows PI of 2.0–2.5. This PI is lower than in the preovulatory phase because of smooth muscle relaxing effect of progesterone. Inadequate progesterone production and therefore corpus luteal inadequacy is suggested by high resistance flow in corpus luteal vessels.[55] Whereas, high spiral artery resistance would suggest inadequate response of endometrium to progesterone. This is because of inadequate progesterone receptors in the endometrium or because of local endometrial cause, like endometrial injury or chronic endometritis.

In luteal phase defect, because of low-progesterone levels, the resistance in the pericorpus luteal vessels is high. Because of low-progesterone levels, there is inadequate relaxation of the muscularis of the uterine artery and therefore the uterine artery resistance is high along with higher resistance in its branches—the spiral vessels.



Figs. 16A and B: Secretory endometrium on B mode as it progresses from early luteal to late luteal phase.

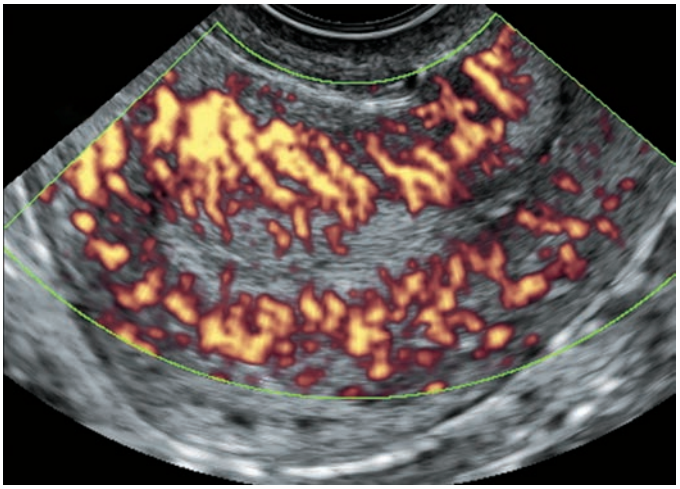


Fig. 17: Endometrial vascularity in mid-luteal phase.

TABLE 2: Corpus luteal flow and spiral artery flow in normal cycle and luteal phase defect (LPD).

	Normal	***LPD***
Perifollicular	0.56 ± 0.06	0.58 ± 0.04
LH peak day	0.44 ± 0.04	0.58 ± 0.04
Mid-luteal phase	0.42 ± 0.06	0.58 ± 0.04
Late-luteal phase	0.50 ± 0.04	0.58 ± 0.04
Phase	*Control RI*	*LPD RI*
Periovulatory	0.53 ± 0.04	0.70 ± 0.06
Mid luteal	0.50 ± 0.02	0.72 ± 0.06
Late luteal	0.51 ± 0.04	0.72 ± 0.04

(LH: luteinizing hormone; RI: resistance index)

Corpus luteal flow and spiral artery flow in normal cycle and luteal phase defect[55] are described in **Table 2**.

CORRELATION OF PROGESTERONE TO ULTRASOUND FINDINGS

Blurring of outer margin of multilayered endometrium suggests initiation of progesterone secretion. Low-resistance flow in corpus luteum with echogenic endometrium and low-resistance endometrial vascularity in mid-luteal phase suggests normal luteal phase. High-resistance corpus luteal flow suggests corpus luteal inadequacy. High-resistance endometrial flow in mid-luteal phase suggests either inadequate progesterone levels or inadequate progesterone receptors in endometrium.

The entire cycle monitoring can be summarized as:

- *On baseline scan:*
  - Early recruitment of the follicle—increased FSH
  - Increased endometrial thickness—high estrogen or progesterone
  - Increased stromal flow—high LH for a short period
  - Increased stromal echogenicity—high LH and anovulation
  - More antral follicles—high androgen
  - High-uterine artery resistance—high androgen
- *Pre-hCG scan:*
  - Good perifollicular flow—good estrogen production
  - Good endometrium with good endometrial flow, cervical mucus—adequate estrogen receptors in endometrium
  - Fluffy endometrial margins—early exposure to progesterone
  - Increasing echogenicity of the follicle wall and increased RI—premature LH surge
- *Luteal phase:*
  - Low-corpus luteal RI—normal progesterone production
  - High-endometrial vascularity—adequate progesterone receptors
  - Low-corpus luteal vascularity—luteal phase defect
  - Low-endometrial vascularity—inadequate progesterone or inadequate progesterone receptors.

CONCLUSION

Ultrasound is the modality of choice to monitor natural or stimulated cycle and understand the hormonal changes. High Androgen leads to more antral follicle cound and raised uterine artery resistance. AMH also can be correlated to AFC. Early recruitment of the follicle represents early fpllicle recruitement, high LH on baseline scan can be diagnosed by increase stromal vascularity and increased stromal vascularity. More antral follicles lead to high oestrogen and also as increased endometrial thickness with multilayered endometrium. High Progesterone also present as thick endometrium but is hyperechoic and the source is residual active.

Adequate oestrogen level and start of the LH surge can be diagnosed by follicular vascularity and its bioeffect can be judged by follicular and endometrial morphology and doppler assessment.It can also judge the approximate time of ovulation that helps to decide the time of IUI. Luteal phase scan can diagnose corpus luteal and endometrial abnormaliites to progesterone.

KEY POINTS

- Ultrasound is an excellent tool for assessment of the menstrual cycle.
- Hormonal changes occurring day-to-day during the menstrual cycle reflects as morphological and vascular changes in the ovary and the uterus.
- Assessing these changes by transvaginal ultrasound and Doppler and correctly interpreting can explain the hormonal basis of these changes.
- Ultrasound with Doppler can thus be used as the only modality for cycle assessment in patients undergoing assisted reproduction technology and may be of help to reduce the cost of the cycle by avoiding certain hormonal

assessments and still maintaining close and accurate watch on the hormonal changes occurring during treatment cycle.

CHAPTER 38

Transvaginal Ultrasound and Doppler in Infertility

Sonal Panchal, Chaitanya Nagori

INTRODUCTION

Transvaginal ultrasound (US) is a modality of choice for assessment of female genital tract and management of infertile female. Doppler further increases its value as it assesses vascular changes which are representatives of hormonal changes occurring throughout the menstrual cycle.

Applications of transvaginal US and Doppler in an infertile female can be divided under two main headings:

1. Diagnosis of abnormalities causing subfertility
2. Cycle assessment.

DIAGNOSIS OF ABNORMALITIES CAUSING SUBFERTILITY

- *Uterine abnormalities:* Congenital and acquired
- Ovarian abnormalities
- Tubal lesions.

Uterine Abnormalities

Congenital Uterine Abnormalities

Incidence of congenital uterine abnormalities is 0.1–3.8% in normal fertile females but reaches 6.7% in infertile patients.[1]

Sensitivity and specificity of various US methods for diagnosis of congenital uterine abnormalities have been given in **Table 1**.[2]

TABLE 1: Sensitivity and specificity of various ultrasound (US) methods for diagnosis of congenital uterine abnormalities.

Ultrasound	*Sensitivity (%)*	*Specificity (%)*
TVS	95.21	92.21
TVCD PD	99.29	97.23
Volume US	98.38	100
Sonohysterography	98.18	100

(PD: power Doppler; TVCD: transvaginal color Doppler; TVS: transvaginal sonography)

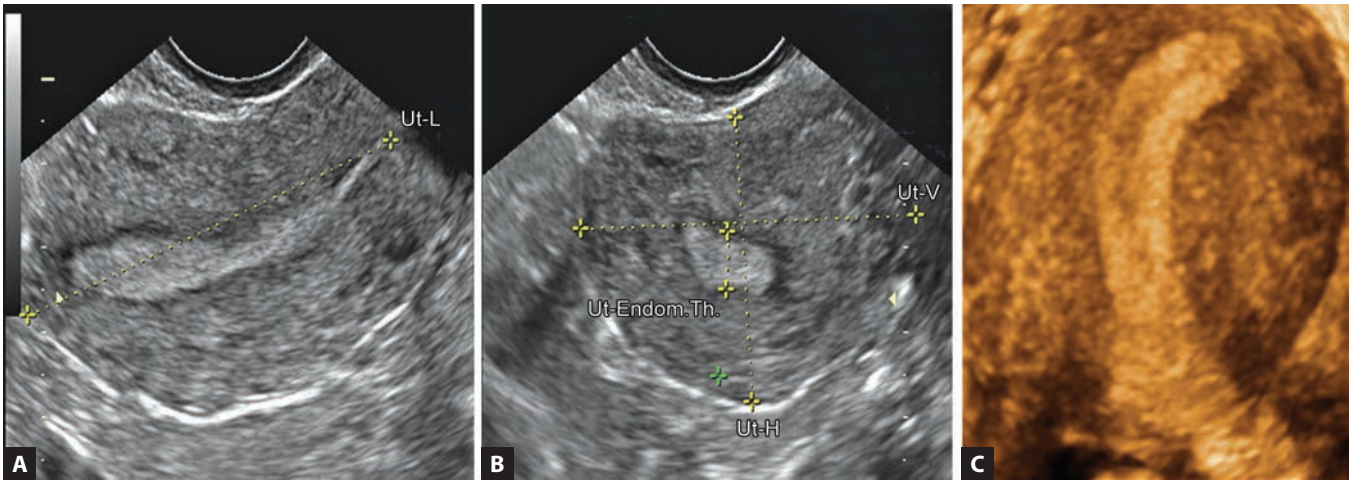
Uterine aplasia: It is suspected in patients with primary amenorrhea. Transabdominal scan with full bladder shows convex base with no dimple. This indicates complete absence of uterus and karyotyping is essential in these patients.

If rudimentary horns or uterus is seen anywhere in pelvis, it is not uterine aplasia, but is hypoplastic uterus. It is identified by pear-shaped isoechoic structure with or without thin echogenic line in the center. Ovaries may be seen in close vicinity to these horns.

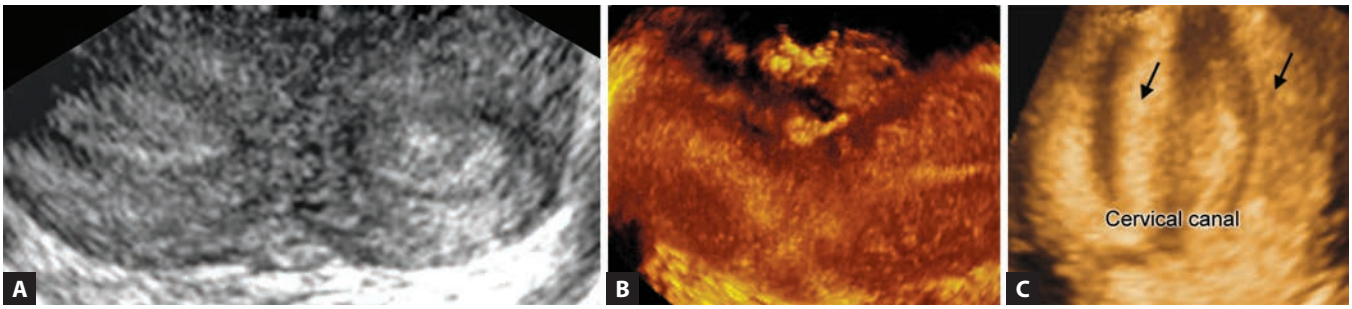
Unicornuate uterus [the American Fertility Society (AFS) classification]:[3] Aplasia or severe hypoplasia of one of the Müllerian ducts leads to unicornuate uterus. When hypoplastic horn is present it may or may not communicate with the other horn. On transvaginal sonography (TVS), in most of the cases, uterus is not seen in midline, but a normal looking long axis of uterus is seen on one side in the pelvis. No uterine shadow or a rudimentary horn is seen on other side. Rudimentary or severely hypoplastic horn is seen as an isoechoic pear-shaped structure with or without a central thin echogenic endometrial line. Ovary is seen near the respective horn.

On transverse scan at the level of uterine fundus a beak-like projection from the endometrial shadow—cornu is seen only on one side. Three-dimensional (3D) US is ultimate and clearly shows a banana-shaped uterine cavity **(Figs. 1A to C)**. According to the European Society of Human Reproduction and Embryology (ESHRE)-the European Society for Gynecological Endoscopy (ESGE)[4] classification, this is called hemiuterus.

Duplication abnormalities: Differential diagnosis of these abnormalities is important as management and prognosis as far as fertility is concerned vary with different conditions. Uterus didelphys, bicornuate uterus, septate uterus, and arcuate uterus are the grades of duplication abnormalities from the most severe one to the least severe one according to AFS classification for Müllerian duct abnormalities. Uterus didelphys and bicornuate are similar to bicorporeal uterus



Figs. 1A to C: Unicornuate uterus: (A) Long axis two-dimensional (2D) ultrasound (US); (B) Transverse 2D US; (C) Three-dimensional (3D) US.



Figs. 2A to C: (A) Transverse section duplication abnormality; (B) Uterus didelphys; (C) Two separate corpus uteri and two cervices (arrows).

on ESHRE-ESGE classification and arcuate uterus, this entity does not exist in this classification.

Uterus didelphys: Uterus didelphys has two separate uteri and two cervices **(Figs. 2A to C)**. Two separate vaginas may be seen on per speculum examination. It has best prognosis of all malformations—fetal survival of 64%. Premature deliveries are common.

On US both cornu of uteri may be closely placed in the center of pelvic cavity and look like any duplication abnormality on transverse section, or may be placed far lateral on the lateral pelvic walls and look like unicornuate uterus one on each side. Two horns may show symmetrical or asymmetrical development. Always look for the ovaries in vicinity of the uterus.

Bicornuate uterus: On B-mode on transverse section tracing the uterus from the cervix to the fundus will show widening and division of the endometrial cavity toward fundus, with indentation on the fundus, looking like a figure of eight.

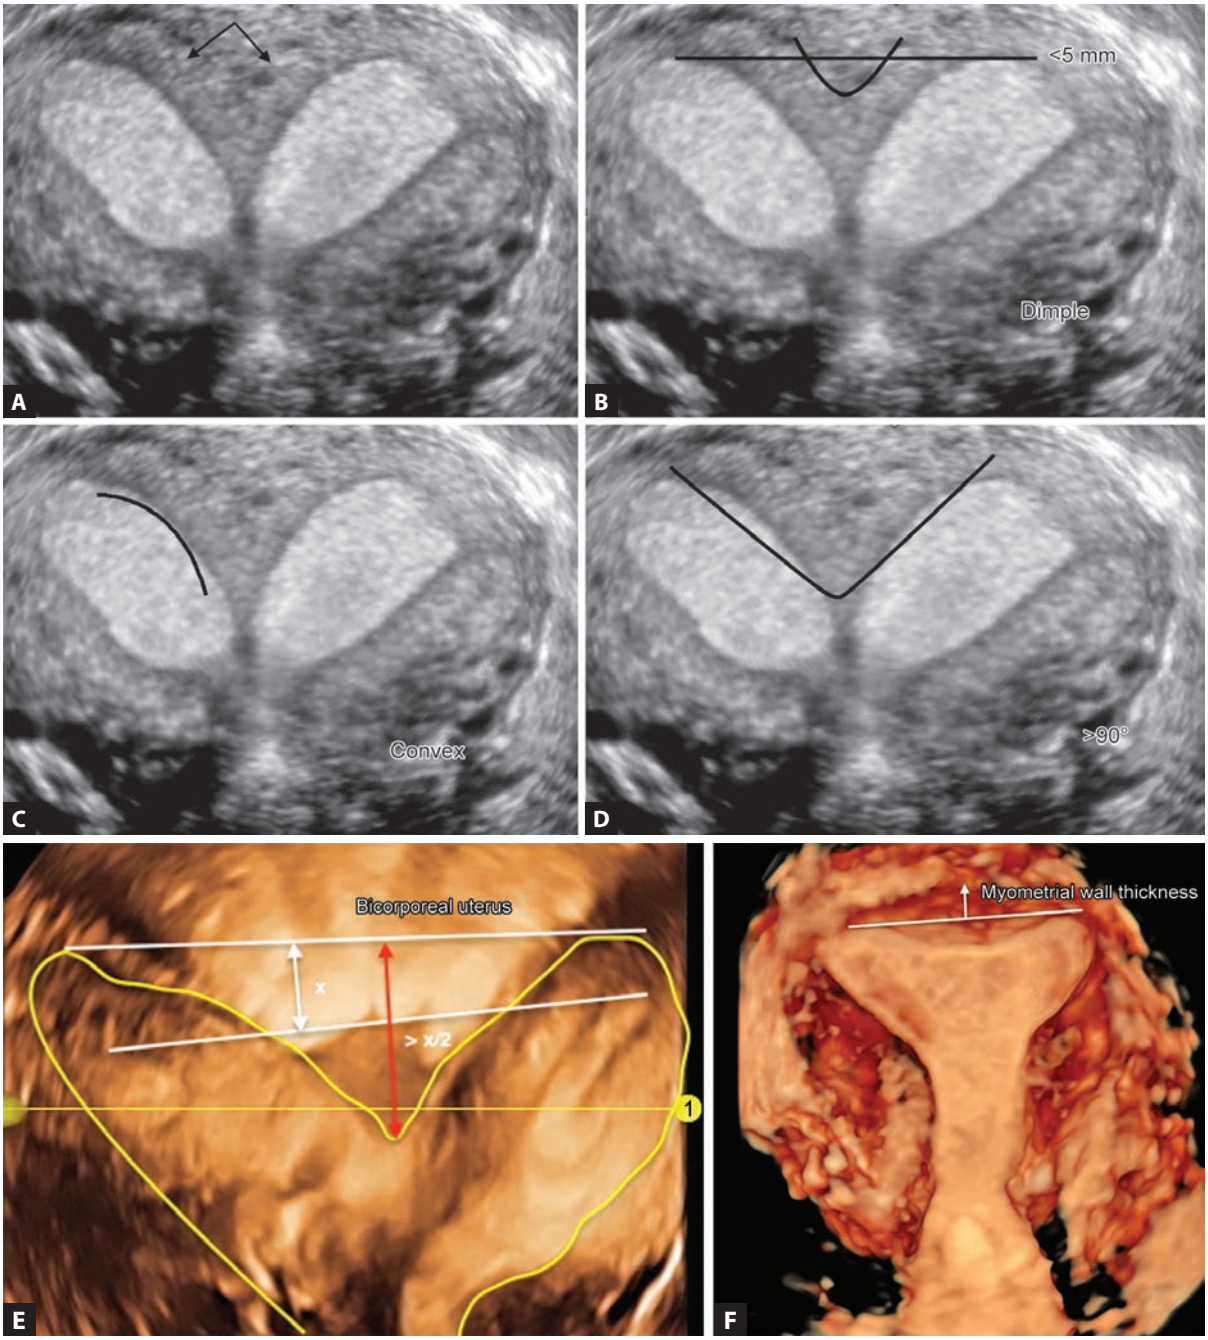
On color Doppler, blood vessels are seen in between the two endometrial cavities and have same resistance index (RI) as myometrium, between 0.58 and 0.84. The uterine arteries on two sides may or may not show a difference in RIs depending on the amount of unification.

Volume US has a very important role to play in the diagnosis of bicornuate uterus as it shows uterus in coronal view. According to AFS classification:

- Fundus of the uterus shows a dimple **(Fig. 3A)**.
- If a straight line is drawn joining the top of the endometrial cavities, the fundus dimple is <5 mm above this line **(Fig. 3B)**.
- Endometrial cavities appear convex medially, meaning they are leaf-shaped **(Fig. 3C)**.[5]
- Angle between the two cavities is >90° **(Fig. 3D)**.
- One more feature seen on 3D US is that myometrial layers can be seen dipping in between the endometrial cavities **(Fig. 3A, arrows)**.

According to ESHRE-ESGE classification a bicorporeal uterus is identified by: Fundal notch, the depth of which is >50% of the myometrial wall thickness with endometrial division **(Fig. 3E)**. Myometrial wall thickness is the longest vertical distance between the intercornual line to the highest point of the myometrium **(Fig. 3F)**.

Septate-subseptate uterus: A septum of the uterus is complete only when it divides the whole uterine cavity up to internal os **(Fig. 4A)** and then it is septate uterus. All other septa are incomplete and the uterus is subseptate.

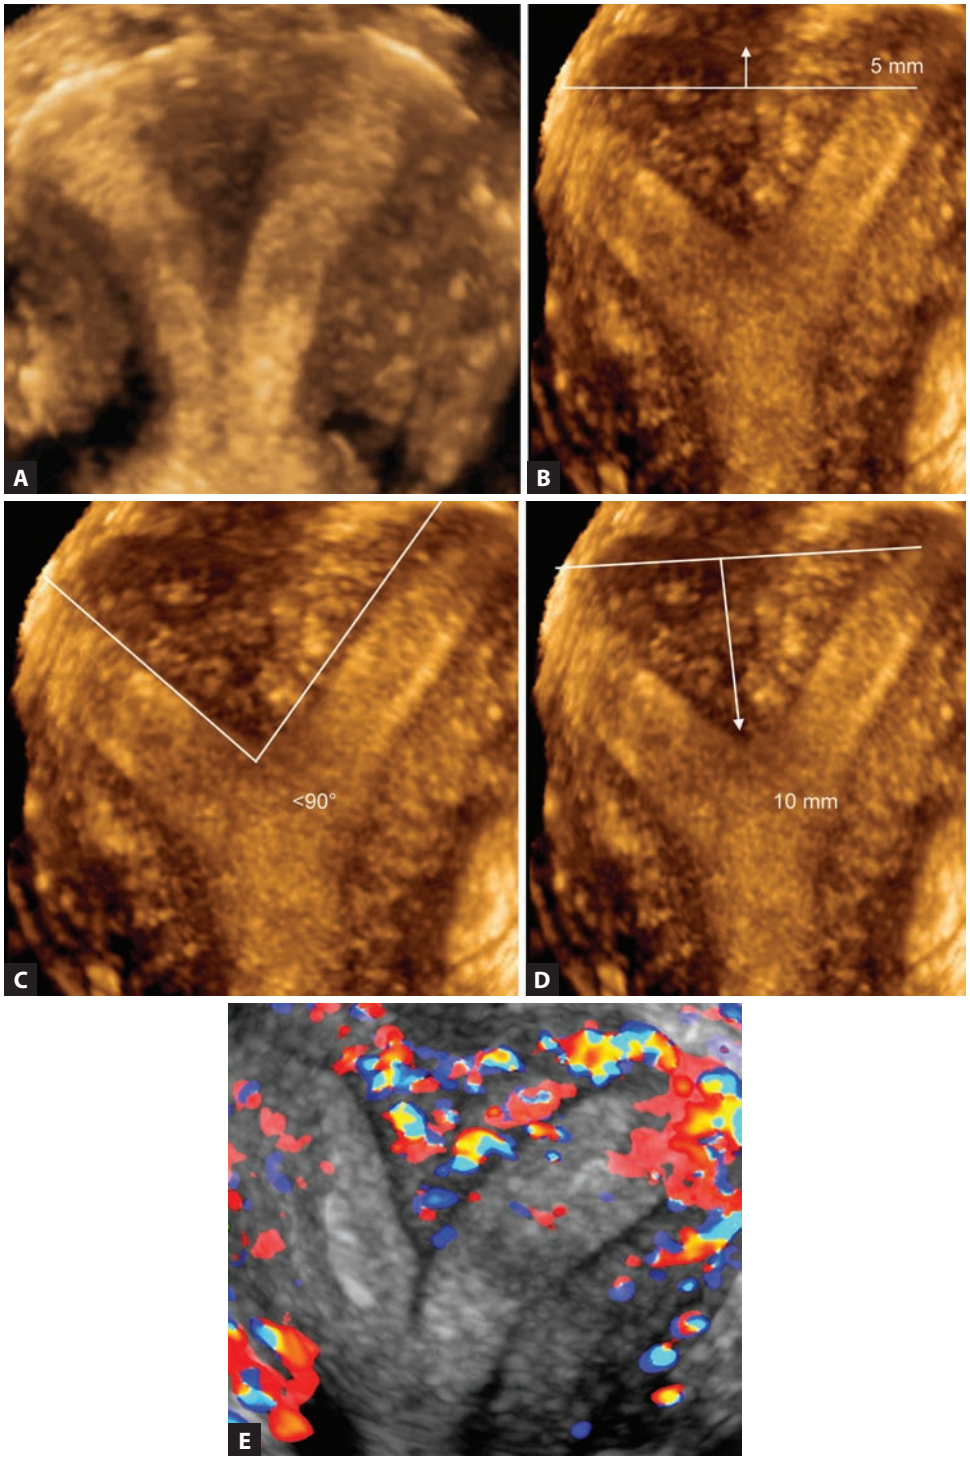


Figs. 3A to F: (A to D) Three-dimensional (3D) ultrasound (US) of bicornuate uterus; (E) Bicorporeal uterus; (F) Measuring myometrial wall thickness.

On B-mode, it is difficult to differentiate between duplication abnormalities of uterus, viz. bicornuate, septate/subseptate, and arcuate. But 3D US is conclusive. Preovulatory or secretory phase are the best phases to diagnose congenital uterine abnormalities especially on 3D US. Sonohysterography and 3D US have 100% sensitivity for diagnosis of septate/subseptate, bicornuate, and arcuate uterus.

Ultrasound features:

- No/minimal indentation on the fundus **(Fig. 4A)**
- At least 5 mm of uterine wall can be seen above the line joining tips of two endometrial cavities **(Fig. 4B)**
- The distance between this line and deepest point between endometrial cavities is >10 mm **(Fig. 4D)**
- Angle between cavities is <90° **(Fig. 4C)**
- Medial margins of the endometrial cavities are more often straight **(Fig. 4C)**
- It has been described in several studies that septa are avascular. But there are controversies regarding this. Vascularity may be seen in 71.22% of septae with RI between 0.68 and 1.00 (0.84) **(Fig. 4E)**.[6]

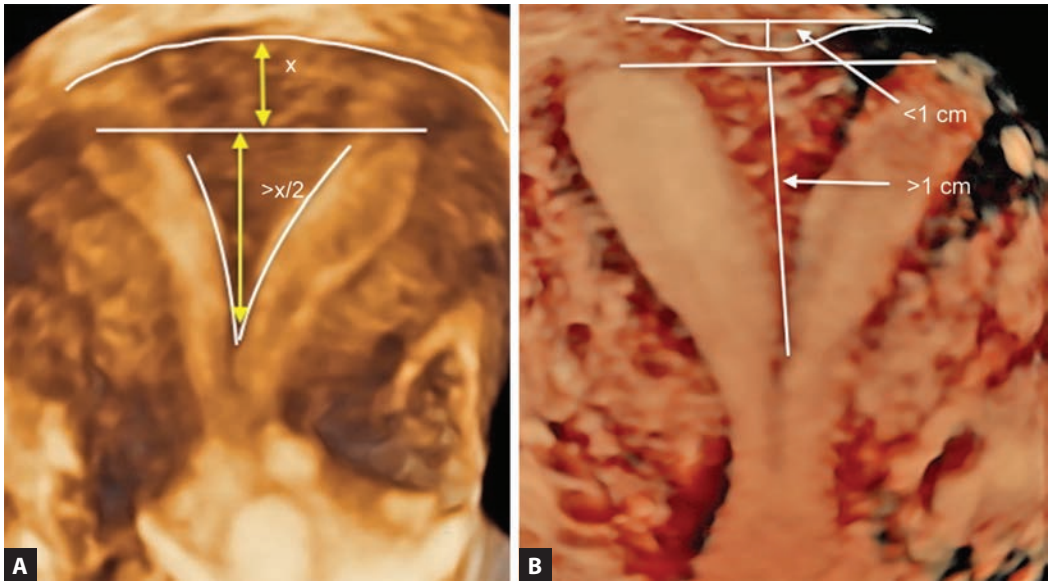


Figs. 4A to E: Septate uterus. (A) Complete septum; (B) Partial septum; (C) Bicornuate uterus with measurement of angle between two horns; (D) Bicornuate uterus with the perpendicular line drawn from the level of cornua to the fundus; (E) Vascularity in septum seen on 3D power Doppler.

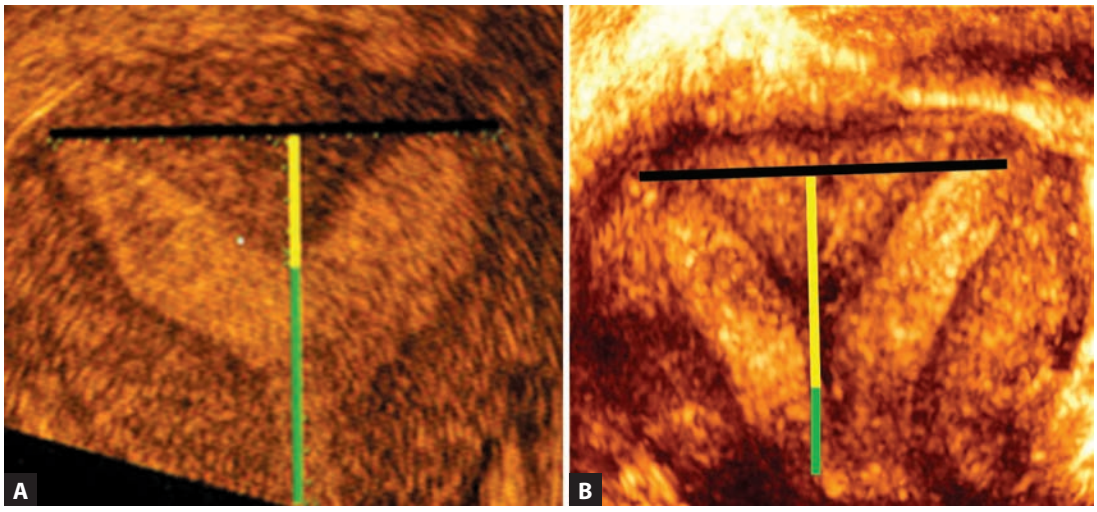
According to ESHRE-ESGE classification a septate uterus is identified by:

- Fundal dip, if present, its depth is <50% of the myometrial wall thickness.
- Depth of the endometrial dip is >50% of the myometrial wall thickness **(Fig. 5A)**.
- There is still a third definition according to CUME (congenital uterine malformation by experts)[7] classification. According to this, a fundal notch if present of <1 cm and an endometrial notch of >1 cm is a septate uterus **(Fig. 5B)**.

Size of septum and implications: It was thought that if the septum divides at least two-thirds of the endometrial cavity **(Figs. 6A and B)**, it was more likely to cause complications but studies have shown that there is no correlation between the septal height and thickness and the incidence of abortions.[6] But still there are other studies that show that whether septate or arcuate uterus, the length of



Figs. 5A and B: (A) Septate uterus [European Society of Human Reproduction and Embryology (ESHRE)-(European Society for Gynecological Endoscopy (ESGE)]; (B) Septate uterus: CUME (Congenital Uterine Malformation by Experts) classification.



Figs. 6A and B: (A) Septum dividing one-third endometrial cavity; (B) Septum dividing two-thirds endometrial cavity.

remaining uterine was significantly shorter and distortion ratio was significantly higher in patients with recurrent miscarriage.[8]

Pitfalls in US-based differential diagnosis: The reliability of color and pulse Doppler for diagnosis of septum is reduced if there is another intracavitary lesion like polyp or submucous leiomyoma or fundal fibroid. Small uterine cavity due to adhesions, shadowing due to fibroids, may affect 3D US diagnosis.

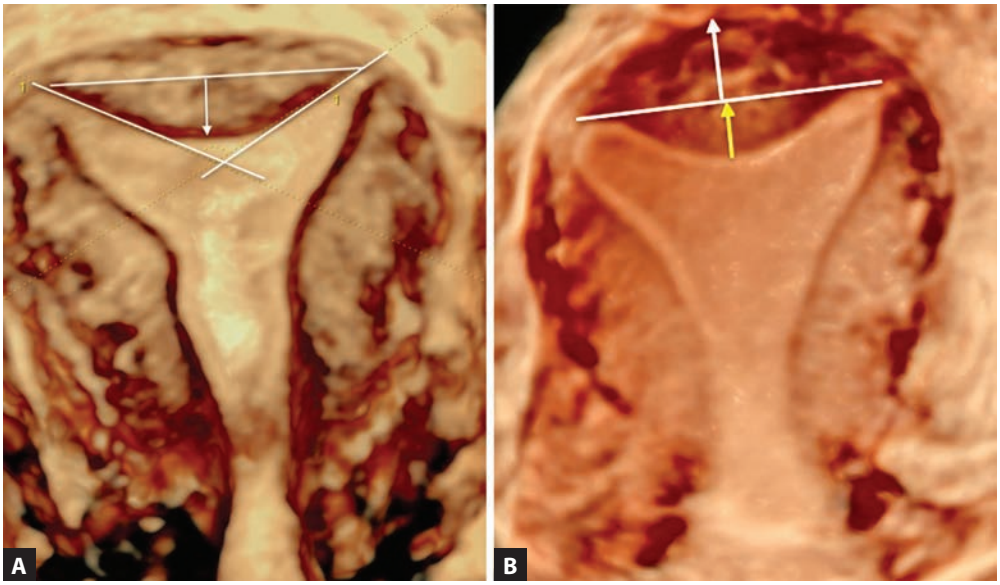
Arcuate uterus: It can be diagnosed on coronal section.

- On 3D US, endometrial cavity is concave at fundus **(Fig. 7A)**.
- External fundal contour is flat or convex **(Fig. 7A).**
- Distance between line touching the tips of cornu and the deepest point between the endometrial cavities is <10 mm **(Fig. 7A)**.
- Angle between the cavities is >90° **(Fig. 7A)**.

Differential diagnosis of duplication abnormalities of uterus (bicornuate uterus vs. septate uterus vs. arcuate uterus) has been discussed in **Table 2**. According to ESHRE-ESGE classification, depth of the endometrial cavity notch of <50% of myometrial wall thickness till fits into a normal uterine shape **(Fig. 7B)**.

Hypoplastic uterus: Uterine body to cervix ratio is 2:1 in adults but in hypoplastic uterus, it is infantile type, i.e., uterus:cervix = 1:1. The 3D US shows a very small uterine cavity with long cervix.

T-shaped uterus: Though rarely seen now, this uterus was earlier seen due to diethylstilbestrol (DES) toxicity **(Fig. 8A)**. A narrow endometrial cavity is usually documented as T shaped uterus. But according to ESHRE-ESGE classification, a uterus with normal uterocervical ratio with increased lateral wall thickness is a T-shaped uterus. Increased lateral wall thickness is documented by drawing a line from cornu



Figs. 7A and B: (A) Three-dimensional (3D) ultrasound (US) of arcuate uterus; (B) ESHRE (European Society of Human Reproduction and Embryology)-ESGE (European Society for Gynecological Endoscopy) classification, normal uterus with concave endometrial contour.

TABLE 2: Differential diagnosis of duplication abnormalities of uterus.

Characteristics	***Bicornuate***	***Septate/ subseptate***	***Arcuate***
External contour	Concave	Flat/convex	Flat/convex
Fundus tip to intercornual line distance	<5 mm	>5 mm	>5 mm
Angle	>90°	<90°	>90°
Endo. intercornual line to endometrial pit distance	—	>10 mm	<10 mm
Medial endo. shape	Convex	Flat	Flat
Myometrial dipping	Present	Absent	—

to internal os. Draw a perpendicular on this line from the deepest point on the lateral endometrial wall. The lateral part of this later line measures the lateral wall thickness. If it is >1.4 times the myometrial wall thickness, it is a T-shaped uterus **(Fig. 8B)**.

The definition of T-shaped uterus by CUME classification is much more simple to understand and use. If the cornual angle of endometrial cavity is <40°, the outer lateral angle is >130° and the distance from the deepest point on the lateral wall of the endometrium to the line joining cornu to internal os is >7 mm, it is a T-shaped uterus **(Fig. 8C)**.

Though it is very immature at this stage to commit, which of these classification systems is best or most accurate. In spite of the fact that there are studies that have claimed that ESHRE-ESGE is a better classification system, there are studies that have also mentioned that this system overdiagnoses septate uterus.

Congenital uterine abnormalities are commonly associated with congenital renal abnormalities like ectopic kidney or unilateral absent kidney. Therefore, an abdominal scan is essential in all patients with congenital uterine malformations.

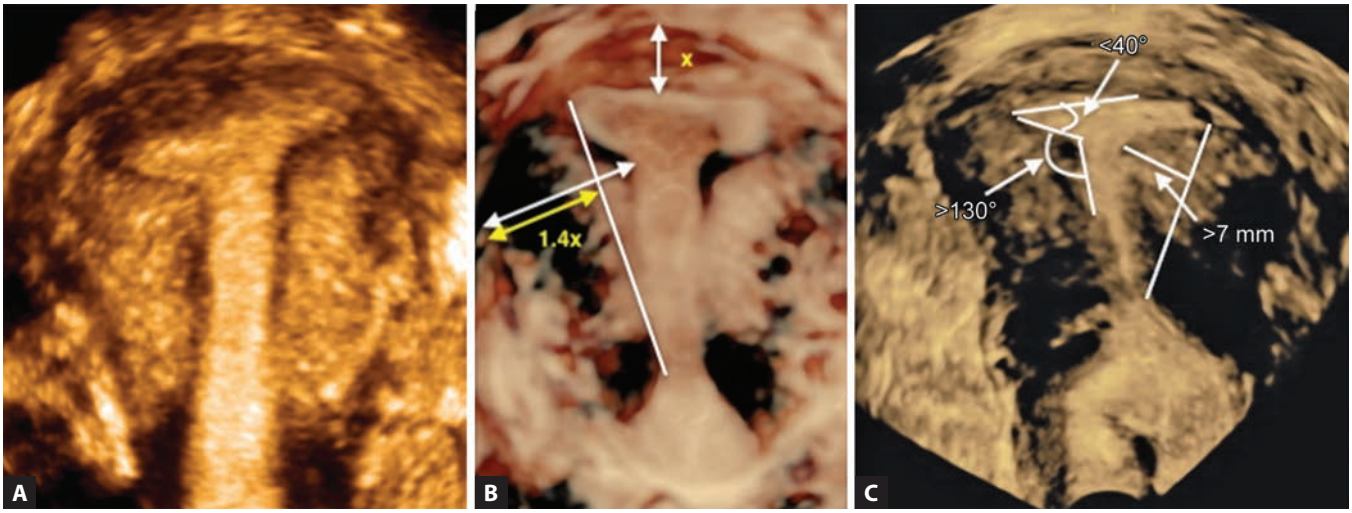
Acquired Uterine Abnormalities

- Myometrial lesions
- Endometrial lesions
- Cervical lesions.

Myometrium: It is normally homogeneously hypoechoic and serosal surface is smooth and regular. Distortion in any of these two suggests myometrial lesion. Myometrial lesions most often seen are fibroids, adenomyosis, adenomyomas, and leiomyosarcomas.

Fibroid:[9] Fibroids are found in 20–40%of women from age 30 onward and are more common in nulliparous.

- Well defined, hypoechoic, homogeneous, round/oval/lobular, solid lesions, with peripheral hypoechoic rim due to displacement of myometrial fibers
- May also show whorled appearance
- Typically shows acoustic shadowing at the margins along with alternate hyper and hypoechoic vertical shadows seen posterior to larger lesions, respectively called edge shadows and fan shadows **(Fig. 9A)**
- Echogenicity increases with amount of fibrous tissue and vascularity.
- Calcification may be seen **(Fig. 9B)**.
- Cystic areas are also seen in fibroid-cystic degeneration **(Fig. 9C)**
- Degeneration in fibroids causes heterogenicity of texture.
- Fibroids typically show peripheral vascularity on Doppler **(Fig. 9D)**
- Vascularity increases with degeneration or necrosis. This vascularity is confined to the fibroid only and is called intralesional vascularity.



Figs. 8A and C: (A) Three-dimensional (3D) ultrasound (US) of T-shaped uterus; (B) T-shaped uterus according to the ESHRE (European Society of Human Reproduction and Embryology)-ESGE (European Society for Gynecological Endoscopy) definition; (C) Attributes of T-shaped uterus using CUME classification.

On color Doppler, peripheral vascularity is typical of a fibroid. These vessels are vessels of displaced muscle fibers and therefore show resistance similar to that of myometrium.[10] Resistance is higher in submucosal fibroids and deep intramural fibroids and lower in subserosal fibroids. When degenerated, the fibroids show lower resistance with internal vascularity in addition to the peripheral vascularity. Amount of vascularity decides the activity or growth potential of fibroid. Uteri with fibroids also show higher uterine artery peak velocity and lower RI (mean: 0.74 ± 0.09).

Fibroids are classified according to their location as subserosal, intramural, and submucosal But their penetration is best described according to FIGO classification[11] **(Fig. 10)**.

Volume US: It is a perfect tool to assess the invasion or distortion of endometrial cavity **(Fig. 11A to C)**. 3D power Doppler (PD) indices are especially useful for follow-up of fibroids in patients who are on GnRh-a therapy, menopausal, or pregnant.

Fibroids affect fertility because of:

- Distortion of endometrial cavity due to submucous fibroid.
- Pressure of the fibroid and stretching of endometrium overlying it causing atrophy of endometrial glands and stroma.
- Low flow due to stretching of vessels and less delivery of hormones.

Diffuse leiomyomatosis is a rare condition in which there is diffuse and uniform involvement of entire myometrium by multiple fibroids.

Fibroids are also seen arising from the cervix and show similar appearances as fibroid in the uterus.

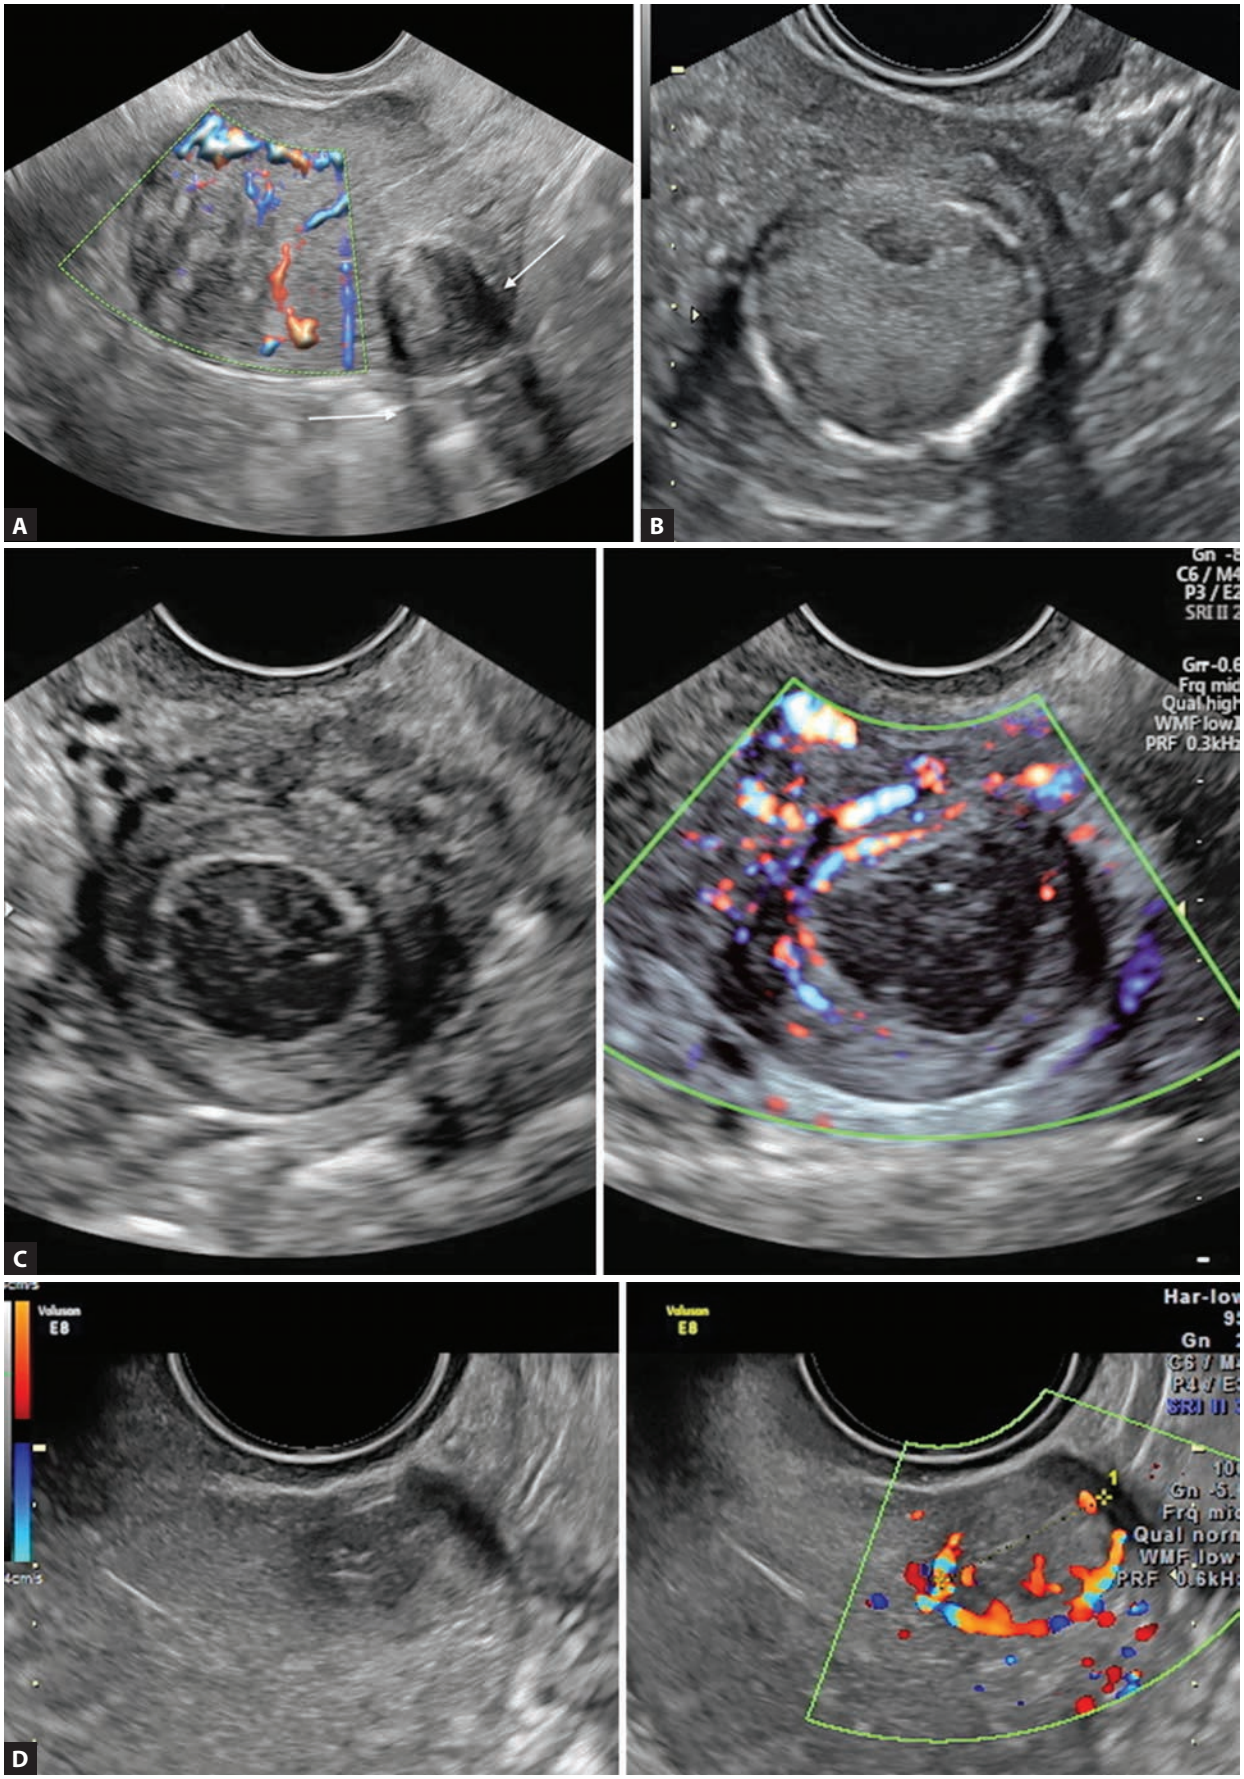
Adenomyosis: Adenomyosis is common in multiparous women.

- It is an invasive lesion and so has indistinct margins.
- It may be generalized involving the whole uterus or localized to one wall or a part of one of the walls. It causes asymmetrical thickening of myometrium.
- It shows heterogeneous echogenicity.
- Pressing the uterus with probe may cause pain.
- Alternate hyperechoic and hypoechoic zones in myometrium are typically described as rain in forest appearance or venetian blind appearance **(Fig. 12A)**. But these are also described as fan shadows.
- Echogenic spots and anechoic areas (myometrial cysts) are commonly seen close to junctional zone **(Fig. 12B)**.
- Typically the myometrium shows alteration in the echogenicity depending on the phase of the menstrual cycle. Isoechoic in the follicular phase and mildly hyperechoic in secretory phase.
- Depending on the severity of the adenomyosis the uterus may or may not appear bulky.

On color Doppler, affected myometrium shows markedly increased vascularity with vascular clumps **(Fig. 12C)**. The normal vascular architecture of spiral arteries is disturbed. Vessels traverse across the lesion-translesional vessels, and have larger diameter than normal spiral vessels.

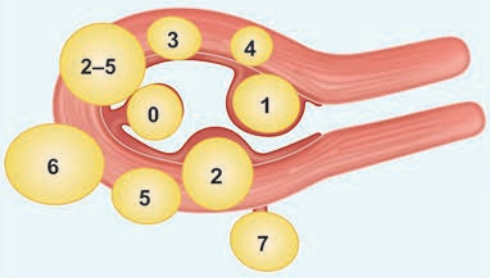
Decreased uterine artery resistance and increased velocity may be seen with large areas of adenomyosis. Though sonohysterography is not a routine investigation for adenomyosis, it shows contrast (negative or positive), percolating into the myometrium.

More difficult situation is the adenomyoma. This is a localized adenomyosis. When seen in the follicular phase, it appears hypoechoic like a fibroid and if fibroid is degenerated it looks like adenomyoma. But like generalized adenomyosis it alters its echogenicity with the phase of the cycle. The main differentiating point between the adenomyoma and the fibroid is the capsular vascularity that is seen in fibroid



Figs. 9Ato D: (A) Fibroid uterus 2D ultrasound (US) with edge shadows; (B) Fibroid with calcification; (C) Cystic degeneration of fibroid; (D) Doppler showing peripheral vascularity of fibroid.

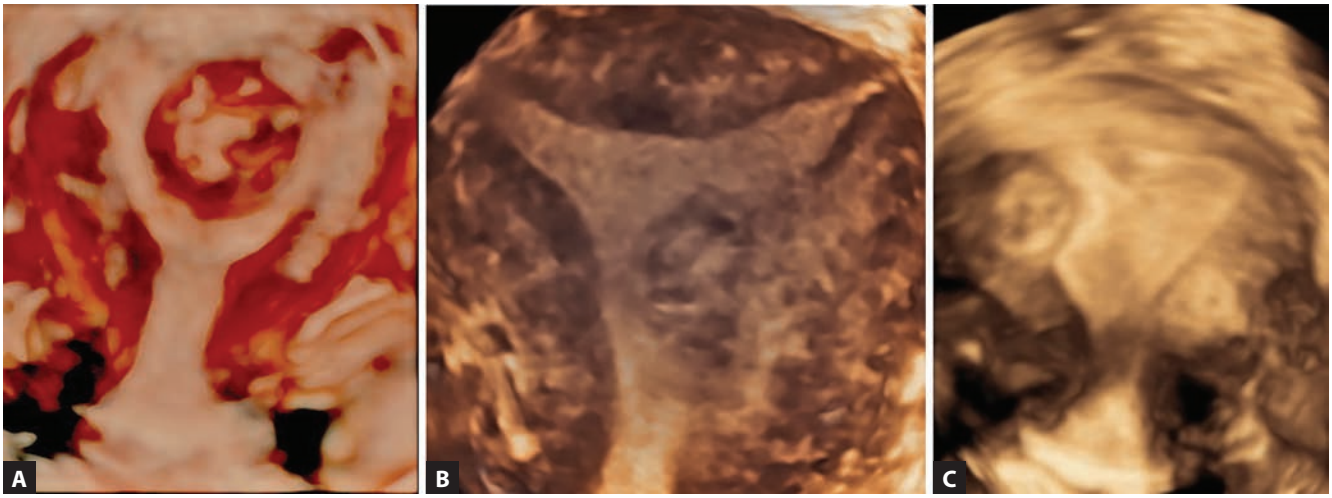
Leiomyoma subclassification system



SM–Submucosal	0	Pedunculated intracavitary
	1	<50% intramural
	2	≥50% intramural
O–Other	3	Contacts endometrium: 100% intramural
	4	Intramural
	5	Subserosal ≥50% intramural
	6	Subserosal <50% intramural
	7	Subserosal pedunculated
	8	Other (specify, e.g., cervical, parasitic)

Hybrid leiomyomas (impact both endometrium and serosa)	Two numbers are listed separated by a hyphen. By convention, the first refers to the relationship with the endometrium while the second refers to the relationship to the serosa. One example is below	
	2–5	Submucosal and subserosal, each with less than half the diameter in the endometrial and peritoneal cavities, respectively

Fig. 10: Leiomyoma subclassification system (FIGO/Palm Coine classiciation).



Figs. 11A to C: (A) Type 0 fibroid; (B) Type 1 fibroid; (C) Type 2 fibroid on 3D ultrasound (US)-rendered images.

but is never seen in adenomyoma. When seen on 3D PD also a vascular fibroid shows circumferentially arranged vessels while in adenomyoma the vascular arrangement is radial or penetrating **(Figs. 12D and 13)**. Endometrial strands extending into myometrium are also seen on 3D US **(Fig. 12E)**. Adenomyoma does not show edge shadow.

Endometrium: It is normally pear shaped and has an intact endometriomyometrial junction (junctional zone) **(Fig. 14A)**. Distortion of endometrial contour and disruption of junctional zone are signs of endometrial pathologies.

Common endometrial pathologies are endometritis, polyps, endometrial hyperplasia, endometrial malignancies, synechiae, and other miscellaneous conditions with residual products of conception in endometrial cavity.

- *Endometritis:* Acute endometritis presents as thick, isoechoic endometrium with disruption of junctional zone **(Fig. 14B)**, minimal fluid in endometrial cavity and increased vascularity, even in early follicular phase.

  Chronic endometritis presents as persistently thin avascular/severely hypovascularized endometrium with disrupted junctional zone. Calcified pelvic lymph nodes or calcified spots in the adnexa are also seen in chronic inflammatory lesions. Tuberculosis is one of the common causes of chronic endometritis, especially in developing countries. Though US is not diagnostic of tuberculous endometritis, but shows certain signs that may raise a suspicion of tuberculous pathology. These are persistently thin endometrium, irregular junctional zone,

fluid in the endometrial cavity with hyperechoic inner margin, micropolyps, vertical orientation of interstitial part of the tube endometrial synechiae, contracted T-shaped endometrial cavity, myometrial cysts with no peripheral vascularity, endometrial, subendometrial, and myometrial calcifications **(Figs. 14C to F)**.

- *Endometrial hyperplasia:* This is a localized overgrowth of endometrium with normal histology, presenting as thick echogenic endometrium, in part or entirely. Endometrial thickness >14 mm in premenopausal patient and <5 mm in postmenopausal patients is hypertrophic. But endometrium thicker than this cut off is often seen

patients on fertility treatment. As long as the morphology is normal, it may be considered normal according to our experience based opinion. Endometriomyometrial junction is well maintained. On color Doppler, it shows regularly placed vessels supplying it with normal branching pattern **(Figs. 15A and B)** and mean RI of 0.55 ± 0.05.

- *Polyps:* Endometrial polyps are projectile solid lesions from the endometrial walls into the endometrial cavity.

Sonographically, they are seen as solid echogenic lesions in the endometrial cavity **(Figs. 16A and B)**. Smaller lesions are easier to diagnose but larger lesions fill up the cavity and look like generalized endometrial thickening but color Doppler helps for differentiation.

On two-dimensional (2D) US, the polyps are best visible in periovulatory phase or in menstrual phase when there is fluid in endometrial cavity. On Doppler, polyp shows a single feeding vessel **(Fig. 16C)** or maximum two vessels very closely placed (pedicular vessels). Infection, necrosis, or atypia may show very low resistance. Vascular pattern has a high accuracy for differential diagnosis of endometrial lesions. Single-vessel pattern for polyp has been presented in **Table 3**.[12]

Polyps may arise in the cervix or may prolapse into cervix if these have long pedicle.

Endometrial fibroids are hypoechoic, well demonstrated in echogenic endometrium of secretory phase and have peripheral vascularity, typical of fibroids **(Figs. 17A to C)**. Rim-like vessel pattern for fibroids has been presented in **Table 4**.[12]

- *Synechiae:* When the endometrium is triple line or the cavity is distended with the fluid, synechiae are seen as lines bridging between layers of endometrium **(Figs. 18A to C)**. On 3D US, it helps in exact assessment of restriction of cavity **(Fig. 18B)** in case of bridging adhesions.

Sonohysterography has 100% sensitivity for the differentiation of all endometrial pathologies **(Fig. 18C)**.

TABLE 3: Single-vessel pattern for polyp.

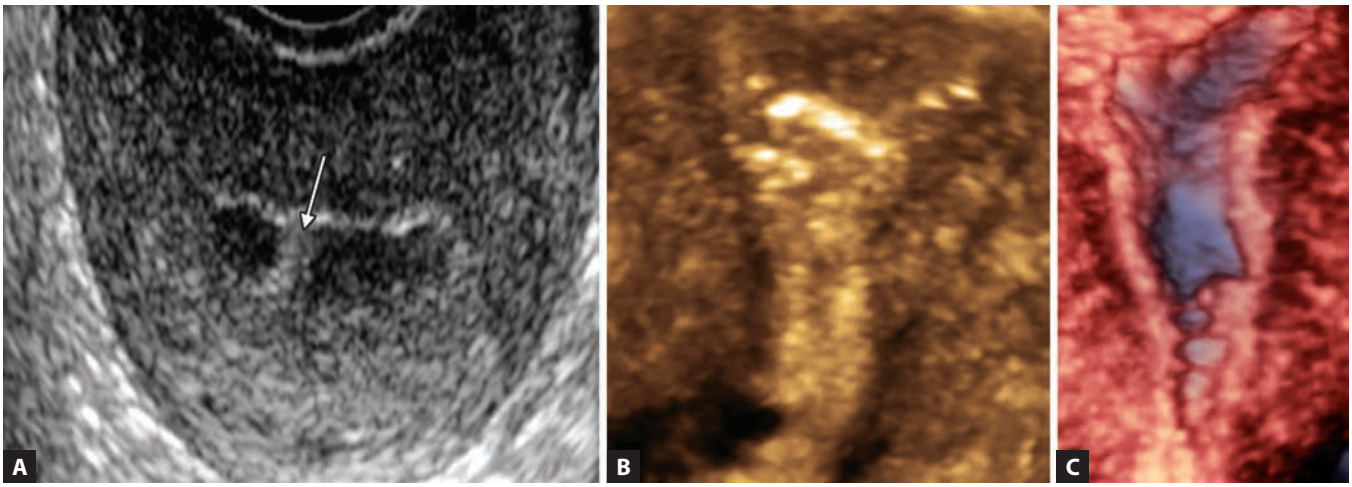

Figs. 18A to C: Synechiae. (A) 2D ultrasound (US) (arrow); (B) 3D US coronal view; (C) Sonohysterography.

Method:

- Lithotomy position
- A 6-French (external diameter 1.6 mm, internal diameter 1.1 mm) Foley's catheter is placed in cervix. Catheter balloon in cervical canal
- Distend balloon with 1.5–2 mL of fluid
- Slowly inject 5 mL of normal saline with 10 mL syringe to distend the uterine cavity
- Remove all metal instruments and introduce the probe into the vagina with catheter in situ
- Transvaginal sonography shows fluid-distended endometrial cavity
- Endometrial lesions will be clearly seen **(Figs. 19A and B)**.

Normal saline is a clear fluid, appears black on US and is therefore known as negative contrast. Positive contrast media like SonoVue (Bracco) is also available. This is an echogenic contrast and obscures solid endometrial lesions but is excellent for sonosalpingography.

Other endometrial lesions are postcurettage endometrial collection, missed abortion, incomplete abortion, etc. These are all avascular and show heterogeneous echogenicity. Clinical history guides to the diagnosis **(Figs. 20A and B)**.

Vesicular mole shows a thick echogenic endometrium with small anechoic areas **(Fig. 21A)**—snowstorm appearance. This echogenicity is higher than that of a normal secretory endometrium as it is because of decidual reaction. If it becomes malignant, it would break the endometriomyometrial interface. On color Doppler, it shows low resistance, low velocity vessels **(Fig. 21B)**. But in very early phase, Doppler will not fill up flow signals, due to very low velocities. Of course, beta-human chorionic gonadotropin (β-hCG) levels and its correlation with US findings are diagnostic. Vascularity is more evident in partial mole than in complete mole.

In patients with missed abortion, progressive disappearance of villous vascularity after embryonic death leads to villous hydrops and this condition is known as a pseudopartial hydatidiform (vesicular) mole. This is not actually a vesicular mole.

Endometrial calcifications are common after curettage and medical termination of pregnancy **(Figs. 22A and B)**.

Adnexa

Adnexal lesions can be categorized as:

- Ovarian lesions
- Tubal/tubo-ovarian lesions
- *Miscellaneous lesions*: Paraovarian cysts, peritoneal inclusion cyst, and broad ligament fibroids.

Ovarian Lesions

Before describing a lesion, it is important to decide the origin of the lesion. The signs used to confirm the origin of the lesion from the ovary are:

- Place a probe in such a way that the lesion and the ovary are seen in the same frame on the screen. Apply pressure with the probe, to separate the two. If probe pressure can displace the two away from each other, the lesion is not arising from the ovary. If the two cannot be separated, the lesion is either adherent to the ovary or it is arising from the ovary.
- If the lesion is arising from the ovary, the lesion will be partially or completely covered by normal ovarian tissue and is typically described as a "rim sign" or "beak sign" **(Fig. 23)**.

Having confirmed the origin of the lesion from the ovary, the differential diagnosis of these lesions can be thought of. We would prefer to do this by dividing these lesions into different categories based on their US appearance.

Ultrasound-based classification of ovarian lesions:

- Nonseptated clear cysts
- Cysts with internal echogenicities and septae
- Solid lesions
- Complex lesions with cystic with solid areas.

Nonseptated clear cysts: These cysts are thin walled, have no internal echogenicities, no septae or no solid areas in it.

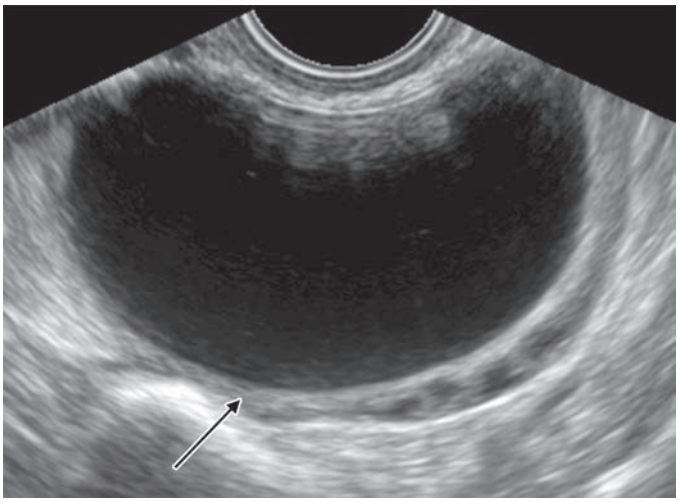

Fig. 23: Beak sign—intraovarian lesion.

The lesions/structures in this category are:

- Follicular cyst
- Simple cyst of the ovary.

Follicular cyst: Follicle starts growing in early follicular phase. It grows till 18–24 mm in diameter before it ruptures due to the surge of luteinizing hormone (LH) to release the ovum that it contains. If the surge is inadequate or does not occur, the follicle will not rupture and will result in a hormonally inactive/only minimally active structure. This is termed as a follicular cyst when it grows beyond 25 mm and persists in luteal phase of the cycle or even in the subsequent cycle. Contrary to the normal follicle, the follicular cyst shows scanty and high resistance flow. But it is ultimately a physiological cyst and would resolve on its own.

Simple cyst of the ovary: It is a thin-walled intraovarian cystic structure usually >5 cm. No internal echogenicities or

septae seen. Doppler shows no flow. It does not resolve on its own and may require US-guided aspiration usually.

Cysts with internal echogenicities and septae:
The most common lesions in this category are:

- Corpus luteum
- Hemorrhagic cyst
- Luteinized unruptured follicle (LUF)
- Endometrioma.

All these structures have thick, shaggy walls, internal echogenicities and avascular septae. The appearance may vary, viz. absolutely isoechoic homogeneous, clear fluid, lace-like or cobweb pattern or ground glass appearance or debris seen as solid areas.

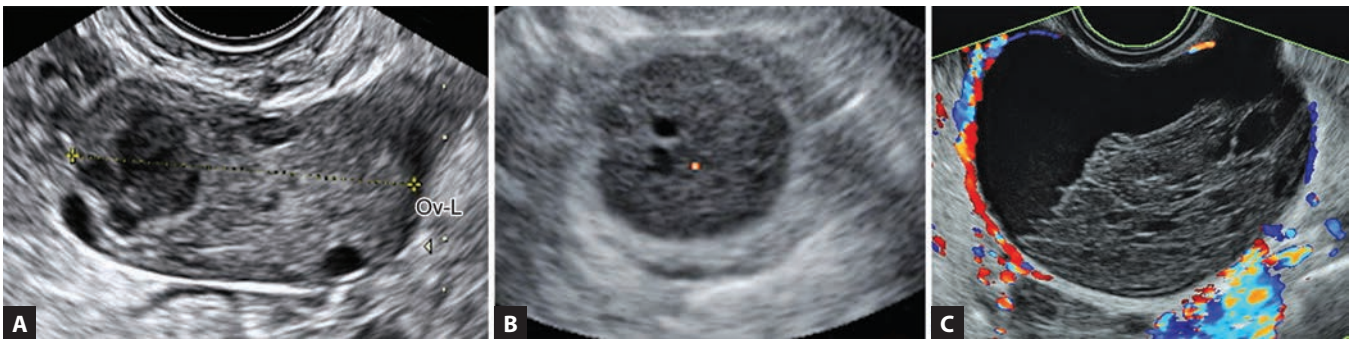
Corpus luteum: It has thick, crenulated walls. Contents of the cyst show heterogeneous echogenicity with or without septae. The echogenicity and appearance of the contents may change at different times. Doppler gives almost a complete ring of color with low resistance (RI <0.5). That is the most characteristic feature to separate it from other lesions with similar appearance on B-mode **(Figs. 24A to C)**.

Hemorrhagic cyst: It is a cyst containing blood. It is most of the times a result of unresolved corpus luteum but is hormonally inactive and therefore shows very scanty and high resistance blood flow. It changes echogenicity over the time due to fibrinolysis of the clot **(Fig. 25).**

Luteinized unruptured follicle: It has thick, echogenic but not very shaggy walls, and does not contain blood or blood products. Therefore, it does show low level internal echogenicity but never lace-like or cobweb echogenicity **(Fig. 26)**.

The three above described lesions (corpus luteum, hemorrhagic cyst, LUF) are physiologic ovarian cysts and 53–89% of these show spontaneous regression on follow-up after 4–6 weeks.[13] To avoid confusing these with other lesions, two scans 2–3 weeks apart should be done so that assessment can be done in two different phases of menstrual cycle and complete or partial resolution of these lesions can be demonstrated.

Endometrioma: Endometriosis is detected in 15% of infertile women. It may cause acquired dysmenorrhea, dyspareunia, irregular bleeding, and infertility. One-third to one-half of the ovarian endometriotic cysts is bilateral. Most endometriomas are positioned medially or retrouterine. Features, typical of endometriomas, are thick shaggy walls with or without septae, internal echogenicities, ground glass appearance, fluid levels (with anechoic fluid anteriorly),



Figs. 24A to C: Different appearances of corpus luteum, also showing ring of color in the last frame.

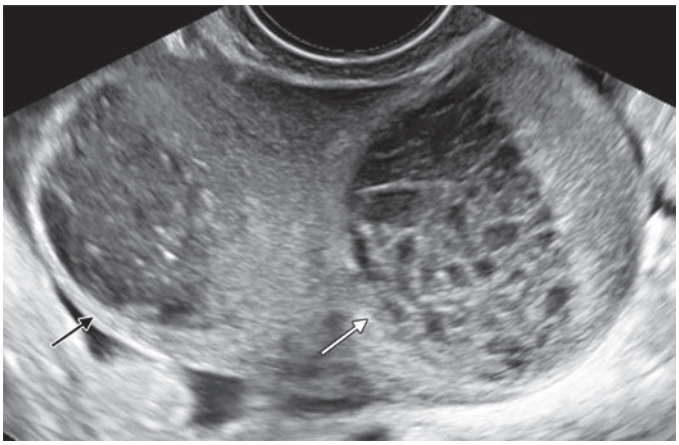


Fig. 25: Hemorrhagic cyst (white arrow) and endometrioma (black arrow).

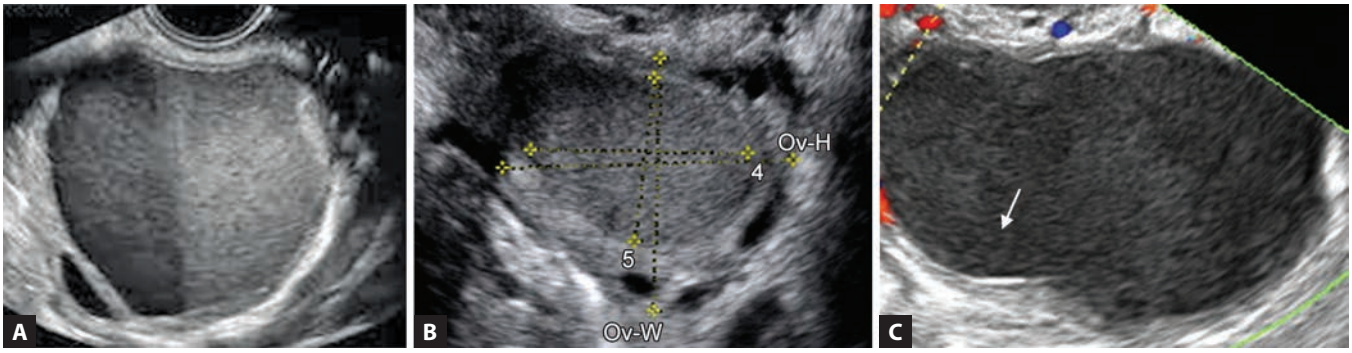
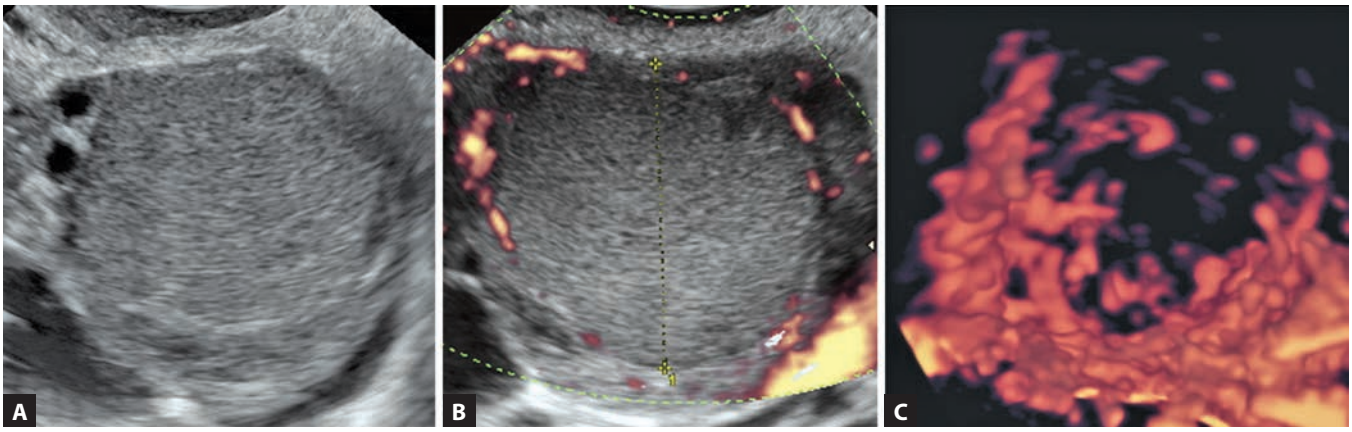
Fig. 26: Luteinized unruptured follicle (LUF): echogenic margins and internal echogenicity.



Figs. 27A to C: Endometrioma showing (A) Fluid level; (B) Ground-glass appearance, and (C) Echogenic flecks in wall.



Figs. 28A to C: Endometrioma: (A) B-mode; (B) Power Doppler (PD) showing short-coursed peripheral vessels; and (C) 3D PD showing bird's nest appearance.

linear echogenic flecks in its walls **(Figs. 27A to C)**, and pain on pressure with the probe. Adhesions are very common. Solid areas may be sometimes seen. Streaming sign is often seen. This is slow downward movement of small low level echogenicities seen in endometrioma (chocolate cyst).

On Doppler: Scattered vascularity at ovarian hilus with moderate vascular impedance has been described in literature. Vascularity is higher during menstruation and in symptomatic patients.[14] Vascularity can be used as a means to decide the mode of therapy for endometriomas. Avascular lesions indicate scarification and are less convenient for delivery of medication and therefore should be considered for surgical therapy.[15]

Three-dimensional US allows detection of surface of the endometrioma, visualization of preserved ovarian tissue, and assessment of the ovarian relationship with neighboring pelvic structures. 3D PD typically shows multiple short-coursed regularly separated pericystic vessels giving a typical bird's nest appearance **(Figs. 28A to C)**.[16]

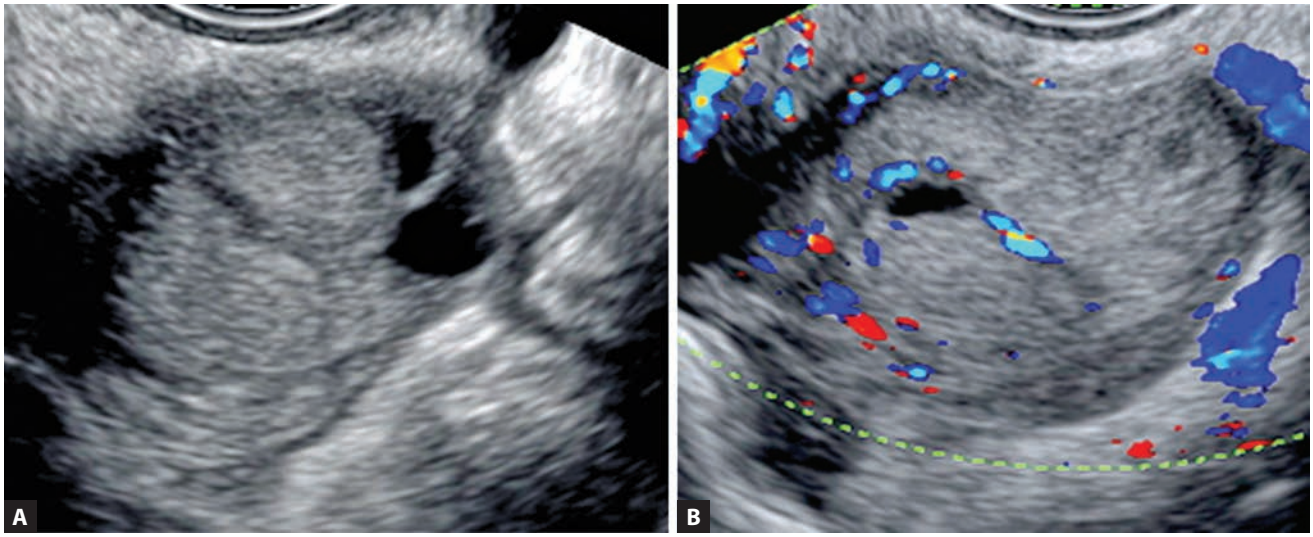
Kurjak et al. have shown a sensitivity of 83.9%, specificity of 97.1%, positive-predictive value (PPV) 82%, and negative-predictive value (NPV) 97.5% of vaginal sonography for characterization of endometriomas. If CA 125 > 35 IU/mL was added as a cutoff to these parameters, the sensitivity and specificity reached 99.04% and 99.64%, and PPV and NPV reached 98.10% and 99.82%, respectively.[15] Similar results were also confirmed by several other workers.

Solid lesions: Most common lesion in this group is fibroma. It is well-defined round/oval lesion with echogenicity like that of a fibroid—hypoechoic, homogeneous, but sometimes may be heterogeneous and may also show calcifications **(Figs. 29A and B)**. These may often be missed when small as fibroma is isoechoic to ovarian stroma. Like fibroids, fibromas also show peripheral vascularity.

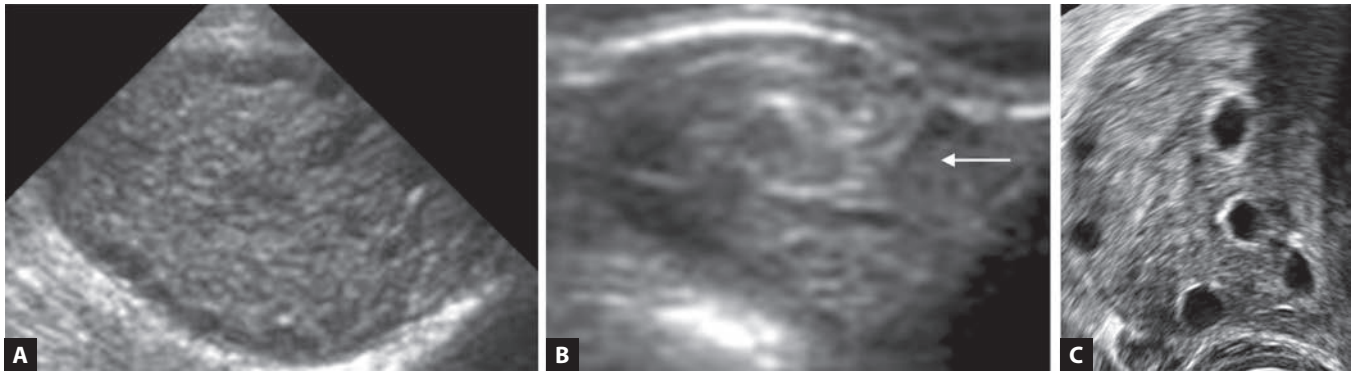
Fibromas may also be pedunculated at times and may be confused with broad ligament fibroids and pedunculated subserosal uterine fibroids. Fibromas can be differentiated from fibroids by tracing the blood supply. Fibromas are often bilateral and may also be associated with ascites and pleural effusion. This complication is known as Meigs' syndrome.

Other lesions in this group are quite rare and may be thecoma, fibrothecoma, Brenner's tumor, etc.

Solid looking ovaries may also be seen in ovarian torsion. Stroma is hypoechoic with peripherally placed small follicles. Vascularity may or may not be present and that decides the viability of the ovary. Definitive sign is a whirlpool sign in adnexa due to twisting of vessels.[17]



Figs. 29A and B: Ovarian fibroma with peripheral vascularity.



Figs. 30A to C: Enlarged ovary with (A) Peripherally placed follicles; (B) Whirlpool sign (arrow); and (C) Follicular ring sign.

Though this sign is not easy to pick up in patients of torsion due to the severe pain that they have.

Follicular ring sign has been claimed to be the earliest sign of ovarian torsion **(Figs. 30A to C)**.[18] This is a hyperechoic line surrounding the small follicles in the torsed ovary. It is a transient sign, only seen during early phase of torsion and is due to ovarian congestion and edema on occlusion of venous and lymphatic flow.

Complex lesions with cystic with solid areas: Lesions in this group have thick walls, with internal echogenicities and also solid projections arising from the walls. Lesions included in this group are:

- Dermoids
- Epithelial tumors
- Endometrioid tumors.

Dermoids: These are often an incidental finding. These are well-defined lesions with thick walls, low-level echoes, fluid-fluid level (with anechoic fluid posteriorly), hyperechoic lines and dots due to hair, hyperechoic/calcified echoes like teeth with posterior shadowing, regional diffuse bright echoes with or without acoustic shadowing due to hair clumps or fat in Rokitansky's protuberance **(Figs. 31A to E)**. 72% of cystic teratomas are avascular.

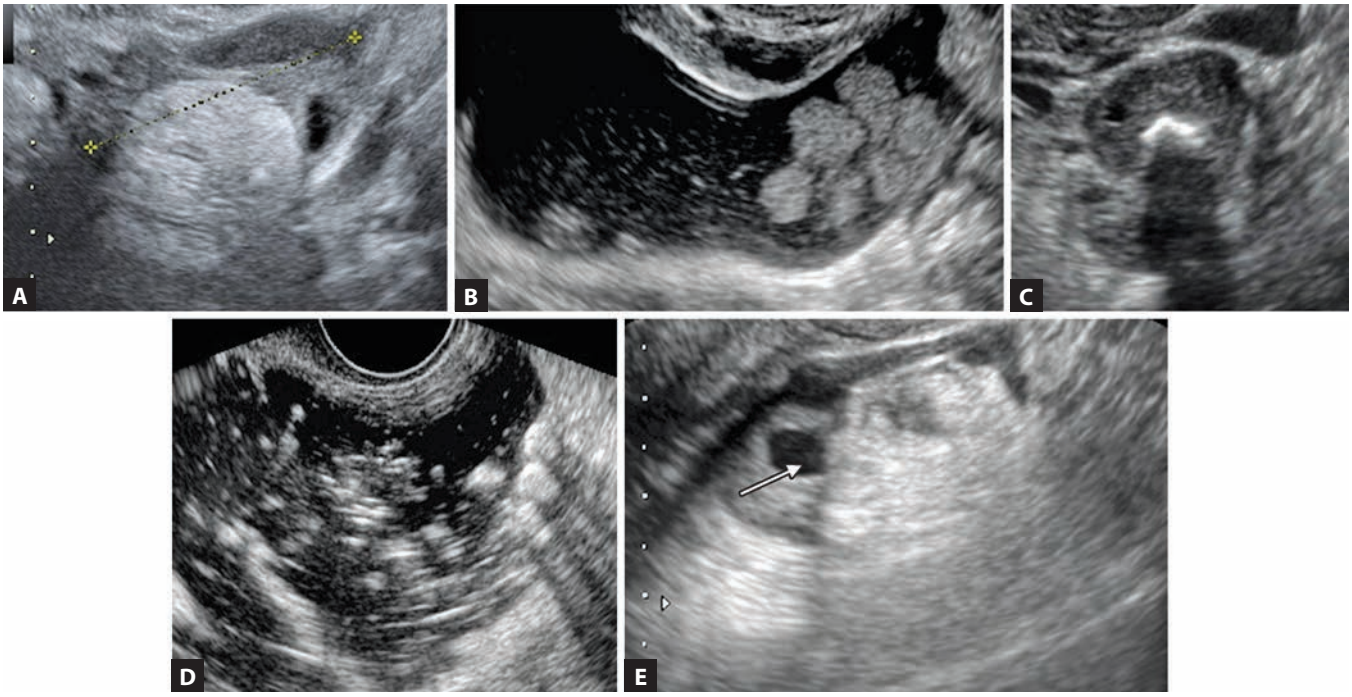
These features have been assigned for definite PPV:[10]

- 80% for shadowing echodensity
- 75% for regionally bright echoes
- 50% for hyperechoic lines and dots
- 20% for fluid-fluid level.

Positive-predictive value for more than two features is 100%.

Morphologic scoring system for dermoids by Kurjak et al. has sensitivity of 93.1% and specificity of 99.4%. Including color Doppler, sensitivity of 99% and specificity of 99.8% can be achieved.[19]

Epithelial tumors: Surface epithelial-stromal tumors account for 60% of ovarian neoplasms and 80–90% of ovarian malignancies. Of all these 46% are serous, 36.5% are mucinous, and 7.5% are endometrioid. These tumors are chiefly cystic, have septae, internal echogenicities, and projections arising from its walls. Benign and malignant counterparts of these tumors have a similar but overlapping US appearance. On US, therefore it is not possible to give



Figs. 31A to E: Dermoids: echogenic mass, hairballs in cyst, small echogenic area, teeth with posterior shadowing and echogenic lines and dots, large Rokitansky's tubercle (arrow).

a histopathological diagnosis. One can only doubt its malignant nature by US and we shall not discuss this here as malignancies are not common in infertile patients.

Tubal Lesions

Pelvic inflammatory disease (PID): Most common of tubal lesions are inflammatory in origin. These lesions are usually a part of PID and may also involve uterus and ovaries also to variable extent.

Inflammation of Fallopian tubes is known as salpingitis. Like inflammation anywhere in the body salpingitis leads to edema and hyperemia. On US, this is seen as thickened adnexa, >10 mm in transverse diameter or thickened tube walls if there is fluid surrounding may be appreciated with central hyperechoic mucosa. Normally, blood vessels are seen in adnexa on color Doppler and are parallel to the long axis of adnexa. But in acute salpingitis several small vessels are seen and these are not parallel to the long axis of adnexa but the run across. On pulse Doppler, these vessels show low resistance (RI < 0.45). In early phase of PID, ovarian parenchymal blood flow also shows low to moderate RI: 0.53 ± 0.09, but in chronic stage, it increases to 0.71 ± 0.09.[20] Regression of the infection on its own or in response to antibiotic, decreases the flow in tubes and ovaries. Salpingitis is usually associated with oophoritis. This is characterized by enlarged ovaries with hypoechoic stroma and increased vascularity. Salpingitis may lead to hydrosalpinx.

On US, extraovarian cystic lesion is seen in adnexa. On rotating the probe 90°, it changes its shape and becomes elongated **(Figs. 32A and B)**. It may typically show a retort, sausage or serpiginous shape. It can be differentiated from bowel by lack of peristalsis and from a blood vessel by Doppler which shows no flow.

It may show incomplete septae that are due to tubal haustra **(Figs. 32A and B)**. On transverse section, this tube gives a cogwheel appearance, due to fibrotic remnants of endosalpingeal tissue, or beads-on-a-string appearance on long axis.[21] The fluid may show low-level echoes if the collection becomes thicker and also at times purulent. 3D US with inversion mode rendering is a very good tool to demonstrate such lesions **(Figs. 33A and B)**.

Extension of the inflammatory process further may also involve the ovary and also sometimes bowel or omentum in vicinity and forms tubo-ovarian abscess **(Figs. 34A and B)**. It is seen as a complex lesion on US with low resistance (RI: 0.44 ± 0.04)[22] vascularity in its solid areas and wall.

Free fluid may be seen in pelvis. Abscess when heals still leaves a cyst behind or it causes fibrous scarring—tubo-ovarian adhesions and then shows high resistance vascularity (RI: 0.75 ± 0.04).

Timor-Tritsch et al. defined the sonographic markers for the tubal inflammation **(Table 5)**.[23]

Clinical correlation is very essential to differentiate inflammatory process from neoplastic process.

Saline infusion salpingography (SIS) and hysterosalpingo-contrast sonography (HyCoSy) are very useful investigations for assessment of tubal evaluation. Though, laparoscopy is a gold standard as these investigations do not give information about tubo-ovarian relations.

Tubo-ovarian complex	36%	2%
Tubo-ovarian abscess	—	—
Fluid in cul-de-sac	50%	10%

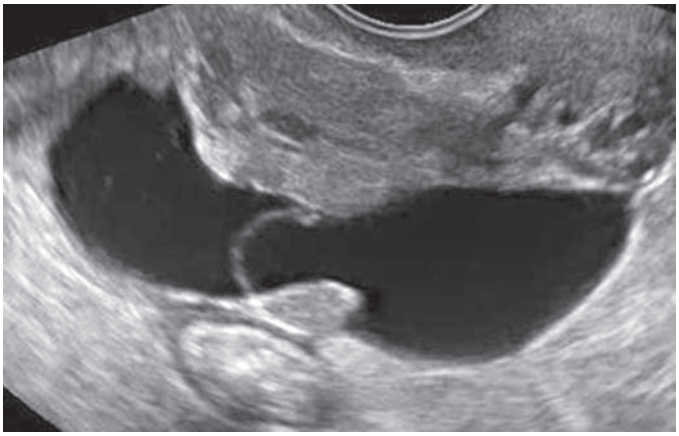

Fig. 35: Peritoneal inclusion cyst: irregular shape and lax septum.

Miscellaneous Lesions

- Broad ligament fibroid
- Peritoneal inclusion cyst
- Paraovarian cyst.

Broad ligament fibroid: On US, it is a well-circumscribed, usually round, hypoechoic lesion. It can be separated from both uterus and ovary by probe pressure and shows peripheral vascularity.

Peritoneal inclusion cyst: It is a fluid collection in the pelvic peritoneum with septations. This fluid collection is not under pressure and therefore changes shape on probe pressure. The septae inside move with respiration, pressure, or with pulsations of nearby vessel. These lesions typically do not show any vascularity **(Fig. 35)**.

Paraovarian cyst: Up to 20% of adnexal masses may be paraovarian cysts. These are benign, avascular lesions with thin walls and anechoic contents. The shape does not change with pressure but can be easily separated from ovary. Adhesions indicate infection and solid projections in it may raise a possibility of malignancy.

CYCLE ASSESSMENT

Cycle assessment consists of baseline scan, preovulatory scan, and secretory scan.

Hormonal changes occurring during the menstrual cycle are reflected as vascular changes and therefore color Doppler in this assessment is mandatory. 3D US is especially useful for volume measurements. 3D PD has given promising results in initial studies.

Baseline Scan

This scan is done on day 2–3 of the cycle. At this time of the cycle, ovaries have no active follicles or residual corpus luteum. This scan is differed to next cycle if the ovaries show any follicle larger than 9 mm or a residual corpus luteum. This scan consists of TVS, transvaginal color Doppler (TVCD), and volume US of ovaries and uterus. It is done to classify the ovary in one of the four categories: (1) polycystic ovaries (PCO), (2) normal ovaries, (3) low reserve ovaries, and (4) poorly responding ovaries. Or in other words to predict the ovarian reserve and response that can guide to decide the stimulation protocols for assisted reproductive technology (ART).

Ovaries

Two-dimensional US assessment of the ovaries consists of assessment of ovarian diameters and volume and counting of antral follicles as quantitative assessment and qualitative assessment of stromal density. Color or PD is used to see the presence of vessels in the stroma. If vascularity is present, pulse wave Doppler is used for quantitative assessment of the flows—intraovarian RI and peak systolic velocity (PSV). Then 3D and 3D PD volume of the ovary is acquired for ovarian volume and stromal volume, counting number of antral follicles. Global vascular indices—vascularity index (VI), flow index (FI), and vascularity flow index (VFI)—may be calculated, the values for these are not yet established but are likely to give promising results. Normal ovaries are 3–6 cc in volume with 512 antral follicles, and stromal flow with RI of 0.58–0.7 and PSV of between 5 and 10 cm/sec.

Ultrasound and Doppler Features for Polycystic Ovaries

Enlarged ovaries (>10 cc in volume) and multiple antral follicles (>20 antral follicles per ovary), according to Rotterdam criteria and dense stroma with or without asynchronous endometrium, are the features of PCO. But each of the features need elaborate discussion.

Enlarged ovaries: On 2D US, an ovary with the longest diameter of >3.5 cm is considered enlarged. Volume of the ovary is calculated by measuring three orthogonal diameters and applying the formula (x × y × z) × 0.523. Calculation of ovarian volume by virtual organ computer-aided analysis (VOCAL) on 3D US is much more accurate **(Fig. 36)**.

According to the Rotterdam criteria, ovarian volume of 10 cc is a criterion for polycystic ovarian disease (PCOD).

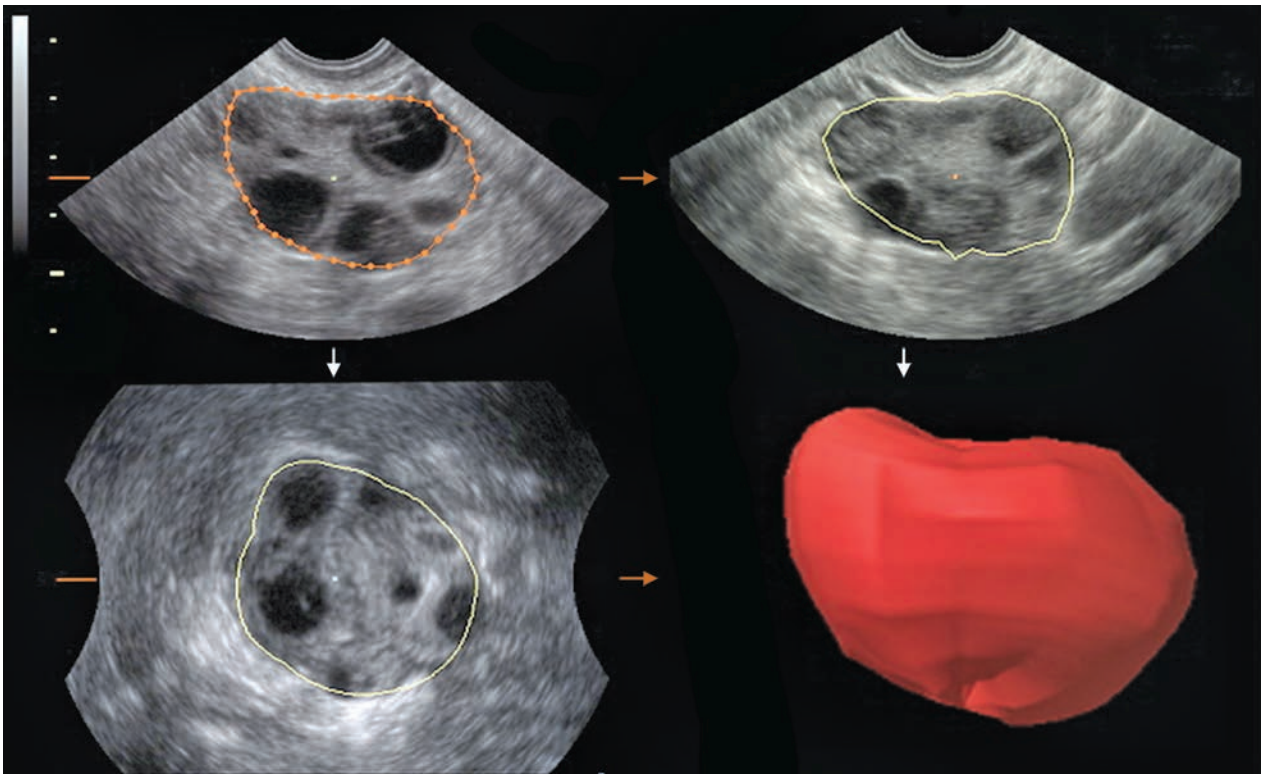

Fig. 36: Three-dimensional ultrasound with volume calculation of ovary by virtual organ computer-aided analysis (VOCAL).

"For an ovarian size of 10 cc, a good correlation has been shown between US diagnosis of polycystic morphology and histopathological criteria for PCO."[24] But reports have also shown that an ovarian size of 6.6 cc has 91% sensitivity and 91% specificity for polycystic ovarian syndrome (PCOS).[25] And yet another report says, "However, ovaries which are normal in volume can be polycystic as demonstrated by histological and biochemical studies (in 20%)".[26] This means ovarian volume cannot be used as the criteria for diagnosis of PCO.

Polycystic ovarian morphology has been found to be a better discriminator than ovarian volume between PCOS and control women.[27]

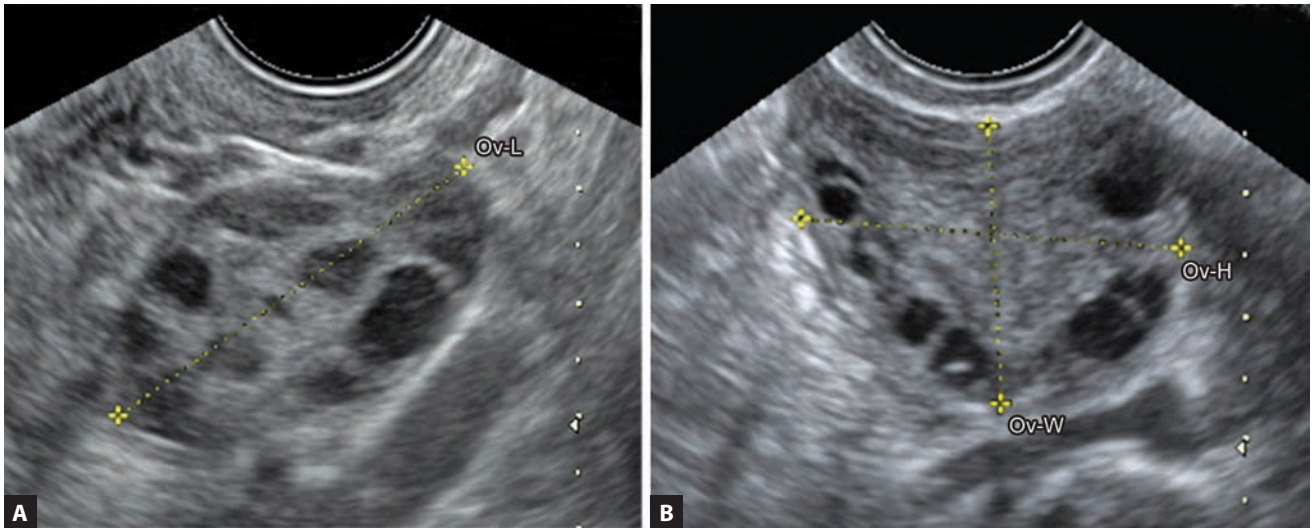
These morphological features are multiple antral follicles, their arrangement, atretic follicles and predominant stroma.

Multiple immature follicles: 20 or more antral follicles[61] of 2–9 mm size have also been quoted as one of the US features of PCOS. But this number has also been reported from 5 to 15 in different reports. Though setting the threshold at 12 for 2–9 mm follicle number per ovary (FNPO) offered the best compromise between specificity (99%) and sensitivity (75%).[28]

The more recent studies suggest FNPO of >19–20[29] antral follicles especially in PCO patients are difficult to count on 2D US. If 3D volume of the ovary is acquired and then is rendered in inversion mode or Sono-automatic volume calculation (Sono-AVC) is used, the antral follicle count is reliably done.

It is known that tonic elevation of LH in PCO patients in follicular phase leads to theca and stromal cell hyperplasia and increased androgen production. This leads to recruitment of multiple follicles in the ovaries. And altered LH:follicle-stimulating hormone (FSH) ratio in PCO does not allow maturation of small follicles, instead these become atretic. In the course of time, these atretic follicles get converted into theca cells and contribute to stroma.[30] In the early phase of the disease, the stroma becomes denser leading to a generalized cystic pattern (GCP) of PCO. As the disease progresses, not only the stromal density but also the stromal volume increases, leading to enlargement of the ovary. Along with this, the follicles are also pushed to the peripheral cystic pattern (PCP) of PCO. This means that from multicystic ovaries (ovaries normal in size having multiple follicles of various sizes and normal stroma) which is a normal appearance in adolescence to GCP PCO and PCP PCO is a process of evolution as a result of high basal androgen levels in these females **(Figs. 37A and B)**.[30] This explains not only the variability in the size of the ovaries but also the variability in the number of antral follicles in patients having oligo-ovulation and hyperandrogenism in patients with PCOS.

Predominant hyperechoic stroma: Polycystic ovaries show a hyperechoic stroma but assessment of this hyperechogenicity is subjective not only to the operator but also to equipment settings.[31,32] Therefore, a more objective or reproducible criteria would be ovarian area or stromal



Figs. 37A and B: (A) Generalized cystic pattern; (B) Peripheral cystic pattern in polycystic ovaries.

TABLE 6: Sensitivity for diagnosis of polycystic ovary syndrome.

Ovarian volume	13.21 cc	21%
Ovarian area	7 cm^2	4%
Stromal area	1.95 cm^2	62%
Stromal/total area	0.34	100%

area. Ovarian area of 5.3 cm^2 on strict longitudinal ovarian section and stromal area of 4.6 cm^2 has high sensitivity for PCOS.[25]

Sensitivity for diagnosis of PCOS has been presented in **Table 6**.[33]

Ovarian volume and stromal volume can be calculated by acquiring a 3D volume of the ovary, calculating its volume by VOCAL and then using threshold volume, adjusting the threshold to exclude the follicles **(Fig. 38)**.

We have found stromal volume to ovarian volume ratio of >70% in an ovary that is larger than 6.6 cc or has >12 antral follicles in 95% of PCOS patients in a study of 800 PCOS patients studied (unpublished data).

Apart from these major features, PCOS patients show atypical endometrium or out of phase endometrium due to the hormonal derangements like high LH and early rise of estrogen due to multiple follicle recruitment and conversion of androgen to estrogen. It has also been observed by some workers that right to left ovarian volume ratio is reversed in PCOS patients. In control patients, left ovary is larger than right, and in PCOS patients right ovary is larger than left.[25]

These ovaries show increased and moderate resistance stromal flow on the baseline scan. Vessels close to the developing follicles are not stromal vessels. On pulse Doppler, these vessels show RI 0.50–0.58.[34] This is a reflection of high LH levels. If these blood vessels also show a PSV of >10 cm/sec, they are prone to hyperstimulation. High androgen levels in these patients also lead to high uterine artery pulsatility index (PI) **(Figs. 39A and B)**.

It is interesting to note here that higher uterine artery PI and lower ovarian stromal vessel resistance are seen in PCP ovaries than GCP ovaries, higher age, amenorrheic, rather than oligomenorrheic patients and in obese, hyperinsulinemic, and hirsute patients.

Second type of ovaries is poorly responding ovaries. These may be any size but have intraovarian stromal RI >0.70, and PSV <5 cm/sec. They have low vascularity and therefore respond to higher doses of stimulation.

Third type is low reserve ovaries which are small-sized ovaries with <2 cm in longest diameter or <3 cc in volume and have <3 antral follicles. They will produce very few follicles with any stimulation.

Based on this, predictors of ovarian response are:[35]

- Number of antral follicles
- Ovarian stromal FI
- Total ovarian stromal area
- Total ovarian volume.

In that order of importance, antral follicle count is a better marker than basal FSH for selection of older patients with acceptable pregnancy offer.[36] Antral follicle count and ovarian volume showed significant correlation with anti-Müllerian hormone (AMH), total testosterone, and free androgen index.[37]

Precise calculation of antral follicle count therefore can help in predicting the ovarian response. This can be done on 2D US by scanning across the whole ovary while counting the follicles. But this has high chances of error when follicles are multiple as in PCO. In these cases, counting the antral follicles by 3D US, using VOCAL, inversion mode **(Fig. 40A)** or Sono-AVC (GE Healthcare) is much more precise. Using this software, each follicle is coded by a different color and diameters and volumes of each are calculated separately.

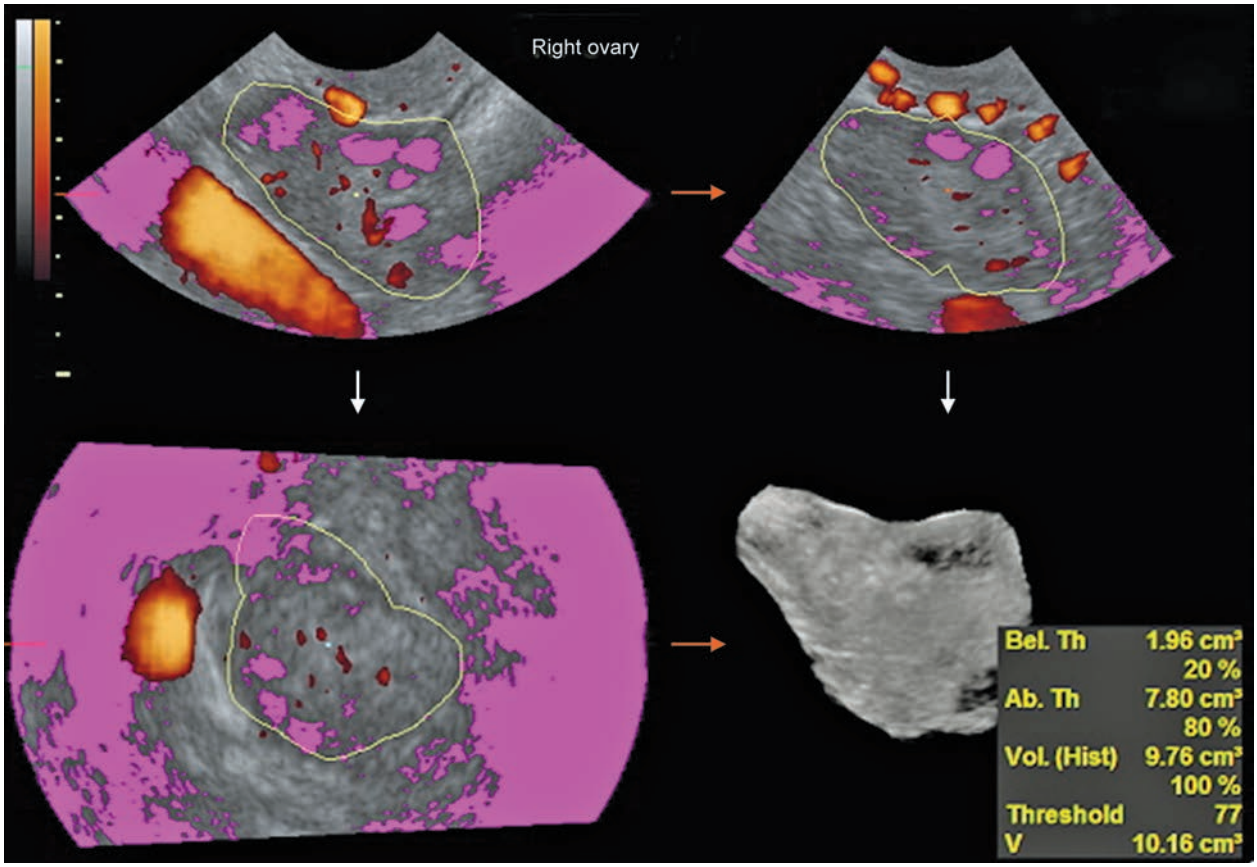


Fig. 38: Three-dimensional ultrasound of ovary with volume calculated by virtual organ computer-aided analysis (VOCAL) and stromal volume calculated by applying threshold volume to VOCAL calculated ovarian volume.

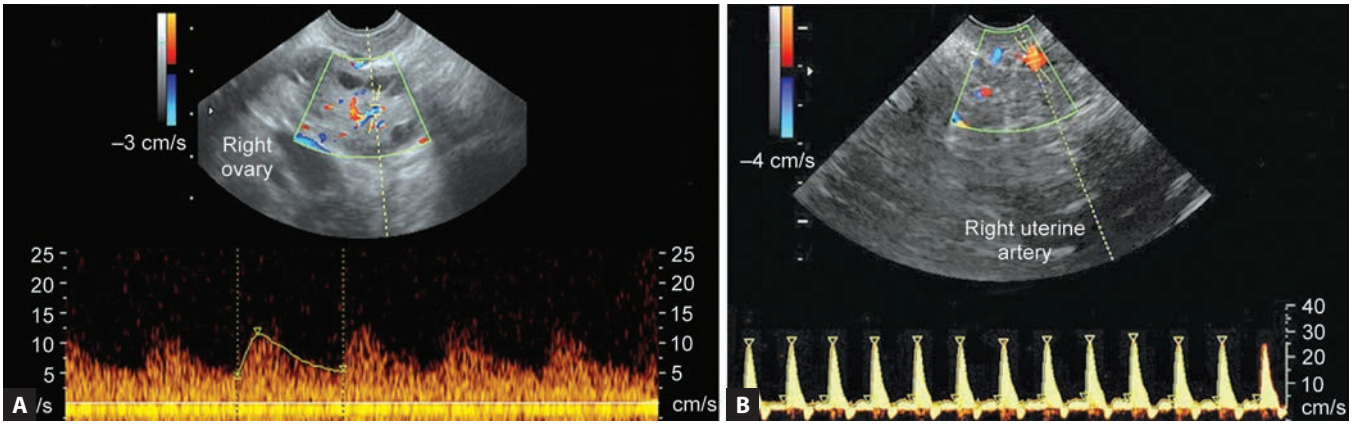


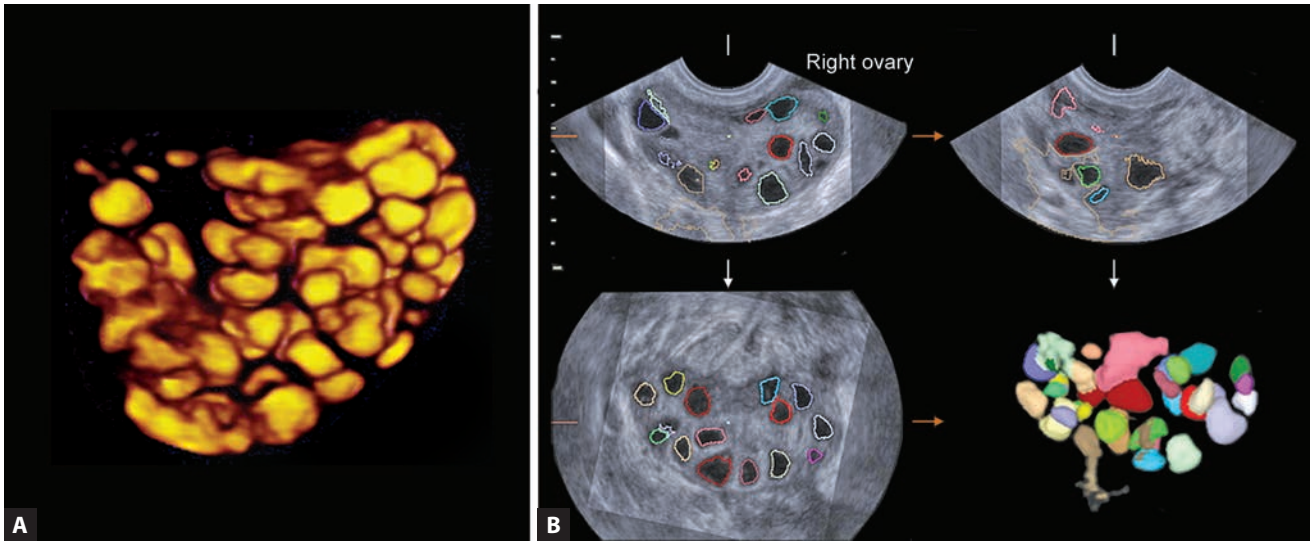
Figs. 39A and B: (A) Low resistance ovarian stromal flow; (B) High resistance uterine artery flow.

This is a more precise method as there is no overcounting of follicles. But to avoid undercounting, postprocessing is required **(Fig. 40B)**.

It has also been shown by Zaidi et al. that stromal blood flow velocity after pituitary suppression was an independent predictor of ovarian response.[28] Kupesic has shown correlation in the ovarian stromal FI and number of mature oocytes retrieved in an in vitro fertilization (IVF) cycles and pregnancy rates.[35]

Uterus

Baseline scan of the uterus is done to assess the uterocervical length by US. Longitudinal section of the uterus is imaged on the screen where whole of the uterus is seen with endometrial cavity starting from fundus to the internal os and external os. For all ART procedures may it be intrauterine insemination (IUI) or embryo transfer (ET), the uterocervical length is measured from the fundal end of the endometrium



Figs. 40A and B: (A) Three-dimensional (3D) volume of polycystic ovary rendered in inversion mode; (B) 3D volume of polycystic ovary with Sono-automatic volume calculation (AVC).

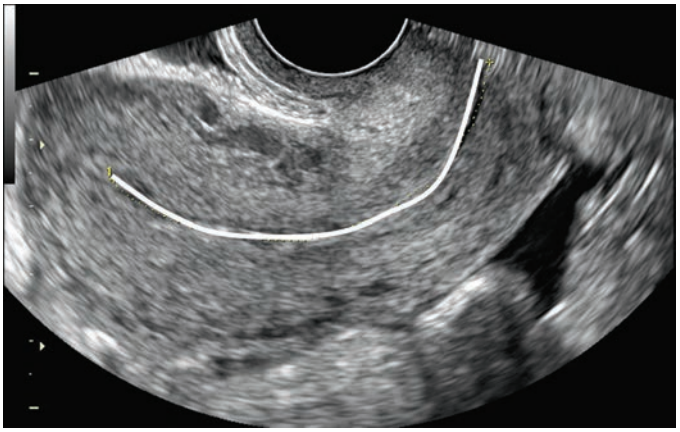


Fig. 41: Measuring functional uterocervical length.

to the external os and is known as functional/physiological uterocervical length **(Fig. 41)**. Doppler of the uterine artery is done. Uterine artery RI >0.79 indicates that high doses of stimulation will be required for endometrial maturation.[38,39] Subendometrial flow on day 2, if it is present, indicates a low receptive endometrium for implantation.

Preovulatory Scan

A follicle that grows to 10 mm is a dominant follicle and grows at a rate of 2–3 mm/day and ovulation occurs at 18–24 mm size. Follicular flow can be first detected when follicular size is 10 mm[40] and its RI starts falling 2 days prior to ovulation.

Features of a Mature Follicle

A rounded 16–18 mm sized follicle with thin walls and no internal echogenicity is seen. A sonolucent halo appears surrounding the follicle 24 hours prior to ovulation. Cumulus oophorus a small projection from wall in the follicular lumen may be seen.

On color Doppler, vascularity is seen covering three-fourth of the follicle. On pulse Doppler, these vessels show RI 0.4–0.48,[41] PSV > 10 cm/sec **(Figs. 42A and B)**. This means that if the follicle is said to be functionally mature when PSV is at least 10 cm/sec, i.e., the time when the LH surge starts and under the effect of that LH, the perifollicular PSV keeps rising constantly. The follicular PSV rises as high as 45 cm/sec before an hour of ovulation. We have done a study of 300 IUI cycles based on this. Single IUI was done between 36 and 38 hours and double IUI were done at 12–14 hours and 36–38 hours after hCG, in all patients in whom perifollicular PSV >15 cm/sec. When perifollicular PSV on the day of hCG was >20 cm/sec, and perifollicular RI was within normal range, double IUI has given higher pregnancy rates **(Fig. 43)**.[42]

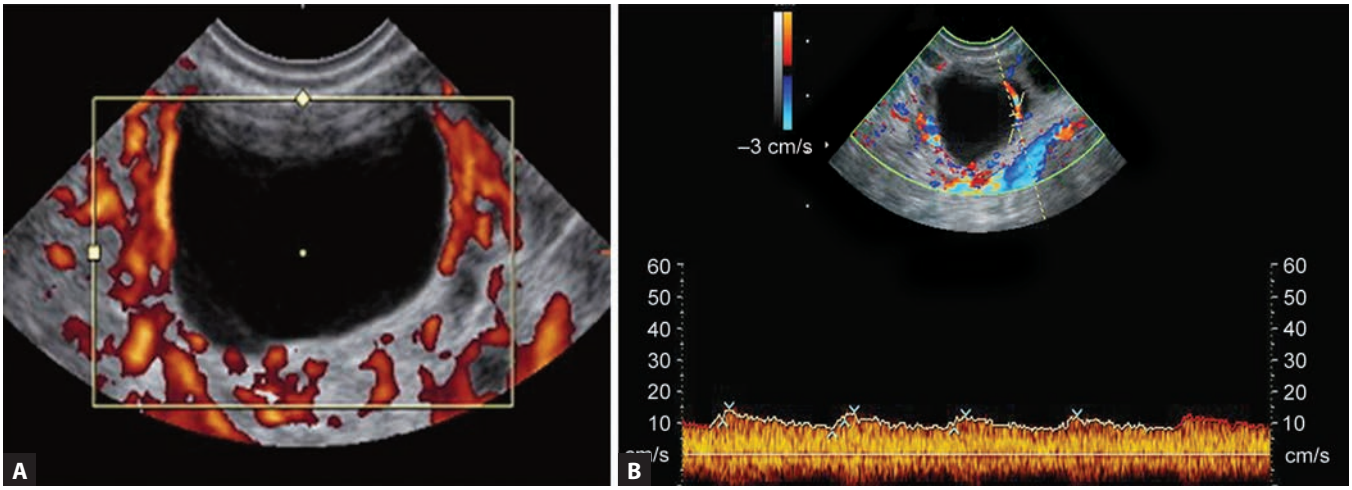
Fertilization of a follicle with a PSV of <10 cm/sec has high chances of embryo with chromosomal abnormality.

Rising PSV with steady low RI suggests that the follicle is close to rupture.[40] Steady or decreasing PSV with rising RI suggests that the follicle is proceeding toward LUF.[43]

Application of 3D US for Follicular Assessment (Figs. 44A to D)

When there is multifollicular development as in PCO the follicular shapes become polygonal and therefore follicular diameter may not be a reliable parameter. Follicular volume by 3D is a more reliable parameter. Follicular volumes of between 3 and 7 cc are optimum for oocyte retrieval. The limits of agreement between the volume of the follicular aspirate and 3D volume of the follicle were +0.96 to –0.43 with 3D and +3.47 to –2.42 by 2D volume estimation.[44]

Cumulus can be seen in 80–90% of follicles using 3D US rendering. This is possible only in up to 30–40% follicles by 2D US. On the day of hCG, if cumulus like echo is not seen



Figs. 42A and B: (A) Perifollicular flow on power Doppler; (B) Spectral Doppler of perifollicular flow.

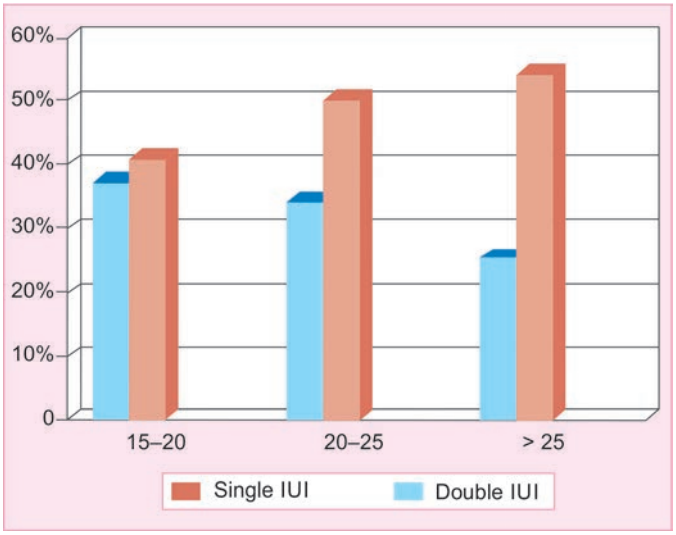


Fig. 43: Graphic representation showing increased pregnancy rates with double intrauterine insemination (IUI) in patients with perifollicular peak systolic velocity (PSV) >20 cm/sec.

in all three planes in the follicle, it is less likely to be mature fertilizable oocyte.[45] This information is especially useful in ART cycles where very few follicles are available. If cumulus is seen in the follicle and ovum is not retrieved, flushing of follicle may be recommended.

Three-dimensional PD gives idea about the global vascularity of the follicle. We have done a large study taking this into consideration. Based on study of >1,000 cycles, follicular volume of 3–7.5 cc, VI >6–20 and FI >35 if used as additional features of a mature follicle apart from the follicular features mentioned earlier in this chapter, these increased the pregnancy rates significantly.[46]

Features of a Mature Endometrium

On 2D US, endometrium should be 6 mm or more in thickness, preferably 8–10 mm. It should have an intact uniform endometriomyometrial junction and should be multilayered. But its morphological assessment is essential.

Endometrial grading:[47]

- *Grade A endometrium:* Multilayered with intervening area more echogenic than myometrium **(Fig. 45A)**
- *Grade B endometrium:* Multilayered with intervening area hypoechoic to myometrium
- *Grade C endometrium:* Homogeneous isoechoic endometrium

Two-dimensional US assesses the anatomy of the endometrium but its functional maturity can be assessed by Doppler of spiral arteries. Vascularity has been considered to be a better marker than morphology for endometrial receptivity.[48]

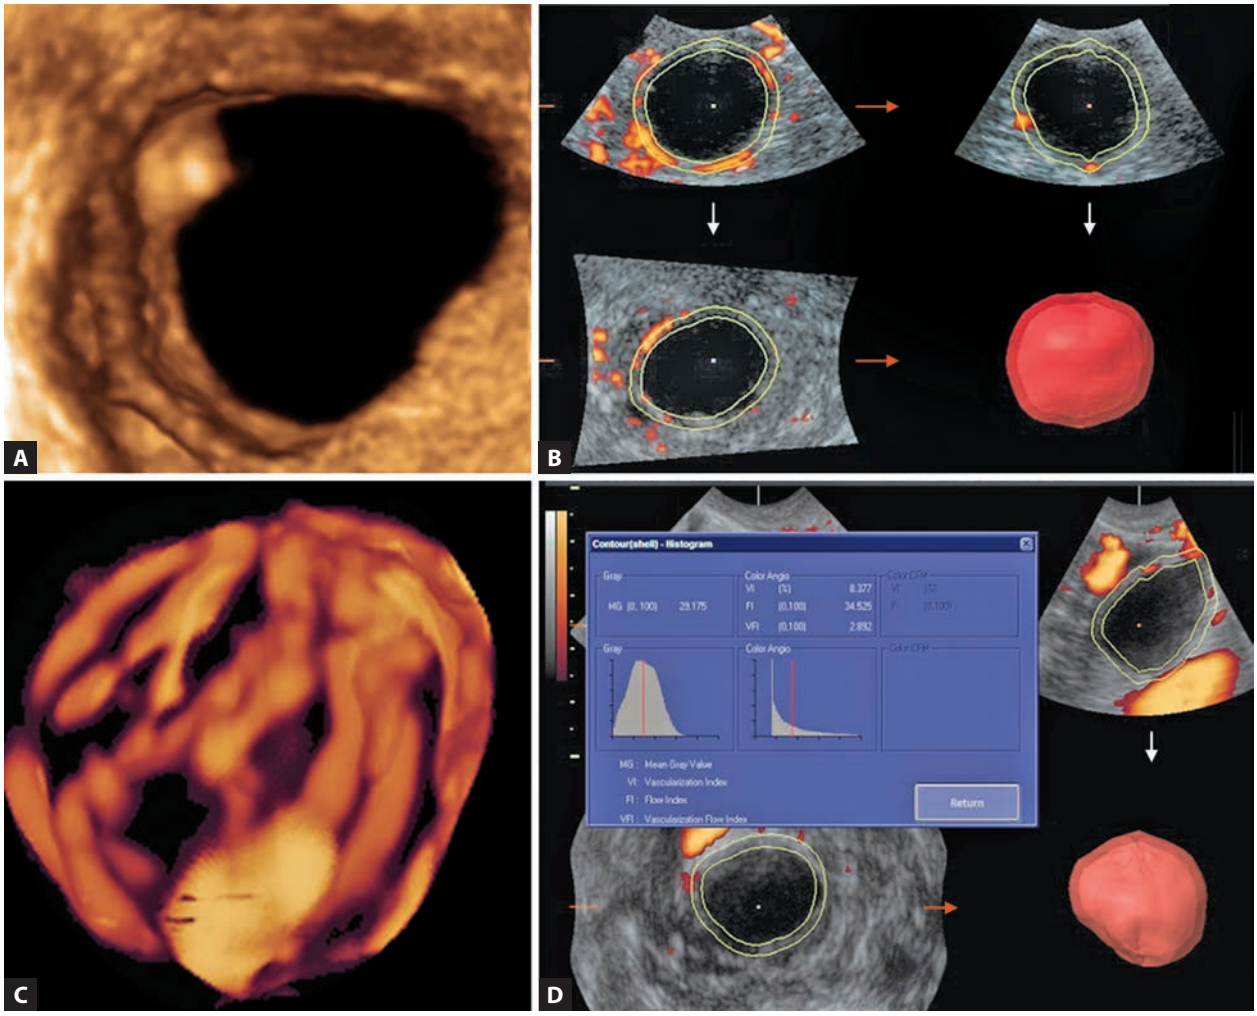
On color Doppler, the vascularity is classified by Applebaum as follows:[48]

- *Zone I:* Blood vessels reaching endometriomyometrial junction surrounding the endometrium
- *Zone II:* Blood vessels reaching hyperechoic endometrial edge
- *Zone III:* Blood vessels reaching internal endometrial hypoechoic zone
- *Zone IV:* Blood vessels reaching endometrial cavity **(Fig. 45B)**

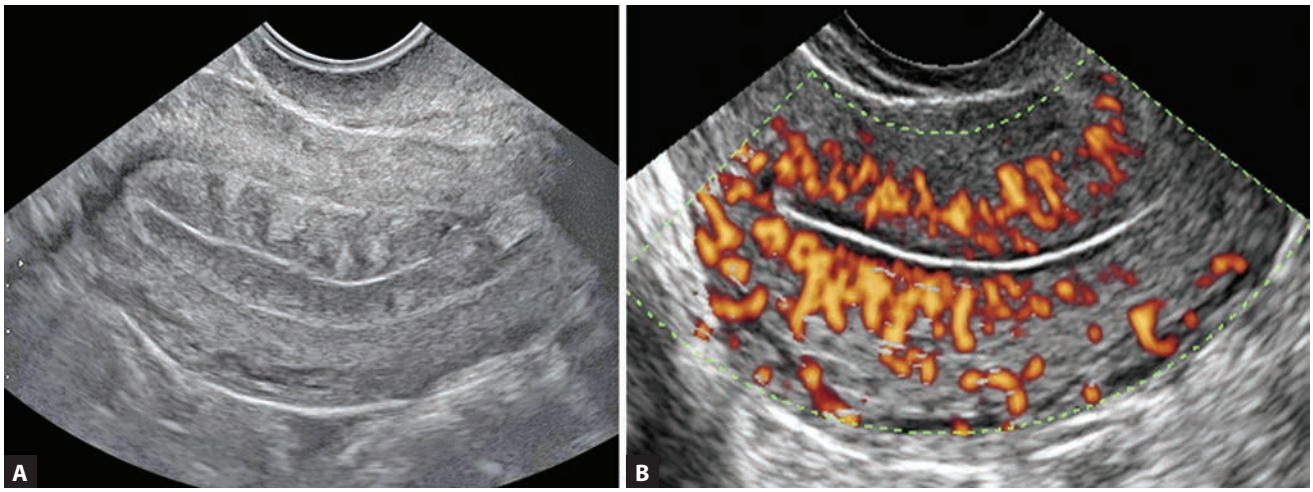
On pulse Doppler, these blood vessels should show RI 0.49–0.59 and PI 1.1–2.3.

Even if TVCD of follicle is normal, endometrial and the uterine artery indices should be within normal limits for implantation. Absent subendometrial and intra-endometrial vascularization on the day of hCG, appears to be a useful predictor of failure of implantation in IVF, irrespective of morphological appearance.[49]

It has also been observed that when pregnancy is achieved in absence of endometrial and subendometrial flow on the day of ET, more than half of these pregnancies will finish as spontaneous miscarriage.[50]



Figs. 44A to D: (A) Cumulus oophorus in follicle on 3D ultrasound (US) of follicle rendered view; (B) 3D power Doppler volume of follicle with virtual organ computer-aided analysis (VOCAL) and shell volume calculation; (C) 3D power angiography of perifollicular flow; (D) Calculation of 3D power Doppler vascular indices (volume histogram) after VOCAL and shell volume for perifollicular flow.



Figs. 45A and B: (A) Grade A endometrium on 2-D ultrasound (US); (B) Zone IV vascularity seen in endometrium on power Doppler.

Apart from endometrium and follicle, it is also essential to evaluate the uterine artery flow on the dominant side before hCG. The normal values of uterine artery are RI 0.60–0.80 and PI 2.22–3.16.[45] Even if TVCD of follicle is normal, endometrial and the uterine artery indices should be within normal limits for implantation. Doppler study for uterine receptivity should be done on the day of hCG. Embryo transfers in IVF cycles are also canceled if the uterine artery

PI >3.2.[51] hCG administration induces significant increase in the resistance of uterine artery for 48 hours and can affect its evaluation on the day of follicular aspiration/rupture therefore Doppler study for uterine receptivity should be done on the day of hCG.[37]

As for the follicle, the endometrium also, if evaluated by 3D and 3D PD, is more reliable. It gives endometrial volume instead of endometrial thickness. When we measure endometrial thickness, we measure it at the thickest part, and this thickness might not be uniform in the whole endometrium. Moreover, sometimes in spite of normal thickness the length of the endometrial cavity may be so little that the total endometrial volume is not enough for implantation. Moreover, 3D PD gives idea about the global vascularity of the endometrium not only in terms of quality but also in terms of quantity, which should be a more useful parameter than 2D Doppler where we can see vessels only in one plane at a time and also interrogate a few vessels not all. In our study, 25 3D PD studies that we have found reliable are endometrial volume >3 cc, FI >20 and VFI >5 **(Figs. 46A and B)**. There are several other people who have also worked on endometrial receptivity assessment by 3D and 3D PD. A study by Merce et al. of 40 IVF cycles has shown endometrial volume of 3–7 mL as most favorable for conception. Median values for a favorable endometrium are 4.28 ± 1.9 mL.[52] Endometrial volume of >2.0 mL has a significantly higher pregnancy rates and no pregnancies were recorded with endometrial volume of <1 mL.[53]

No pregnancy was documented when endometrial volume <3 mL and VI <10. Exceptionally better pregnancy rates were achieved with endometrial volume >7 ml and subendometrial VI between 10% and 35%.[51]

A study by Kupesic et al. shows lower RI of 0.49–0.57 in subendometrial vessels and FI of 11.0–15.4 in conception cycles as compared to 9.5–13.3 otherwise.[54]

Vascularity flow index on the day of trigger is more sensitive than volume, VI, and FI for prediction of pregnancy. VFI >0.24 has sensitivity of 83.3%, specificity of 88.9%, PPV 93.8%, and NPV 72.3% for prediction of pregnancy with 33% pregnancy rate.[55]

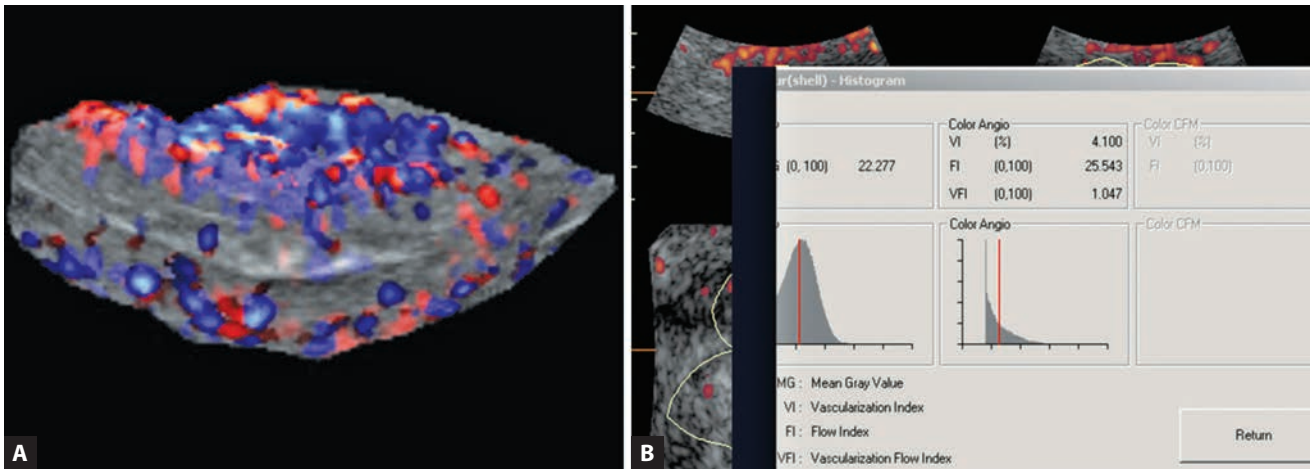
Scoring system has also been developed for endometrial receptivity, which apart from the endometrial thickness, morphology, vascularity, and uterine artery. Doppler also includes uterine contraction count. Calculating contractions/minute, >5 contractions/minute is considered bad for implantation and, 3–5 contractions/minute is considered good for implantation. This is purely based on the fact a uterus which is highly contractile, will not allow implantation. Though this scoring system is not practically applicable as even with full scores pregnancy might not occur.

Secretory Scan

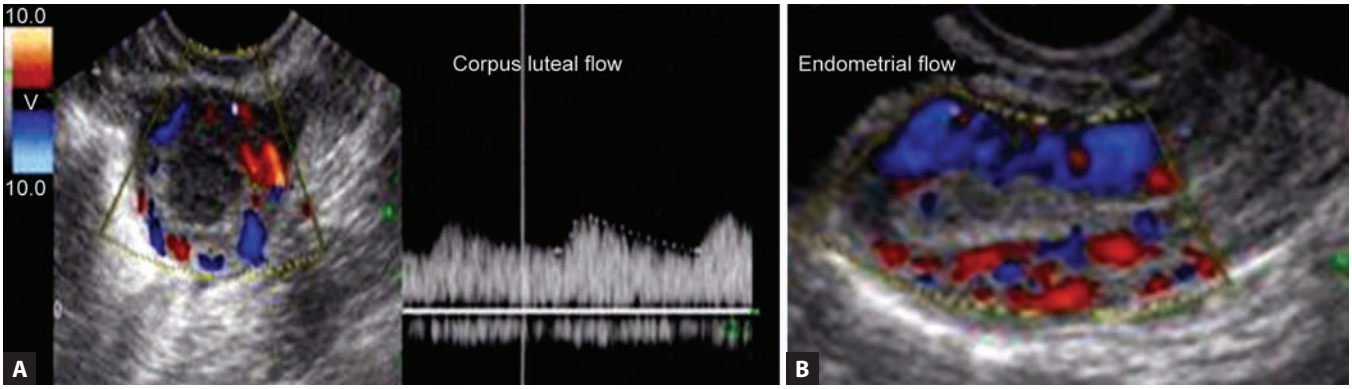
With the rupture of the follicle, corpus luteum is formed and secretory changes are seen in the endometrium in the form of echogenicity of the endometrium which starts from outside, proceeding to the central line making a ring sign of the endometrium.[56]

Assessment of the corpus luteum endometrium and uterine artery by Doppler gives information about the luteal phase normalcy and progesterone levels. A clear correlation between RI of corpus luteum and plasma progesterone levels has been seen in natural cycle. RI of the corpus luteum can therefore be used as an adjunct to plasma progesterone assay as an index of luteal function.[57]

A healthy corpus luteum will show a vascular ring surrounding itself on color Doppler and on PD these vessels show RI 0.35–0.50, PI 0.70–0.80 **(Fig. 47A)**, and PSV 10–15 cm/sec.[43,58] This resistance starts increasing on day 23 of the cycle in a nonconception cycle. Endometrial Doppler shows branches of spiral arteries piercing the outer echogenic margins of the endometrium and better if vascularity reaches the central line with RI 0.48–0.52 **(Fig. 47B)**. Uterine artery at this time of the cycle is 2.0–2.5 and PSV 15–20 cm/sec.



Figs. 46A and B: (A) Three-dimensional (3D) power angiography; and (B) Volume histogram of endometrium.



Figs. 47A and B: (A) Corpus luteum; and (B) Endometrial Doppler in secretory phase.

Based on these values, abnormal parameters indicate luteal phase problems like LUF or luteal phase defect.

Luteinized Unruptured Follicle

On 2D US, LUF is seen as persistent follicle with thick walls and progressive loss of cystic appearance which is difficult to differentiate from corpus luteum. Endometrium is thick and echogenic and no fluid is seen in pouch of Douglas (POD). On Doppler, perifollicular RI is 0.51–0.59, which is higher than normal and remains almost steady till the end of the cycle. Nondominant ovary also shows similar Doppler indices. Endometrial flow is also absent.[43]

Luteal Phase Defect

On Doppler, corpus luteum shows high resistance RI 0.58 ± 0.04. Bilateral ovarian RI shows no difference. Increased resistance is also seen in spiral arteries RI 0.72 ± 0.06.[59]

Increased resistance to uterine blood flow in the midluteal phase may be an important contributing factor to some causes of infertility and the cause of some previously "unexplained" infertility.[60] Segmental uterine and ovarian artery perfusion demonstrates a significant correlation with histological and hormonal markers of uterine receptivity and may aid assessment of luteal phase defect.

As quoted by Golan et al., Shoham et al., and Tan SL et al.:

"In the hands of experienced operators, ultrasound alone suffices for cycle monitoring, with no necessity for additional hormonal estimations."

CONCLUSION

Though follicle size and endometrial thickness assessment that are commonly used as monitoring tools for managing treatment cycles, this is grossly inadequate information for the same. Study of the blood flows by doppler helps to monitor the cycles more closely as these reflect the hormonal changes and allows the functional assessment of the follicle and endometrium through out the cycle.

KEY POINTS

- Three-dimensional US is a modality of choice for differential diagnosis of congenital uterine abnormalities.
- Sonohysterography is a modality of choice for differential diagnosis of endometrial pathologies.
- Color Doppler helps for differential diagnosis of myometrial and endometrial lesions.
- Ovarian lesions must be assessed at least twice, 2–3 weeks apart before stamping the diagnosis.
- For complex adnexal masses, clinical correlation is important.
- Baseline scan is a must before starting ART.
- Stromal morphology and vascularity assessment are must to diagnose PCO.
- Timing of hCG should never be decided without color Doppler assessment of follicle and endometrium.
- Luteal phase Doppler is a key to diagnose luteal phase problems.

CHAPTER 39

Polycystic Ovary Syndrome

Gotte Jhansi, Vyshnavi A Rao

INTRODUCTION

Polycystic ovary syndrome (PCOS) is a complex heterogeneous endocrine disorder, occurring due to synergistic interaction of genetic, epigenetic, and environmental factors, associated with both reproductive and metabolic abnormalities resulting in short- and long-term consequences in women's health.[1]

Anovulatory disorders account for about 30–40% of female infertility, with PCOS accounting for 80–90% of World Health Organization (WHO) group 2, normogonadotropic, normoestrogenic anovulation (hypothalamic-pituitary-ovarian dysfunction).[2]

The first description was given by Stein and Leventhal (1935) in seven women with variable clinical characteristics (i.e., obesity, hirsutism, acne, amenorrhea, sterility, and occasional menometrorrhagia) associated with bilateral enlarged polycystic ovaries (PCO) with thickened capsules and designated their name for the syndrome.[3] Later in the1960s, the term "polycystic ovary syndrome" and its abbreviation PCOS appeared, gradually replacing the Stein–Leventhal syndrome designation.

It is now well-recognized that PCOS is not necessarily a disease [earlier known as a polycystic ovarian disease (PCOD)], but rather a cluster of features that may predispose to various diseases in different stages of life, such as anovulatory infertility, type 2 diabetes mellitus (T2DM), and metabolic syndrome (MebS).[4] PCOS is known now as an endocrine, metabolic, and chronic inflammatory disorder, with hyperandrogenemia, insulin resistance (IR), and obesity as the key factors that influence the expression and symptoms of the condition.[5] The syndrome is associated with a heterogeneous collection of signs and symptoms forming a spectrum, with a mild presentation in some at one end, to the other end of the spectrum causing severe disturbance of reproductive, endocrine, and metabolic function.

This chapter reviews the diagnostic criteria, etiopathophysiology, clinical manifestations, evaluation, management in adolescents, women of reproductive age, pregnancy and menopause, and the long-term sequelae of this disorder.

DIAGNOSIS—EVOLUTION OF THE DIAGNOSTIC CRITERIA

- The diagnosis of PCOS has remained controversial for many years, as the symptoms and signs are heterogeneous, depending on the population and life stage of the women affected.
- For many years, PCOS was only diagnosed in those with increased luteinizing hormone (LH) or altered LH/follicle-stimulating hormone (FSH) ratio[6] and in those with chronic anovulation. However, these excluded many patients with full-blown disorders.
- Later, the diagnosis was based on the finding of hyperandrogenism (HA) and chronic anovulation after the National Institutes of Health consensus conference in the United States (NIH criteria)[7] **(Table 1)**. Again this criterion excluded many subjects, previously diagnosed with PCOS, as in the United Kingdom and other parts of Europe, NIH criteria were never used and the diagnosis was based on ultrasound morphology (and HA).
- Also, few ovulatory women present with all the features of PCOS, including HA and hyperinsulinemia (HI), and hence there is no reason to make the diagnosis of PCOS only in those with chronic anovulation.[8]
- Finally, the Rotterdam criteria[9] was adopted, and both NIH and the Endocrine Society have endorsed the Rotterdam criteria, which is the most widely adopted criteria **(Table 1)**.
- While the Rotterdam criteria are simple and easier to follow, problems in diagnosing PCOS using these criteria often occur because of:
  - Changing ultrasound criteria for the definition of PCO
  - Polycystic morphology on scan is seen in about 25–30% of normal women without any clinical features of PCOS.[10]
  - Low sensitivity (68–72%) of assessment of ovarian volume (OV) by ultrasound[8]

TABLE 1: Defining polycystic ovary syndrome (PCOS)—the evolution of the diagnostic criteria.

Parameter	*NIH Consensus 1990*[7]	*ESHRE/ASRM/Rotterdam Consensus 2003*[9]	*AEPCOS definition 2009*[11]	*NIH 2012 extension of ESHRE/ASRM 2003*[12]
Criteria	• Clinical and/or biochemical HA • Oligo/amenorrhea, anovulation	• Clinical and/or biochemical HA • Oligo/amenorrhea, anovulation • PCO appearance on ultrasound	• Clinical and/or biochemical HA • Oligo/amenorrhea, anovulation • PCO appearance on ultrasound	• Clinical and/or biochemical HA • Oligo/amenorrhea, anovulation • PCO appearance on ultrasound
Limitations	Two of two criteria required	Two of the three criteria required	Androgen excess and one other criterion	Two of three criteria are required; and identification of specific phenotypes **(Table 2)**

(AEPCOS: Androgen Excess and PCOS Society; ESHRE/ASRM: European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine; HA: hyperandrogenism; Excluding all causes for androgen excess and anovulation; NIH: National Institutes of Health; PCO: polycystic ovaries)

  - Low sensitivity of commercially available androgen assays
  - Leads to significant increase in the number of subjects diagnosed with PCOS, as well as broadens the heterogeneity of PCOS phenotypes when compared with the NIH definition[4]
- However, the Androgen Excess Society (AES) has proposed that HA should be mandatory for the diagnosis of PCOS.[11]
- The global use of varying diagnostic criteria raised issues of compatibility for PCOS research worldwide and confusion within clinical practice. Therefore, the NIH 2012 undertook an Evidence-Based Methodology PCOS Workshop to address the "benefits and drawbacks" of existing diagnostic criteria.[12] The panel then recommended the use of the broader European Society of Human Reproduction and Embryology (ESHRE) or American Society for Reproductive Medicine (ASRM) 2003 criteria, but with the description of the PCOS phenotype as proposed by Azziz et al. **(Table 1)**.[13]

TABLE 2: Classification of polycystic ovarian syndrome phenotypes.[13,17]

Parameter	*Phenotype A*	*Phenotype B*	*Phenotype C*	*Phenotype D*
PCOS features	HA/OD/PCOM	HA/OD	HA/PCOM	OD/PCOM
HA	+	+	+	–
OD	+	+	–	+
PCOM	+	–	+	+
NIH 1990 criteria	X	X		
Rotterdam 2003 criteria	X	X	X	X

(AEPCOS: ANDROGEN Excess and PCOS Society; HA: hyperandrogenism; NIH: National Institutes of Health; OD: ovulatory dysfunction; PCOM: polycystic ovarian morphology)
Source: Lizneva, et al.[17]

PREVALENCE

- The prevalence of PCOS is determined by the diagnostic criteria used, ethnic origin, and population of women studied. The overall incidence varies from 8% to 10%.[14]
- The prevalence among women of fertile age is 6–10% using the NIH criteria, 10% using the Androgen Excess and PCOS Society (AEPCOS) criteria, and 14–20% using the broader Rotterdam criteria.[15]
- The incidence is higher in the South Asian population which is about 50%, as against the Caucasian population, where the incidence is 5–25%.[16]

POLYCYSTIC OVARY SYNDROME—PHENOTYPES

- Four phenotypes have been identified, which may be influenced by genes, nutrients, physical activity, pollutants, psychological stress, and androgen excess and act to program and modify epigenome leading to PCOS **(Table 2)**.[13]
- Approximately, 75% of PCOS have the classic type and the remaining 25% are evenly divided between ovulatory and nonhyperandrogenic PCOS phenotypes.[13]
- Phenotypes A and B (classic or hyperandrogenic PCOS) have greater menstrual irregularity, HA, total and abdominal obesity, and IR, and are at risk for T2DM, MebS, and cardiovascular disease (CVD).[13]
- Phenotype D (nonhyperandrogenic PCOS), who do not demonstrate overt evidence of androgen excess, have little risk of metabolic dysfunctions.[17]
- Phenotype C (ovulatory PCOS) have lower body mass index (BMI), lesser degrees of HA and HI, milder forms of dyslipidemia, and reduced incidence of MebS.[17]

Pathophysiology

Genetics: Familial with clustering of cases, more common in monozygotic identical twins than in dizygotic or non-identical twins[18]

- Mode of inheritance could be oligogenic or polygenic.[18]
- Autosomal dominant, with variable penetrance or X-linked[18]
- Mutations in the candidate genes involved in any of the metabolic and reproductive pathways **(Table 3)**[18,19]
- Genome-Wide Association Studies (GWAS) identify susceptibility loci for PCOS on chromosomes 2p16.3, 2p21, and 9q33.3, and it is known that LH or chorionic gonadotropin receptor (LHGCR) and FSH receptor are both located on 2p21.18.18.

Various hypotheses have been implicated:

- *Fetal origin:* In utero programming
- *LH hypothesis:* Neuroendocrine defect with an increase in both the amplitude and pulse frequency of LH secretion
- *Ovarian hypothesis:* Primary defect of sex steroid synthesis resulting in hyperandrogenemia
- *Adrenal hypothesis:* Alteration in cortisol metabolism
- *Insulin hypothesis:* Defect in insulin action resulting in HI
- *Altered sympathetic tone:* High sympathetic activity.

TABLE 3: Candidate genes involved in polycystic ovary syndrome.

Steroidogenesis and metabolism	• *CYP11a (P450scc)* • *CYP17 (P450c17)* • *CYP19 (P450arom)*
Insulin receptors and substrates	• Beta-cell function: *TCF7L2, KCNJ11* • Insulin resistance: *IR, PPARỸ*
Ovary	• *Follistatin* • *Fibrillin-3* gene
Androgen action	*Androgen receptor*
Obesity	*Fat mass and obesity-associated gene (FTO)*
• Genes involved in gonadotropin release, regulation, and action • Genes encoding inflammatory cytokines	

Fetal Origin: In Utero Programming

- *Barker's hypothesis (fetal origin of adult disease):* Exposure to in utero HA may disturb the epigenetic reprogramming in the fetal reproductive system, thereby resulting in PCOS phenotype after birth.[20,21]
- However, it is unlikely that maternal androgen excess has a significant impact on fetal testosterone levels because of the efficient "buffering" by high circulating concentrations of sex hormone-binding globulin (SHBG), which reduces the biologically available fraction of testosterone and by placental aromatase activity which converts androgen to estrogen.
- An increased prevalence is seen in women with fetuses having androgen excess disorders such as classical congenital hyperplasia (21-hydroxylase deficiency) and congenital adrenal virilizing tumors.
- The fetal ovary and/or the fetal adrenal are genetically predisposed to secrete an excess of androgen **(Fig. 1)**.[4]
- The fetal ovary shows increased protein expression of P450c17 and an abundance of androgen receptors during follicle formation.

Neuroendocrine Dysfunction

- Increased LH pulse frequency and amplitude with relative FSH deficiency.[22,23]
- The term normogonadotropic anovulation does not apply to all PCOS, as about 60–75% showed elevated basal LH levels.[9,11] However, the LH/FSH ratio may be elevated in up to 95% of individuals.[9]
- More gonadotropin-releasing hormone (GnRH) neurons and/or greater GnRH neuronal connectivity leads to increased GnRH drive.[4]

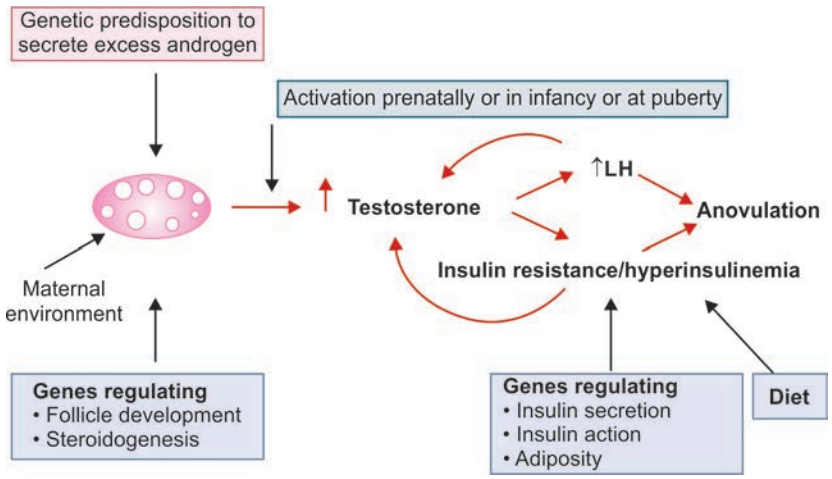

Fig. 1: The proposed developmental origin of polycystic ovary syndrome. (LH: luteinizing hormone)
Source: Franks S, et al.[4]

- Impaired inhibition of hypothalamic GnRH pulsatility, rather than acceleration of the GnRH pulse generator due to:[22,23]
  - HA (prenatal or prepubertal): Androgens block the inhibitory effect of progesterone on the hypothalamus.
  - Estrogen-progesterone feedback: Reduced sensitivity of the GnRH pulse generator to the negative feedback effects of sex steroids (progesterone and estrogen).
  - Anovulation and absence of luteinization → decrease progesterone levels → decrease negative feedback (hypothalamic/pituitary) → pituitary LH
  - HI
  - Estrone hypothesis: Peripheral aromatization of androstenedione (ASD) → estrone → pituitary LH secretion
  - Other neuroendocrine signals such as gamma-aminobutyric acid (GABA), serotonin, dopamine, opioids, anti-Müllerian hormone (AMH), and adiponectin may alter GnRH signalling.[4]
- Rapid GnRH pulse frequency without the normal cyclic variation seen in ovulatory women ~1 pulse/h → pituitary LH secretion → stimulates ovarian theca cells → androgens.
- It is a matter of debate whether the hypothalamic defect is primary or secondary.
- It has been reported that altered kisspeptin signaling could lead to disruption in the GnRH pulse generator. However, the exact role is still to be determined.[24]

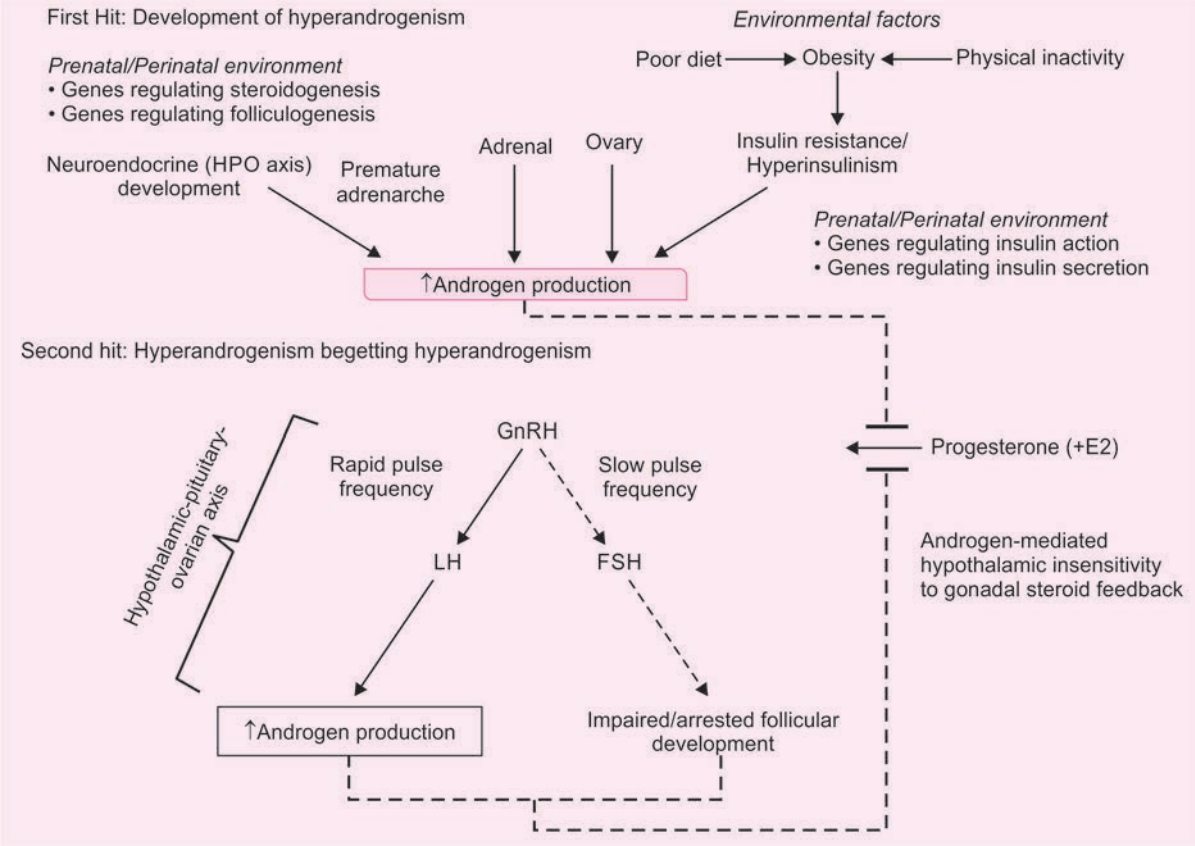
Ovarian Hypothesis

The basic dysfunction lies within the ovary causing exaggerated androgen production. There is increased thickness of ovarian stroma, due to theca cell hyperplasia with deposition of collagen, manifesting as stromal echogenicity on ultrasound imaging and increased vascularity due to transforming growth factor (TGF) and vascular endothelial growth factor (VEGF) hyperactivity.

Alterations in both theca and granulosa cell function:

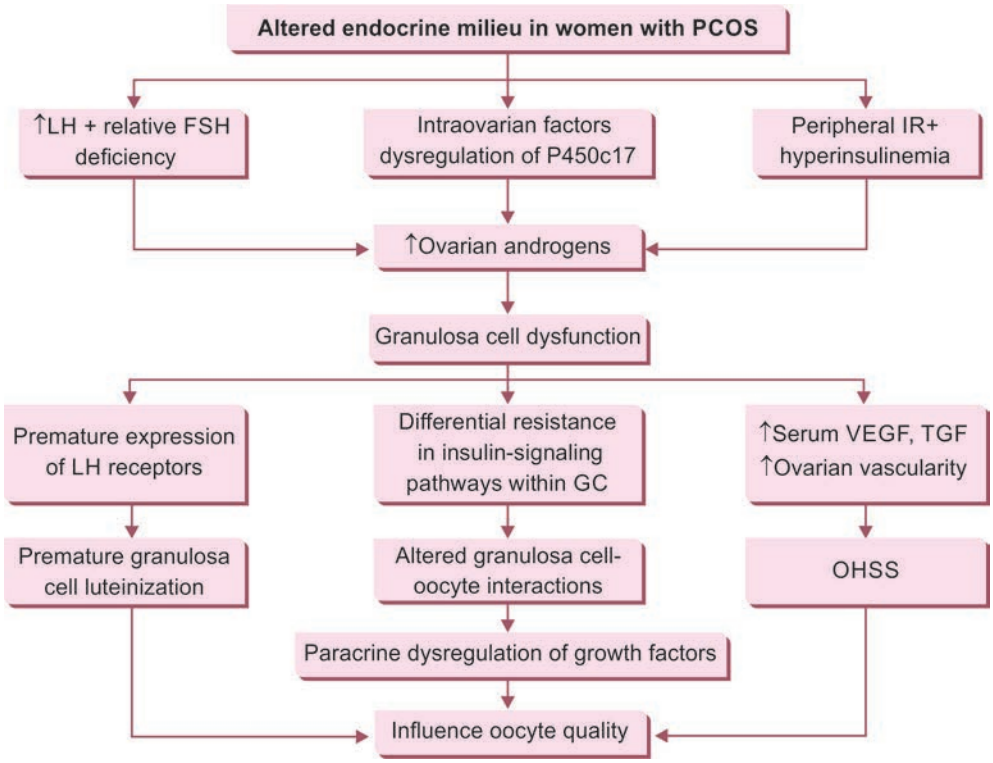
- Development of HA: Two-hit hypothesis—First "hit", one or more of the different mechanisms causing excess androgen production[23] **(Flowchart 1)**. For the second "hit", the preexisting HA reduces the sensitivity of the GnRH pulse generator to progesterone-mediated slowing during pubertal maturation sustaining HA, resulting in a vicious cycle.[23]
- Dysregulation of 17-hydroxylase and 17, 20-lyase activities, both properties of P450c17 (the rate-limiting enzyme in androgen biosynthesis) resulting in androgen activity.[23]

Flowchart 1: Development of hyperandrogenism.



(E2: estradiol; FSH: follicle-stimulating hormone; HPO: hypothalamic-pituitary-gonadal; LH: luteinizing hormone)
Source: Bremer AA.[23]

Flowchart 2: Altered endocrine milieu in polycystic ovary syndrome.



(FSH: follicle-stimulating hormone; GC: granulosa cell; IR: insulin resistance; LH: luteinizing hormone OHSS: ovarian hyperstimulation syndrome; TGF: transforming growth factor; VEGF: vascular endothelial growth factor)

- Intraovarian factors—inhibins, retinoids, and AMH increase ovarian androgen production while inhibiting aromatase activity.[25]
- Androgens induce HI and HI exaggerates androgen secretion, leading to a "vicious circle" of androgens–insulin–androgens.[21]
- As a result of all these, the endocrine milieu is altered in PCOS causing dysfunction of granulosa cells as depicted in **Flowchart 2**.
- All three main androgens—testosterone (produced equally from the ovaries and adrenal glands), androstenedione [(of which >90% is produced in the ovaries), and dehydroepiandrosterone sulfate [(DHEAS—mainly produced in the adrenal glands)] could be elevated.[11]
- Androgen excess could exert its effects, at one or more stages of development from fetal life, adolescence [when there is transient activation of the hypothalamic-pituitary-gonadal (HPO) axis], or adulthood.[4]
- The evolution and severity of its phenotypic expression result from the impact of environmental influences (both pre- and postnatal) on genetic and epigenetic factors in utero **(Fig. 2)**.[23]

Disordered folliculogenesis:

- Excess androgens and reduced levels of oocyte-secreted growth factors, mainly growth differentiation factor-9 (GDF-9) and bone morphogenetic protein 15 (BMP-15) encourage the development of preantral and small antral follicles from their primordial and primary stages, leading to small-follicle excess which produces AMH in increased concentrations.
- A higher initial population of primordial follicles and/or slower atresia could also exist.[25]
- Follicular defect in PCOS compared with normal folliculogenesis is shown in **Figure 3**.
- Arrested follicles are hyperresponsive to gonadotropins (GTs) and prematurely reach a level of maturity where they produce sufficiently high levels of circulating estradiol (E2), suppressing FSH to a level that is too low to encourage further development of healthy follicles in the cohort **(Flowchart 3)**.
- Relative FSH deficiency → impairs aromatization of androgens to estrogens in granulosa cells → impairs follicular development and maturation and luteal progesterone release → sustained HA and ovulatory dysfunction.[21]
- Interference with dominance: The attenuated FSH responsiveness and premature luteinization of granulosa cells distort the selection of the dominant follicle (DF), leading to follicular arrest.
- Lacker's model: Tracks the maturity of a cohort of follicles as a function of time through the selection phase. If all follicles are of "low sensitivity", then normal ovulatory

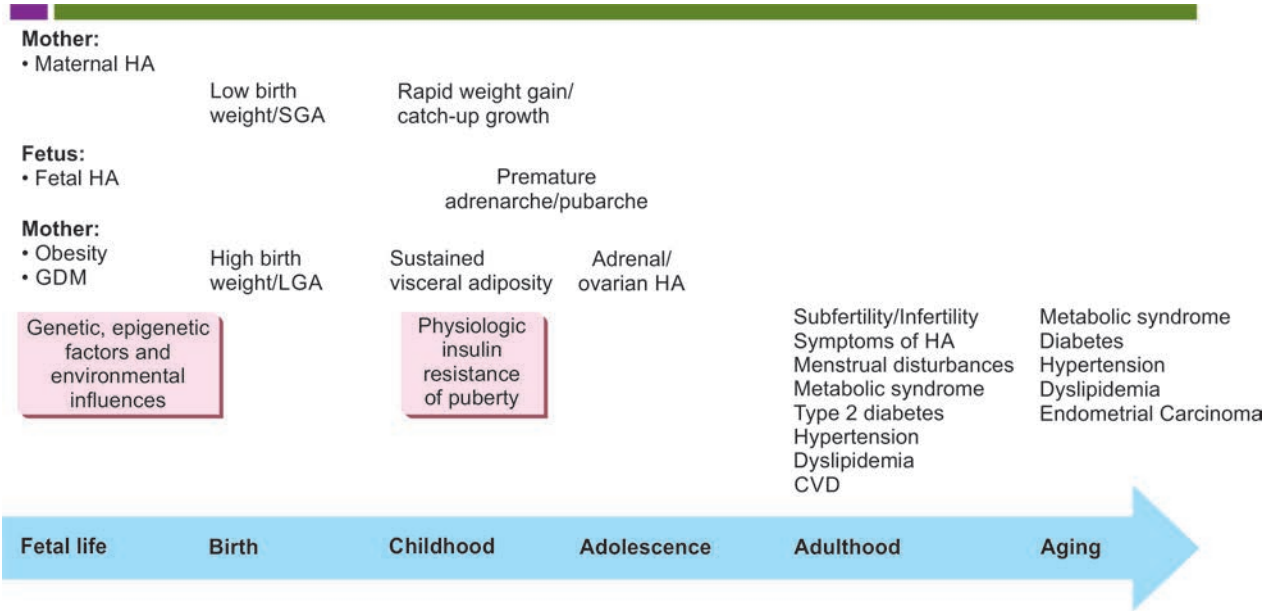


Fig. 2: Proposed evolution of PCOS from fetal life to adulthood. (CVD: cardiovascular disease; GDM: gestational diabetes mellitus; HA: hyperandrogenism; LGA: large for gestational age; SGA: small for gestational age)

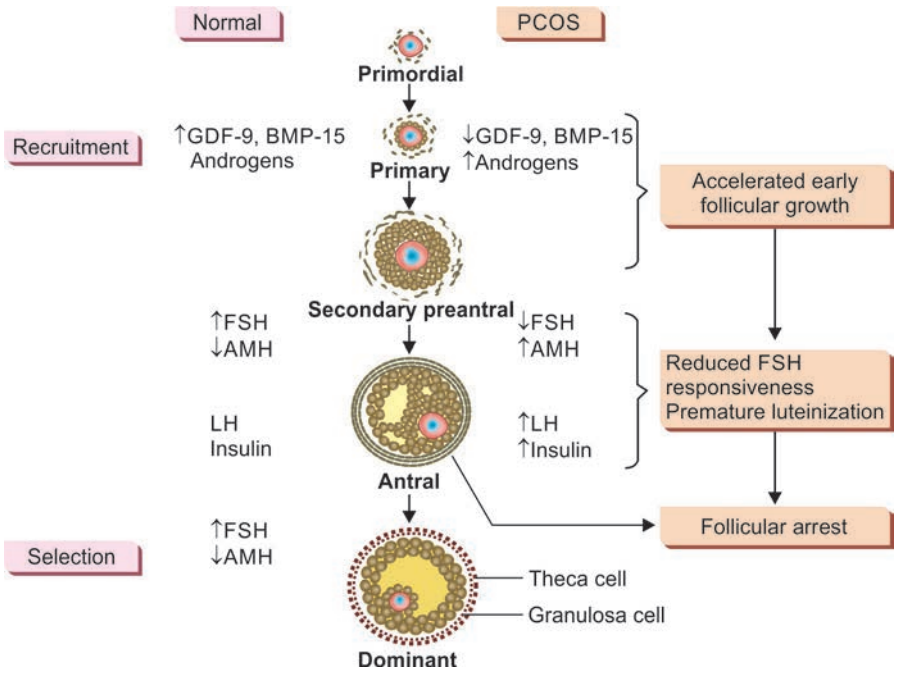

Fig. 3: Normal folliculogenesis and follicular defect in polycystic ovary syndrome (PCOS).
(AMH: anti-Müllerian hormone; BMP-15: bone morphogenetic protein 15; FSH: follicle-stimulating hormone; GDF-9: growth differentiation factor 9; LH: luteinizing hormone)
Source: Diamanti-Kandarakis E.[25]

cycles occur and if the majority of follicles are of "high sensitivity" then it results in a follicular arrest.[26]

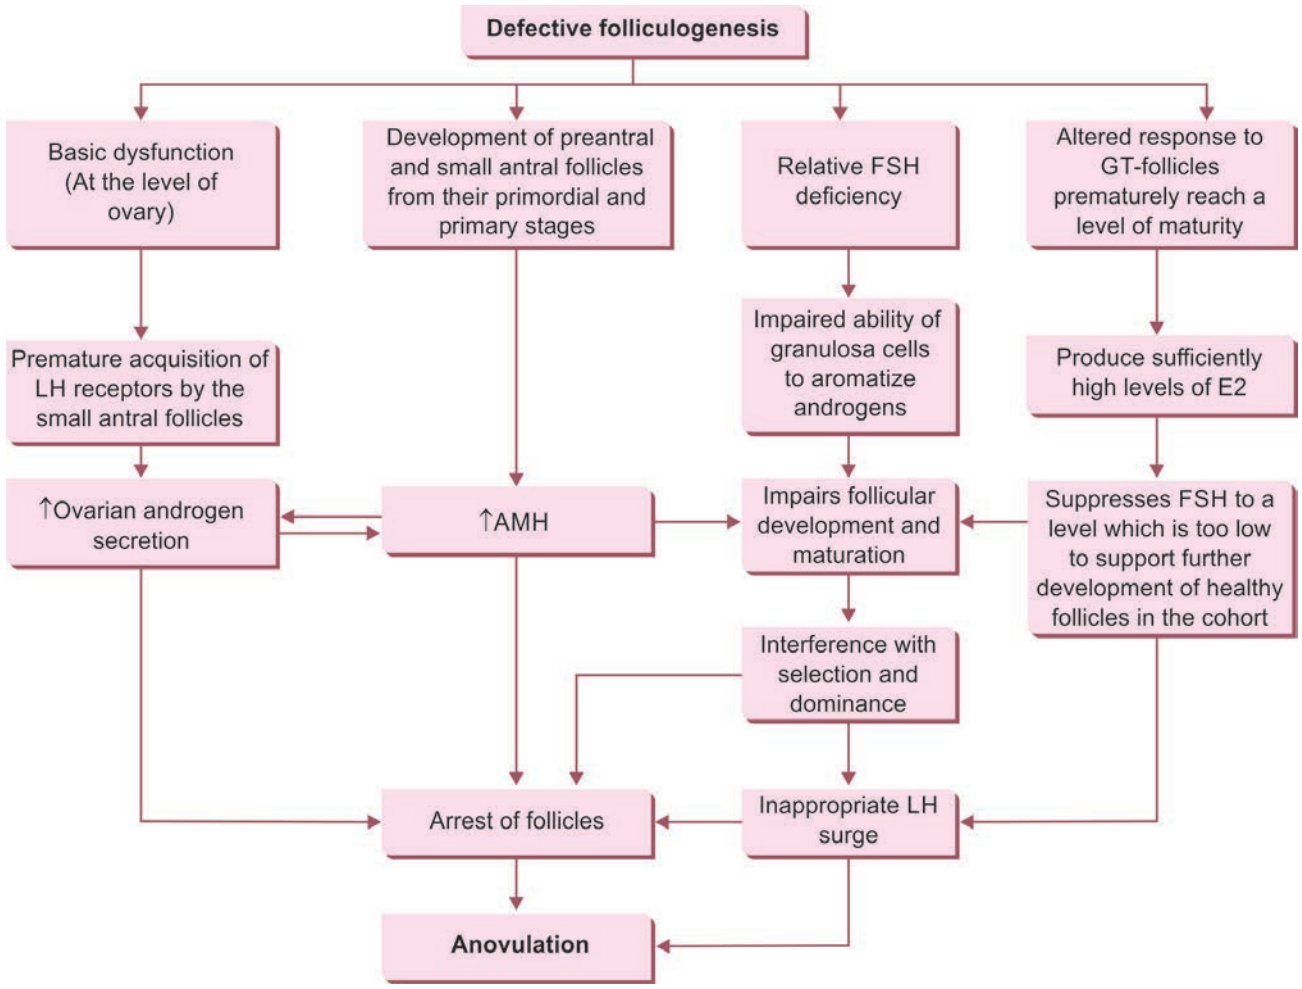
Abnormalities of estrogen secretion:

- Estrogen secretion, especially E2, is usually low-to-normal without midcyclic increase due to arrested folliculogenesis.[26]
- High production of testosterone results in high estrone levels, further increasing LH levels, which in turn results in hyperplasia of the ovarian stroma and theca cells, leading to increased androgens, thus perpetuating the vicious cycle of excessive androgen and LH production.

Role of anti-Müllerian hormone:

- Anti-Müllerian hormone, a member of the TGF-beta superfamily, is derived specifically from the granulosa cells of early developing preantral and antral follicles.

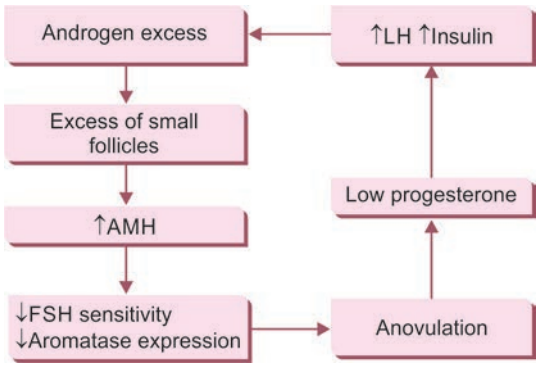
Flowchart 3: Defective folliculogenesis.



(AMH: anti-Müllerian hormone; E2: estradiol; FSH: follicle-stimulating hormone; GT: gonadotropin; LH: luteinizing hormone;)

- PCOS has increased (2–3-fold) circulating concentrations of AMH due to:[27,28]
  - Increased AMH production by individual follicles
  - Abnormally elevated LH
  - Elevated androgens
  - – HI
  - Advanced glycation end products (AGEs), or decreased soluble receptor for AGE (sRAGE)
  - Genetic factors such as variants of *ACVR1* gene 3
  - Increased follicular number (FN) with increased granulosa cell mass
- Increased AMH levels inhibit FSH-stimulated follicular activation and growth resulting in the arrest of follicles
- AMH also inhibits the action of FSH-induced aromatase production which is likely to contribute to HA.[21]
- AMH has a paracrine effect on theca interna cells, leading to theca cell dysregulation, resulting in increased androgen production.
- Stockpiling effect: AMH Hypothesis **(Flowchart 4)**.[21]
- AMH has good predictive accuracy for PCOS and correlates with the severity, making it a good candidate as an additional criterion for the diagnosis of this syndrome.[29]

Flowchart 4: Stockpiling effect: AMH hypothesis.



(AMH: anti-Müllerian hormone; LH: luteinizing hormone; FSH: follicle-stimulating hormone)

- Elevated serum AMH concentrations are predictive of poor response to various therapies of PCOS including weight loss, ovulation induction (OI), metformin therapy, and laparoscopic ovarian drilling (LOD), while responders to treatment were found to have a decline in AMH levels.[28]

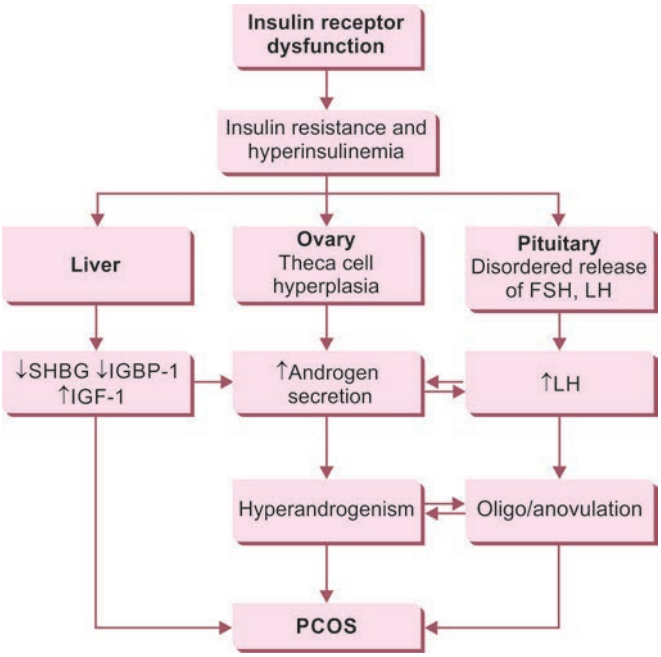
Adrenal Hyperandrogenism

- Increased adrenal activity of P450c17.[23]
- Insulin indirectly enhances hypothalamic corticotropin-releasing hormone (CRH) secretion.[23]
- Adrenal hyperresponsiveness to adrenocorticotropic hormone (ACTH)
- Accelerated cortisol turnover secretion.

Insulin Hypothesis

- Insulin resistance is defined as "a state (of a cell, tissue, or organism) in which a greater than normal amount of insulin is required to elicit a quantitatively normal response" and maintain glucose levels within the normal range.[30,31]
- HI occurs secondary to resistance at the insulin receptor, decreased hepatic clearance of insulin, and/or increased pancreatic sensitivity.
- Overall IR is seen in 50–70% of PCOS (approximately 80–95% of obese PCOS and 40–75% of lean PCOS).[30,31]
- Insulin acts through its receptor to initiate a cascade of post-receptor events within the target cell. Phosphorylation causes insulin receptor substrates 1–4 (IRS1–4) to promote glucose uptake via the transmembrane glucose transporter type 4 (GLUT4), and also intracellular protein synthesis.
- In PCOS, the binding of insulin to the receptor induces serine phosphorylation instead of tyrosine autophosphorylation. Serine phosphorylation increases the activity of P450c17 in both the ovary and adrenal, thus promoting androgen synthesis.
- Individuals with IR may be overtly diabetic or merely have IR detected by testing.
- Methods for detecting IR:[31]
  - Euglycemic hyperinsulinemic clamp technique is the gold standard test and measures insulin-mediated glucose disposal in vivo. However, it has no clinical application, as it is invasive, expensive, and time-consuming, and requires experienced personnel.
  - Determination of insulin levels—fasting state or after oral glucose tolerance test (OGTT) and measurement of fasting glucose/insulin ratio
  - HOMA—homeostasis model assessment index
  - QUICKI—quantitative insulin sensitivity check index
  - Insulin tolerance test—assessment of sequential plasma glucose levels after administration of intravenous insulin.
  - FSIVGTT—estimation of an index of insulin sensitivity, by applying the minimal model technique to data obtained from the frequently sampled intravenous glucose tolerance test (FSIVGTT).
- All of the above measures have limitations, primarily the lack of a standardized universal insulin assay, changes in beta-cell function with the development of diabetes (which alters the sensitivity of the tests), and normal physiological fluctuation in insulin levels.[31]
- The degree of HI correlates with the syndrome's severity.[30]
- Specifically, resistance to the metabolic actions of insulin has been reported in the liver, skeletal muscle, and adipose tissue, whilst the adrenal gland and ovary are insulin-sensitive.
- HI suppresses hepatic SHBG production and exacerbates HA **(Flowchart 5)**.[32]
- Although IR and HI are central to the pathophysiology, it is not a part of the diagnostic criteria.
- It is still been debated whether HA results from HI or HI results from HA or they are independent variable.[33]

Flowchart 5: Insulin resistance leading to PCOS.



(FSH: follicle-stimulating hormone; IGBP-1: insulin growth factor-binding protein; IGF: insulin growth factor; IR: insulin resistance; LH: luteinizing hormone; PCOS: polycystic ovary syndrome; SHBG: sex hormone-binding globulin)

Altered Sympathetic Nervous System

There is evidence of high sympathetic activity in PCOS, independent of BMI, with animal models to support increased sympathetic innervation in the appearance of cysts.[34]

AT THE PERIPHERAL COMPARTMENT (SKIN AND ADIPOSE TISSUE)

- In the skin, HI increases the activity of the enzyme 5-alpha (α)-reductase which converts testosterone to the stronger androgen dihydrotestosterone (DHT) causing hirsutism and acne.

- HI stimulates insulin-like growth factor receptor 1 (IGFR-1) present in the epidermis which leads to stimulation of tyrosine kinase growth factor-signaling pathways, causing proliferation of keratinocytes and fibroblasts, leading to skin thickening, resulting in acanthosis nigricans. Histopathology of acanthosis nigricans shows hyperkeratosis, acanthosis, and papillomatosis with or without basal hyperpigmentation.
- In cases of severe IR, hyperandrogenic insulin-resistant acanthosis nigricans (HAIRAN) syndrome is seen.
- In adipocytes, testosterone appears to induce serine phosphorylation of IRS-1, with upregulation of lipase expression in visceral adipose tissue (VAT) resulting in visceral adiposity and associated health disorders.

Associated Features

Inositol Deficient State

- Inositol (InS) is a member of the vitamin B-complex family. It is not an essential vitamin, as it can be manufactured by the body, but it tends to be deficient in women with PCOS.
- Free InS is transported actively across the intestinal wall by a sodium-dependent active mechanism, a process that can be inhibited by glucose. Circulating InS is then taken up by tissues by a membrane-associated sodium-InS cotransport mechanism.
- InS is incorporated into cell membranes as phosphatidyl myo-inositol (MI), the precursor of inositol phosphatidyl phosphate (IP3), which acts as a second messenger for both insulin and FSH, causing glucose uptake and FSH signaling.
- In human ovaries, 99% of the intracellular pool of InS comprises MI and the remaining consists of D-chiro-inositol (DCI). DCI is synthesized from MI through the epimerase enzyme in the theca cells, which in turn is stimulated by insulin.
- In PCOS, there occurs a defect in tissue availability or altered metabolism of inositol phosphoglycans (IPGs) or IPG mediators and increased epimerase activity, all leading to deficiency of MI, which decreases phosphatidylinositol-3-kinase (PI3K) activity and IP3 **(Fig. 4)**.[35]
- MI causes the release of calcium in the oocyte through IP3 and thereby promotes both nuclear and cytoplasmic maturity of the oocytes. A correlation between MI concentration in the follicular fluid and high oocyte quality has been reported in a few studies.[36]
- In PCOS, MI deficiency and increased DCI/MI ratio may adversely affect glucose uptake and metabolism of both the oocytes and follicular cells, probably compromising the oocyte quality.

Leptin Resistance

- Both obese and lean PCOS have higher circulating concentrations of leptin. However, leptin resistance is more commonly seen in insulin-resistant and obese PCOS as compared to lean PCOS.[37]
- Abnormalities of leptin secretion causes defective suppression of appetite, which perpetuates obesity in PCOS.
- Hyperleptinemia is inversely related to the degree of fertility.

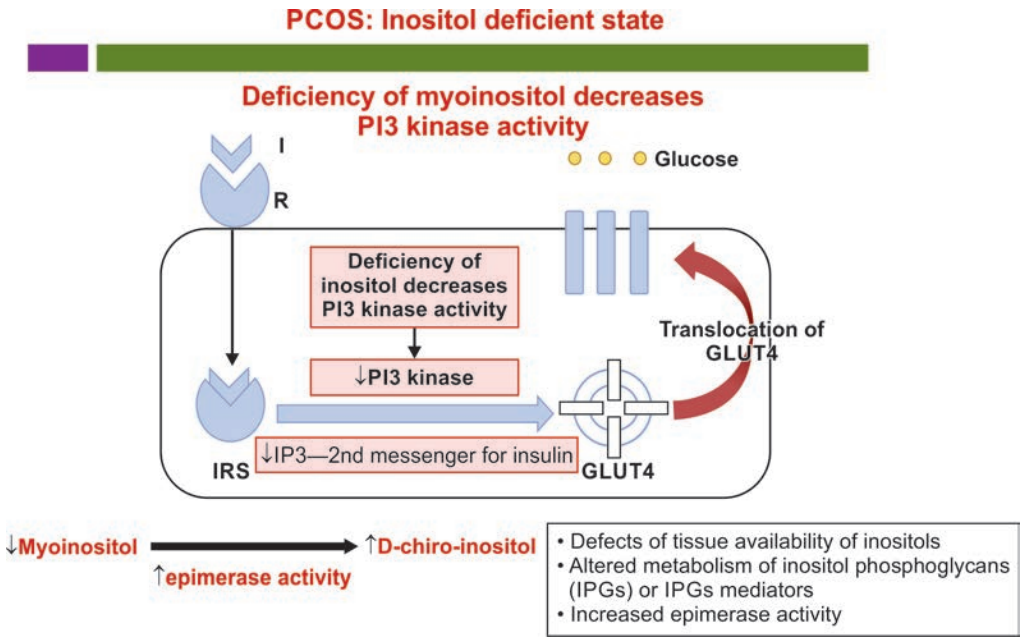


Fig. 4: Inositol deficiency.
(GLUT4: glucose transporter type 4; IP3: inositol phosphatidyl trisphosphate; IRS: insulin receptor substrates; PI3K: phosphatidylinositol-3-kinase)

- At the level of the ovary, deficiency of leptin or of its receptors and hyperleptinemia impairs the selection of DF causing the arrest of follicular development. It also decreases oocyte maturity and fertilization contributing to poor quality embryos and endometrial dysfunction, all resulting in lower pregnancy rates (PRs).[31,37]

Obesity and Polycystic Ovary Syndrome

- Obesity is seen in about 50–65% of women with PCOS.[37]
- Rather than PCOS leading to obesity, obesity amplifies the clinical severity of PCOS, thereby increasing the risk of metabolic dysfunction.[37]
- Obesity is associated with a reduction in SHBG, and a consequent increase in free testosterone.[36]
- There is an increased number of adipocytes that amplifies IR and HI, exacerbating HA.[3]
- Increased 5α-reductase activity and an increase in ACTH drive associated with obesity also contributes to HA.[37]
- The "adipose tissue expandability hypothesis" may also account for the pathogenesis of PCOS in some individuals.[38] An individual's metabolic set-point determines the caloric load which can be stored safely in the adipose tissues. A caloric load which exceeds this set-point results in lipotoxicity [condition with elevated free fatty acids, hypertriglyceridemia, low adiponectin levels, and high interleukin-6 (IL-6) and tumor necrosis factor alpha (TNF-α)], and the potential for ectopic fat deposition (fat in nonadipose tissues such as liver, skeletal muscle, and pancreas), all of which contribute to IR and its consequences.[38]
- Apple-shaped (android) obesity with visceral adiposity, typically seen in PCOS is associated with a more adverse metabolic risk profile than pear-shaped (gynecoid) obesity.
- It has been observed that ovulatory women as compared to anovulatory women with PCOS have lesser visceral obesity and exhibit lesser adipocyte dysfunction.[39]
- Measurement of waist circumference, therefore correlates more closely with metabolic risk than BMI.
- Circulating concentrations of adiponectin were found to be lower in both lean and obese PCOS, when compared to women without PCOS.[40] It is known that adiponectin is protective against IR, diabetes, and CVD, and also inhibits androgen production by theca cells.
- Obesity negatively affects fertility, reduces the response to GTs, and adversely affects both implantation and PR.[41]
- In adipose tissue, relatively inert androgens undergo aromatization into estrogens, predominantly estrone, causing menstrual dysfunction more so in obese women and it is this group, who are at risk of endometrial carcinoma by the unopposed estrogenic stimulation.
- The metabolic phenotype of PCOS (obesity, acanthosis nigricans, and IR) is predominantly seen in South Asians.[15]
- Obese PCOS has a higher incidence of IR, which predisposes to both impaired glucose tolerance (IGT) and T2DM.[42]
- *Oxidative stress and low-grade inflammation:* These are two features shared by both obese and nonobese PCOS due to:
- Advanced glycation end products: Hyperglycemia with induction of alternate pathways—hexosamine, polyol, and protein kinase C pathways causes oxidative damage with the release of free radicals, reactive oxygen species (ROS), and AGE, resulting in endothelial dysfunction. They increase vascular permeability and arterial stiffness, inhibit vascular dilatation by interfering with nitric oxide (NO), and also bind macrophage, endothelial, and mesangial cells to induce the release of a variety of cytokines.[43]
- AGE–RAGE system interaction: AGEs circulate and act on cell surface receptors, such as the receptor for AGE (RAGE). AGE receptors in circulating blood, called soluble RAGEs (sRAGE) can bind their ligands (AGEs) in the circulation, thus preventing the adverse intracellular events of the AGE–RAGE axis. The AGE–RAGE system interaction leads to activation of secondary messenger, activating nuclear factor-kappa B leading to the development of a proinflammatory state, cellular toxicity, and damage. In PCOS, there is an increased activity of this system at the serum, adipose tissue, and ovary levels **(Flowchart 6)**.
- In PCOS, numerous biochemical inflammatory and thrombotic markers of CVD risk circulate in excess like TNF-α, IL-6, IL-18, IL-17, factor VIIc, tissue plasminogen activator (tPA), fibrinogen, plasminogen activator inhibitor-1 (PAI-1), thrombomodulin, D-dimers, antithrombin III (ATIII), asymmetric dimethylarginine (ADMA), AGEs, malondialdehyde (MDA), and NO compared with non-PCOS controls.[44,45]

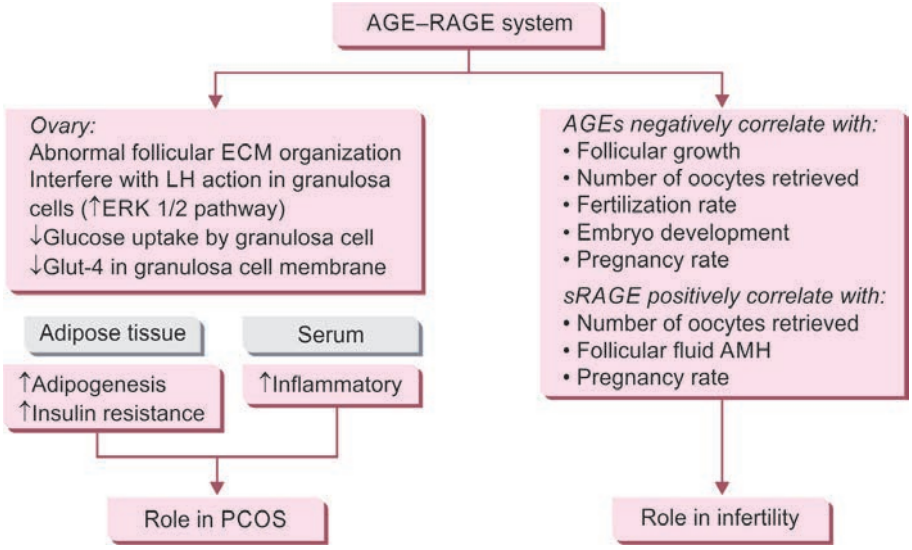
Vitamin D Deficiency

- Vitamin D binds to the vitamin D receptor, activates the peroxisome proliferator activator receptor-γ, and stimulates the expression of insulin receptors, thereby enhancing insulin-mediated glucose uptake.[46,47]
- Vitamin D deficiency in PCOS contributes to IR, HA, ovulatory dysfunction, and MebS.[46,48]

Role of Melatonin in PCOS

- Melatonin is a hormone of the pineal gland which maintains normal circadian rhythms and governs the release of pituitary GTs.

Flowchart 6: Relationship of the AGE–RAGE system with PCOS and infertility.



(AGE: advanced glycation end products; AMH: anti-Müllerian hormone; RAGE: receptor for AGE; ECM: extracellular matrix; ERK: extracellular signal-regulated kinase; sRAGE: soluble RAGE; GLUT-4: glucose transporter type 4)
Source: Merhi Z.[44]

- ROS produced within the follicles, especially during ovulation are scavenged by melatonin, thereby reducing the oxidative stress involved in oocyte maturation and embryo development.
- In PCOS, even if there are high concentrations of melatonin in serum, there is a deficiency of this indoleamine within the follicles resulting in low intrafollicular melatonin levels, affecting follicular growth, ovulation, and oocyte quality.[49]
- Melatonin can also alter the leptin levels, contributing to the pathophysiology of PCOS.[49]

Environmental Factors

It has been observed that serum levels of bisphenol A (BPA) are elevated and associated with hormonal and metabolic abnormalities in PCOS compared with BMI-matched healthy controls.[50] However, this needs to be further evaluated.

Immune Dysfunction

- Those with shorter leukocyte telomere lengths were found to have a higher risk of PCOS than those with longer telomere lengths, after adjustment of age.[51]
- All PCOS phenotypes have increased CD^4+$CD28^{null}$ T lymphocytes compared to controls, with the nonhyperandrogenic phenotypes showing the highest levels. $CD4^+CD28^{null}$ exerts proinflammatory, proatherogenic activity, by producing high levels of interferon (IFN)-γ, TNF-α, IL-2, and cytolytic enzymes, all of which increase the risk of cardiovascular (CV) events. Hence, CV risk evaluation should be performed in all PCOS phenotypes.[52]

Follicle-stimulating Hormone Receptor Polymorphism

- The FSH receptor variants Alanine–Threonine change at position 307 (Ala/Thr 307) and serine–serine at position 680 (Ser/Ser 680) were found to be significantly more prevalent among anovulatory women.[53,54]
- The FSH receptor polymorphism homozygous of Ser/Ser 680 allelic variant was associated with higher basal FSH and LH levels, higher frequency of HA, decreased FSH sensitivity, decreased ovarian responsiveness, requiring a significantly higher GT dose compared with Asn/Asn 680 and Asn/Ser 680 variants.[54,55]
- Also, in a few studies, the genotype asparagine—Asn68054 and alanine—Ala307 of the FSH receptor has been correlated with the risk of developing ovarian hyperstimulation syndrome (OHSS).[55]

Lean versus Obese Polycystic Ovary Syndrome

- About 20–50% of women with PCOS are of normal weight or thin.[56]
- HI is a common finding in both obese and nonobese PCOS populations. However, lean PCOS tends to have comparatively lower HI and IR.[57]
- The degree of HI- and HA-related clinical features is more pronounced in obese as compared to lean PCOS.
- HI in lean PCOS is due to increased pancreatic β-cell activity and reduced hepatic clearance of insulin.[56]
- Leptin resistance and adipokines inhibit GnRH secretion, hence lower LH levels in obese women, compared to lean PCOS, who tend to have higher LH levels.
- Differences between lean versus obese PCOS are shown in **Table 4**.

- Lean PCOS treated with metformin for 4–6 weeks demonstrated a decrease in insulin concentrations, a decrease in free and total testosterone concentrations, with the restoration of menstrual cycles.[57]

Management of Lean Polycystic Ovary Syndrome[58]

Management of lean PCOS is depicted in **Flowchart 7**.

TABLE 4: Differences between obese versus lean polycystic ovary syndrome (PCOS).

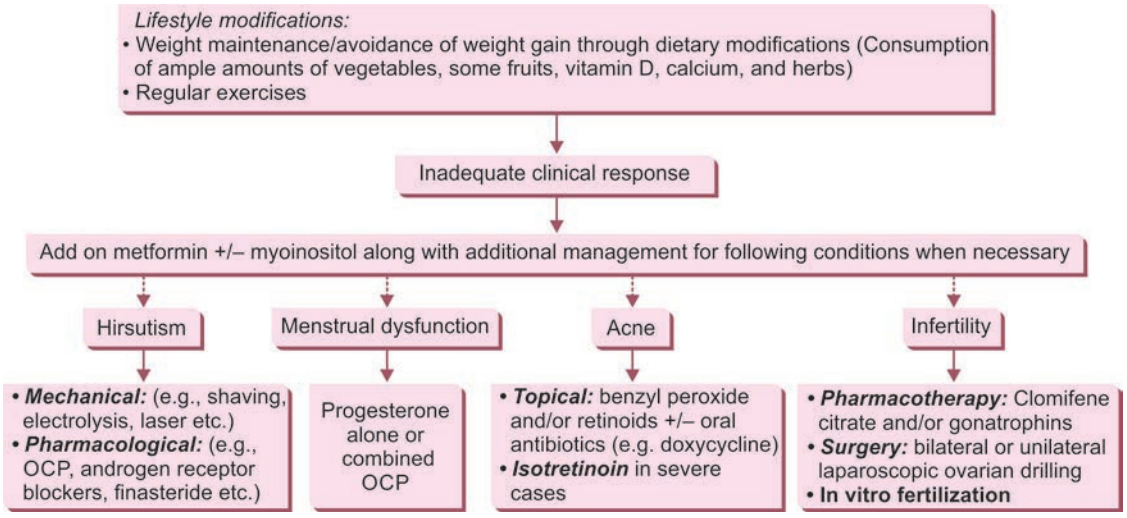
	Obese	***Lean***
LH/FSH	↑	↑↑ Defect in HPO axis
↑Androgen secretion	↑IGF-1 ↓IGFBP-1 ↓SHBG	↑GH
Hyperinsulinemia	IR	↑β-Cell function Decreased hepatic clearance of Insulin
IR	+++	+
Androgens	Testosterone + DHEAS	Testosterone
Hypertension	↑↑	↑
IGT	↑↑(about 30–35%)	↑(about 10%)
Diabetes mellitus	↑↑ (about 7–10%)	↑(3%)
Endometrial hyperplasia	↑↑	↑

(DHEAS: dehydroepiandrosterone sulfate; FSH: follicle-stimulating hormone; GH: growth hormone; HPO: hypothalamic-pituitary-gonadal ; IGF-1: insulin-like growth factor 1; IGFBP-1: insulin-like growth factor–binding protein 1; IGT: impaired glucose tolerance; IR: insulin resistance; LH: luteinizing hormone; SHBG: sex hormone-binding globulin)

Metabolic Complications

- Women with PCOS have an estimated 2.2-, 2.5-, and 4-fold increased prevalence of metabolic dysfunctions, IGT, and T2DM, respectively in both BMI and non-BMI-matched studies.[42,59]
- Dyslipidemia is the most common metabolic dysfunction in PCOS,[58] and PCOS is the leading cause of dyslipidemia among women of reproductive age.[61]
- Classic PCOS demonstrates 75–85% of IR, some form of metabolic dysfunction, and is at increased risk of IGT and diabetes.[15,62]
- Oxidative stress caused by ROS production in immune cells plays a fundamental role in the genesis and progression of endothelial dysfunction, which leads to the development of arterial hypertension and CVD.[63]
- Cross-talk between IR and chronic inflammation generates an environment conducive to the development of cardiometabolic disorders.
- MEbS or the IR syndrome or "syndrome X", first described in 1988 is a constellation of risk factors, identified as a "common soil" for the development of both CVD and T2DM.[64]
- Two classifications are used to define MebS. Firstly, under the National Cholesterol Education Program
- Adult Treatment Panel (NCEP ATP) III criteria[64] modified for the Asian population,[65] MebS is present, if at least three out of five criteria are present **(Table 5)**. Secondly, according to International Diabetes Federation,[66] the diagnosis of MebS requires WC >80 cm, and additionally two of the criteria as mentioned in **Table 5**.
- Prevalence of MebS varies, based on age, gender, and ethnicity, from 7% to 50%, with South Asians having a high prevalence of about 50% and in India being 7.9–46.5%.[67]
- The prevalence of MebS, hypertension, and dyslipidemia was observed to be increased in mothers, fathers, sisters,

Flowchart 7: Management algorithm for Lean polycystic ovary syndrome.



(OCP: oral contraceptive pill)

TABLE 5: Diagnostic criteria for the metabolic syndrome according to NCEP ATP III.[60]

Three of the following conditions:	
I. Central obesity (waist circumference in cm): • Male • Female	 ≥102 ≥88
II. Elevated triglycerides (mg/dL)	≥150
III. Decreased HDL cholesterol (mg/dL): • Male • Female	 <40 <50
IV. Elevated arterial blood pressure (mm Hg)	≥130/85
V. Elevated fasting blood glucose (mg/dL)	≥110

Source: Third Report of the National Cholesterol Education Program (NCEPIII) Expert Panel on Detection, Evaluation and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, ATP III).

BOX 1: Polycystic ovary syndrome (PCOS) who are at risk of metabolic dysfunction and cardiovascular disease (CVD).[63]

At high risk, if:
- Metabolic syndrome
- Type 2 diabetes mellitus
- Overt vascular or renal disease

At risk, if:
- Obesity (especially abdominal)
- Smoking
- Dyslipidemia
- Impaired glucose tolerance
- Hypertension
- Subclinical cardiovascular disease
- Family history of premature CVD

Source: Wild RA, et al.[63]

and brothers of PCOS women as shown in a recent systematic review.[61]

- Genetics, lifestyle, obesity, and IR are all etiological factors in the development of MebS.[61]
- PCOS individuals with a BMI > 30kg/m^2, and high-risk ethnic groups including South Asian, Hispanic, and Polynesian women with a BMI >25 kg/m^2, dyslipidemia, overt vascular or renal disease, or family history of T2DM are at risk of metabolic dysfunction **(Box 1)**.[68,69]
- The presence of MebS is one of the strongest and earliest predictors of CVD **(Box 1)**.[63] Hence, both the American College of Obstetricians and Gynecologists (ACOG) and the AEPCOS guidelines recommend that PCOS patients should have a complete fasting lipid profile evaluation as a part of CV risk assessment.[13,63]

CLINICAL PRESENTATION

Symptoms

- *Hirsutism, acne, and alopecia*: These are dermatological manifestations of HA which vary widely between different ethnic groups.
  - *Hirsutism*, excessive growth of thick, terminal, coarse hairs in androgen-dependent areas of the face and/or body in females in a male-type pattern, is seen in about 75–80% of PCOS. The modified Ferriman–Gallwey score is used to grade hirsutism.[11] A score of 0 (none) to 4 (severe) in nine areas of the body is assigned a maximum score of 36. Scores of <4 indicate mild, 4–7 moderate, and ≥8 severe hirsutism.[11]
  - *Acne*, a pilosebaceous unit disorder occurring predominantly on the lower face, neck, chest, and upper aspect of the back, occurs in about 20–40% of PCOS.[11]
  - *Androgenic alopecia* or male pattern balding is seen in severe cases of androgen excess and is relatively less common in PCOS. Diffuse loss of hair occurs from the anterior mid-vertex area extending to the crown with preservation of the frontal anterior hairline, and is seen in about 10% of PCOS cases.[11] It is graded according to the Ludwig's visual score.
- *Menstrual disturbances* are seen in about 60–85%.[69] The degree of ovarian dysfunction, the amount of follicular activity, and the circulating concentration of estrogens stimulating endometrial development will determine whether women would have amenorrhea or oligomenorrhea (cycle length more than 35 days). Sporadic anovulatory cycles do occur among regularly menstruating women. About 47% will have oligomenorrhea (8 or fewer cycles per year), amenorrhea in about 51%, and polymenorrhea (frequent cycles occurring at intervals of <26 days in length) in about 1.5–2.7%.[69]
  - *Normal menstrual cycles* are seen in about 12–20%.[11,30,31]
  - *Abnormal uterine bleeding (AUB)*:[30,36] AUB is due to chronic unopposed action of estrogen on the endometrium, seen in about 29% of cases.
- In the absence of ovulation, there is continued endometrial proliferation without progesterone-induced shedding. The endometrium being fragile, and vascular with minimal stroma results in bleeding that is erratic, and inconsistent in duration, cycle, and amount of flow. The ESHRE 2018 guidelines on PCOS define irregular menstrual cycles as follows:
  - Normal in the first year post menarche as part of the pubertal transition
  - >1 to <3 years post menarche: <21 or >45 days
  - >3 years post menarche to perimenopause: <21 or >35 days or <8 cycles per year
  - >1 year post menarche >90 days for any one cycle
  - Primary amenorrhea by age 15 or >3 years post thelarche (breast development). When irregular menstrual cycles are present, a diagnosis of PCOS should be considered and assessed according to the guidelines.[2]

- *Obesity:* 50–76%[30,37,69]
- *Asymptomatic*: 20%
- *Subfertility or infertility*: In about 74% of cases (50% with primary infertility and 25% with secondary infertility), due to oligo/anovulation and the combined effects of obesity, metabolic, inflammatory, and endocrine abnormalities on oocyte quality.[69]

Clinical Signs

- *Acanthosis nigricans:* Presents as dark brown, velvety, thickened cutaneous plaques, most often seen on the back of the neck, axillae, beneath the breasts, and exposed areas (elbows, knuckles). It has been reported in 5–10% of PCOS and in about 50% of obese PCOS.[69] Occurs as a result of IR, with an increased risk of diabetes, and lipid abnormalities. Management involves treating the underlying disorder and laser or surgical excision of the lesion. Although, topical tretinoin and calcipotriol have been used with limited success.
- *Clinical signs of HA*—hirsutism, acne, or alopecia
- *Obesity and central abdominal obesity*.

Signs of Polycystic Ovarian Morphology on Ultrasound

- *Polycystic ovarian morphology (PCOM):* Finding of increased follicle number per ovary [(FNPO) of ≥12] measuring 2–9 mm and/or increased ovarian size (OV ≥10 cc) in one or both ovaries on transvaginal sonography (TVS) as per the Rotterdam criteria **(Fig. 5)**[9,69] Recently ESHRE has updated the transvaginal ultrasound criteria as a FNPO of >20 and/or an OV ≥10 mL, ensuring no corpora lutea, cysts or DFs are present.[11]
- The AEPCOS task force observed that 70–90% of women with PCOS would demonstrate PCOM, although the false-positive rate was as high as it was seen in up to one quarter of unselected reproductive-aged women.[11] However, the observed frequency of PCOM in the PCOS population in a recent systematic review was found to be 28–40%. Depending on the age and ethnicity of the study population:[15]
  - FN thresholds do not apply to women <18 and >35 years.
  - Stromal hyperechogenicity is due to stromal abundance.
  - Arrangement of antral follicles may have a generalized or peripheral distribution.
  - Arrangement of follicles and stromal echogenicity, however, is not relevant to making a diagnosis.[9]
  - Unilateral PCOM is also diagnostic.[9]
  - PCO can also be observed during pubertal development, in about 25–30% of normal women and in those using oral contraceptive pills (OCPs) (about 14%), and in about 30–50% of patients with functional hypothalamic anovulation.[13,30]
  - FNPO ≥12 threshold leads to overdiagnosis of both PCOM and PCOS. Therefore, with the availability of better ultrasound resolution (i.e., transducer frequency ≥8 MHz) to identify even follicles smaller than 2 mm, the FNPO threshold was raised to 19 and subsequently ≥25, which gave a sensitivity of 81% and specificity of 92% for making a diagnosis of PCOS.[70] However, there is no consensus on the precise number.[68]
  - FNPO is recommended over OV, since FNPO has been shown to have greater predictive power for PCOS and less variability among populations aged 18–35 years. OV may have a role in instances when image quality does not allow for reliable estimates of FNPO, especially when the transvaginal route is not feasible.[70]
- *Differential diagnosis of PCOM—multicystic ovaries:* Fewer cysts (6–10/ovary), larger (up to 10 mm), and distributed throughout the ovary with no stromal hypertrophy; seen in mid-late normal puberty, hyperprolactinemia, hypothalamic anovulation, and weight-related amenorrhea
- Three-dimensional ultrasound has allowed a better and more objective assessment of ovarian morphology, considerably reducing intra and interobserver variability of 2D imaging.
- *Other imaging variables used to define PCOM:*
  - *Assessment of ovarian stroma*: By 3D ultrasonography, stromal volume can be measured through calculation and subtraction of total follicular volume from the total OV. The ratio of ovarian stroma to the total ovarian size of 0.32 indicates an association with hyperandrogenaemia.[70]
  - *Ovarian vascularization:* A higher ovarian stromal blood flow and reduced uterine perfusion on 3D power Doppler is seen in PCOS. However, the lack of uniform data and absence of cut-off values make vascular indices impractical for discriminating between polycystic and normal ovaries.[70]

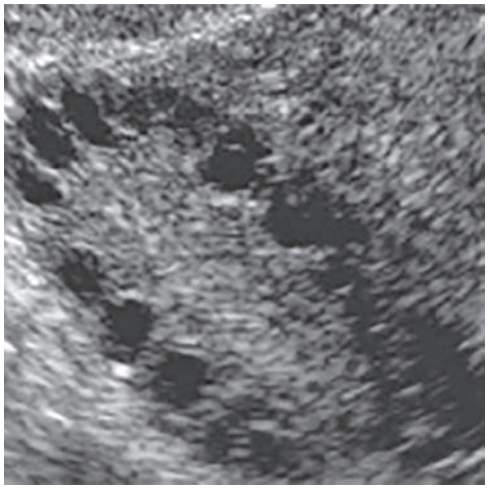


Fig. 5: Polycystic ovarian morphology on transvaginal sonography.

Possible Late Sequelae[62]

- Impaired glucose tolerance
- DM
- Dyslipidemia
- Hypertension
- CVD
- Nonalcoholic fatty liver disease
- Obstructive sleep apnea
- Quality of life (QoL) affected with manifestations of anxiety, depression, psychological, and behavioral disorders
- Endometrial hyperplasia
- Endometrial carcinoma—2.7–2.9-fold risk
- (?) Ovarian cancer and breast cancer.

EVALUATION

- Patient history of any predisposing factors to PCOS (low birth weight with excessive catch-up growth, history of large for baby syndrome, or premature adrenarche/pubarche) to be noted.
- *Family history:* Approximately 35% of mothers and 40% of sisters of women with PCOS are affected.[11] However, the phenotypic and genetic heterogeneity in the family, inconsistent diagnostic criteria, and relative infertility make linkage analyses difficult. Family history of T2DM to be noted.
- *Menstrual history:* Menarche and nature of menstrual cycle to be enquired about. Irregular cycles (>35 or <21 days) continuing for more than 2 years after the onset of menarche are likely to reflect oligoovulation or anovulation.[68]
- Psychological issues, depression, and/or anxiety should be routinely screened for and, if present, appropriate counseling and intervention should be offered by a qualified professional.
- Given that PCOS is a diagnosis of exclusion, the clinical evaluation of the syndrome is aimed at excluding other causes of androgen excess and menstrual dysfunction **(Box 2 and Table 6)**.

BOX 2: Differential diagnosis of polycystic ovary syndrome.

- Nonclassic or late-onset congenital adrenal hyperplasia (NC-CAH)-21-hydroxylase deficiency
- Androgen-secreting tumor
- Primary hypothalamic amenorrhea
- Primary ovarian failure
- Thyroid disorder
- Prolactin disorder
- Exogenous androgens
- Cushing syndrome
- Acromegaly
- Idiopathic hirsutism
- Genetic defects in insulin action

- *Evaluation of HA:* HA, detected in about 60–80% of PCOS, is yet challenging to diagnose. Either clinical evidence or biochemical assessment of HA should suffice to define HA in PCOS as the degree of hirsutism or acne that correlates poorly with circulating androgen concentrations.
- Virilization (masculinization of body musculature, severe or extreme male-pattern balding or hirsutism, clitoromegaly), rarely a sign of PCOS, suggests disorders of androgen-secreting tumors, or androgenic substance abuse or severe IR (i.e., mutations in the insulin receptor gene).[11]
- *Physical examination:* Blood pressure (BP), BMI, WC, signs of HA (hirsutism, acne, and/or alopecia), and signs of IR (acanthosis nigricans)
- *Measurement of waist circumference:* Ethnic-specific BMI cut-off points should include WC measurement to identify those at risk and apply secondary prevention despite a "lower" BMI in high-risk groups.
- Waist-to-hip ratio (WHR) can be used as a surrogate marker for central fat accumulation, with a value of >0.8 suggestive of visceral adiposity.[69]
- *Biochemical assessment of HA:* The total testosterone is generally more markedly elevated in PCOS and is a good screening tool to exclude other of androgen excess.[11]
- Since the existing assays for measurement of androgens lack accuracy, recently, liquid chromatography-mass spectrometry has been adopted as the gold standard by many of laboratories, although expensive and normal ranges for different populations are yet to be formulated.
- *Screening for glucose intolerance and HI:* 75 g OGTT is regarded as the "gold standard" to screen and detect abnormal glucose tolerance in PCOS who are at high-risk (obese) and in high-risk ethnic groups (South Asian, Hispanic, Polynesian) to be performed at initial evaluation.[68]
- PCOS up to 35% exhibits IGT (140–199 mg/dL) and up to 10% have noninsulin-dependent DM
- Women with PCOS who are overweight (BMI ≥25 kg/m^2) and who are not overweight (BMI <25 kg/m^2), but with additional risk factors such as advanced age (>40 years), personal history of gestational diabetes, or family history of type 2 diabetes (T2D), should have a two-hour post 75 g OGTT performed (*RCOG Green-Top Guideline*).[71]
- In those with impaired fasting glucose or IGT after a two-hour OGTT, an OGTT should be performed annually (*RCOG Green-Top Guideline*).[71]
- A serum HbA1c may be performed, if the patient is unable to complete the OGTT.[68] The American Diabetes Association (ADA) defines raised HbA1c as >5.7%, and as diagnostic for T2DM at >6.4%. However, this has not been validated as in PCOS, the intrinsic IR is primarily at the level of the skeletal muscle, rather than at the liver, and fasting glucose and HbA1c may not reflect post-OGTT hyperglycemia.[72]

TABLE 6: Investigational profile in polycystic ovary syndrome (PCOS).

Test	*Normal (N) and values in PCOS (may vary with local laboratory assays)*	*Additional points*
Pelvic ultrasound	• *B-mode ultrasound:* To assess: – Polycystic ovarian morphology (PCOM) – Endometrial thickness – Stromal echogenicity: Hyperechoic, more than the echogenicity of the myometrium – Stromal/ovarian area >0.32, in HA PCOS[70] • *Doppler*: Stromal vascularity: increased	• As per the Rotterdam criteria, follicular number per ovary (FNPO) for the definition of PCOM is ≥12 • The AEPCOS Task Force recommends FNPO with a threshold of ≥25, but only when using maximal resolution with transducer frequency ≥8 MHz[70] • Subjective with intraobserver and interobserver variability
Testosterone (T)	• Total T (N): 20–80 ng/dL (0.5–3.5 nmol/L); PCOS: >60 ng/dL ≤150 ng/dL (>2.5 but ≤5 nmol/L) • PCOS: free T >0.75 ng/dL • Elevated free T levels is observed in about 70% PCOS[11] • About 20% and 40% of PCOS will have androgen levels within the "normal" range[11] • DHEAS—(N): 100–360 mg/dL • PCOS—moderately elevated	• Total T ≥150–200 ng/dL (≥6.94 nmol/L) warrants further evaluation • Most commercial androgen assays are highly variable, inaccurate with little specificity • A total testosterone is adequate for general screening, preferably early morning sample[37] • The assay of minor androgens, like ASD or DHEAS, does not add much value and is primarily indicated in women with rapidly progressive virilization or severe clinical HA • DHEAS is elevated in 25–35% of PCOS[11] • Majority of those with elevated DHEAS, the free and total testosterone is also elevated[73] • Existing laboratory assays do not evaluate the hormonal bioactivity, explaining the poor correlation between circulating androgen levels and clinical symptoms
Free androgen index (FAI): T×100/SHBG	• FAI >8.5—PCOS • SHBG (N): 16–119 nmol/L; PCOS <5 nmol/L	• Insulin suppresses SHBG, resulting in a high FAI in the presence of normal total T • FAI is thought to be the most sensitive indicator of hyperandrogenism • Measurement of SHBG assists in calculating FAI, may have a role in metabolic assessment as a surrogate marker for IR in PCOS[68] • Limitation: expensive
• FSH • LH E2	• N: 2–8 IU/L • N: 2–10 IU/L • N: 50–80 pg/mL	• Measured in early follicular phase on days 1–5 of cycle or at random in those with amenorrhea or oligomenorrhea[68] • To rule out WHO 1 and 3 anovulatory disorders 70–75% of PCOS show elevated basal LH levels[9,11]
LH:FSH ratio		• ↑LH: FSH ratio (>2:1) has been regarded as a marker of PCOS, more so in lean than in obese PCOS • Ratio varies with assays used to measure. • Hence, not a reliable diagnostic criterion
AMH	• N: 1.1–3.5 ng/mL or 5–15 pmol/L • PCOS: >5 ng/mL or >35 pmol/L	• Serum AMH ≥35 pmol/L showed 92% sensitivity and 97% specificity in the diagnosis of PCOM. • Serum AMH level-surrogate marker, as a substitute for antral follicle count (AFC) in PCOS diagnosis.[74] • The lack of standardization of AMH assay makes it unreliable.

Contd…

Contd…

Test	*Normal (N) and values in PCOS (may vary with local laboratory assays)*	*Additional points*
• Prolactin • Thyroid-stimulating hormone (TSH)	• N: 25–30 ng/mL • b N: 0.5–2.5 mLU/L	• Measure if oligo-/amenorrheic • To rule out WHO 4 anovulatory disorders (hyperprolactinemic anovulation)
Assessment of ovulation: a. Progesterone (P4) b. Ultrasound (US)	a. Measure mid-luteal P4 levels 7 days before anticipated menses in two consecutive cycles	• A single mid-luteal phase (day 21) P4 >10 ng/mL or 30 nmol/L confirms ovulation • Limitation: Peak P4 levels remain only for a short time. Hence, sample not taken at appropriate time might result in a low value • The "gold standard" would be US confirmation of follicular development and subsequent evolution of the follicle to a corpus luteum, combined with biochemical evidence of ovulation[68] • Additionally, US assessment of the endometrium benefits
a. 17-Hydroxyprogesterone: 17-OHP b. 24-hour urine free cortisol c. Overnight dexamethasone suppression test	• 17-OHP >200 ng/dL—to do Corticotropin stimulation test • 17-OHP >800 ng/dL establishes the diagnosis of late onset congenital adrenal hyperplasia	a. To rule out nonclassical/late onset congenital adrenal hyperplasia and c. To rule out Cushing syndrome
a. Fasting insulin (FI) b. 2-hour post-prandial insulin (PPI) c. Fasting glucose/insulin (FG/FI) ratio	a. FI (N): <30 µU/mL; IR: >20–30 µU/mL b. PPI (N): <80–100 µU/ml; IR: >100 µU/mL c. FG/FI (N) >4.5; IR <4.5	Not routinely measured due to lack of standardized insulin assay Instead OGTT done
OGTT	2-hour 75 g glucose	a. Fasting values:[72] • Normal: <100 mg/dL • Impaired: 100–125 mg/dL • Type 2 DM: >126 mg/dL b. 2-hour glucose values:[72] • Normal: <140 mg/dL • Impaired: 140–199 mg/dL • Type 2 DM: 200 mg/dL IGT: in 35–45% of PCOS[62,75] Type 2 DM: Prevalence is 10–15%, increases by 2% annually[62] For 6.2 years, the conversion rate, from IGT to diabetes was 54%[75]
Others: a. Serum homocysteine (SH) b. Lipid profile c. Endometrial sampling	a. SH (N): 5–11 µmol/L; PCOS: >11 µmol/L[76] b. Triglycerides ≥150 mg/dL HDL cholesterol ≤40 mg/dL	c. Endometrial sampling in women with potential long-term exposure to unopposed estrogen stimulation

(AEPCOS: Androgen Excess and PCOS Society; AMH: anti-Müllerian hormone; ASD: androstenedione; DHEAS: dehydroepiandrosterone sulfate; DM: diabetes mellitus; FG: fasting glucose; FSH: follicle-stimulating hormone; HA: hyperandrogenism; IGT: impaired glucose tolerance; IR: insulin resistance; LH: luteinizing hormone; OGTT: oral glucose tolerance test; OHP: hydroxyprogesterone; SHBG: sex hormone-binding globulin)

BOX 3: Screening strategy for PCOS: Recommendations by the ESHRE Capri Workshop Group.[69]

- Measure BMI and waist circumference at every visit
- Complete lipid profile and repeat every 2 years if normal
- 2 hour 75-g oral glucose tolerance test (OGTT): Repeat every 2 years if normal, and sooner in those with the below mentioned risk factors. Consider using HbA1c
  - Age >40 years
  - BMI >25 kg/m^2 (Asian population)
  - Waist to hip ratio >0.85
  - Hyperandrogenemia with anovulation
  - Acanthosis nigricans-stigmata of IR
  - History of gestational diabetes mellitus (GDM)
  - Family history of DM
- Measure the clinical blood pressure at each visit.
- Suggestion: Assess for depression, anxiety and quality of life

(BMI: body mass index; DM: diabetes mellitus; ESHRE: European Society for Human Reproduction and Embryology; HbA1c: hemoglobin A1c; PCOS: polycystic ovary syndrome)

TABLE 7: Management of polycystic ovarian syndrome.

Lifestyle modification	Healthy diet and exercises to achieve and maintain optimal BMI
Manage dermatological manifestations	• OCPs • Antiandrogens
Manage menstrual dysfunctions	Regulation of menstrual cycle and induction of withdrawal bleeds: • OCPs • Progestins
Manage infertility	• Ovulation induction—oral ovulogens, gonadotropins • Laparoscopic ovarian drilling • Intrauterine insemination • In vitro fertilization
Manage adverse metabolic dysfunctions	• Improve insulin sensitivity—insulin sensitizers • Statins • Antioxidants

(BMI: body mass index; OCP: oral contraceptive)

- Screening strategy for PCOS as per the *Recommendations by the ESHRE Capri Workshop Group* **(Box 3)**.[69]
- TVS in those with AUB or oligomenorrhea (intervals between menstruation of more than 3 months corresponding to fewer than four periods each year) to evaluate the endometrial thickness and if evidence of hyperplasia, to consider endometrial sampling or hysteroscopic directed endometrial biopsy.

MANAGEMENT

It depends on the age, clinical manifestations of the disorder, and concern for fertility. Treatment is a multidisciplinary approach involving a gynecologist, pediatrician, endocrinologist, dermatologist, cardiologist, diabetologist, and geriatrician.[62] Management of polycystic ovarian syndrome is shown in **Table 7**.

First-line Treatment: Lifestyle Modifications

- *First-line therapy for all PCOS women:* Lifestyle modifications targeting weight loss in those obese and overweight and prevention of weight gain in lean women.[64-68]
- To optimize adherence with lifestyle interventions, psychosocial factors be considered and necessary support provided.

Weight Loss

About 5–10% of weight loss is found to be effective to decrease testosterone levels, increasing SHBG levels, attenuating IR and other metabolic aberrations, with a 30% reduction in visceral fat, normalizing cycles in 44% of patients, and thereby improving fertility.[69-77]

Methods:

- Diet: Atkins diet;[77] intakes of low-glycemic index diet such as vegetables, fruit, fiber, wholegrain foods, and high protein from vegetable sources. To avoid refined carbohydrates and transfat-containing hydrogenated oils. A low-calorie diet of ~1,000–1,200 kcal/day with a calorie restriction of 500 kcal/day restriction typically reduces total body weight by ~10% over 6 months.[77]
- Exercise: Aerobic exercises 3–4 times/week for 20–30 minute sessions burn 100–200 kcal with 40% improvement in insulin sensitivity in 48 hours.[78] The US Department of Health and Human Services (DHHS) guidelines recommend either 150 minutes of moderate-intensity exercise per week or 75 minutes of vigorous-intensity exercise.[78] PCOS patients should be encouraged for vigorous physical activity as it has been demonstrated that every hour of vigorous exercise reduced a patient's odds of MebS by 22%.[79]

Pharmacological agents:

- Amphetamines, rimonabant, and sibutramine licenses as antiobesity drugs have been withdrawn because of their adverse effects.
- Orlistat is a lipase inhibitor that acts by reducing intestinal absorption of fats. An oral dose of 120 mg three times a day with meals; also decreases the absorption of fat-soluble vitamins, especially vitamin D; mainly associated with gastrointestinal side effects and has been approved for long-term treatment of obesity.[80]
- Drugs recently approved by the United States Food and Drug Administration (US-FDA) are lorcaserin, phentermine plus topiramate extended-release,

naltrexone sustained-release, and liraglutide. However, the adverse effect profile of these pharmacological agents is yet to be understood and is not widely available for use in the majority of the countries.[81]

Bariatric surgery: Bariatric surgery may be an option for morbidly obese women with PCOS (BMI of 40 kg/m^2 or more or 35 kg/m^2 or more with a high-risk obesity-related condition) if standard weight-loss strategies have failed (RCOG Guideline 33).

Management of Hirsutism/Alopecia/Acne

Hirsutism

Antiandrogens:

- Spironolactone (aldosterone-antagonist diuretic): Mechanism of action—competitive antagonist for the androgen receptor, suppresses cytochrome P450, inhibits ovarian and adrenal steroidogenesis, and directly inhibits 5-α-reductase activity. Dosage—100–200 mg/day. Common side effects—numbness, muscle pain, nausea, hypotension, fatigue, dizziness, menstrual irregularity, and hyperkalemia; need to monitor potassium and creatinine levels
- Flutamide (androgen receptor antagonist): Inhibits androgen uptake. Dosage—250 mg/day; limited value because of its dose-dependent hepatotoxicity.
- Finasteride: Inhibitor of type II 5-α-reductase and blocks the conversion of testosterone to DHT. Dosage—5 mg daily. Adverse effects—hepatotoxicity. Contraindicated in women of reproductive age due to the risk of feminization of male fetuses and liver abnormalities; finasteride 0.05% as the gel has been used for the treatment of female pattern hair loss.
- Cyproterone acetate (CPA): It is the most commonly used antiandrogen with progestogenic activity. Mechanism of action—competition for 5-α-reductase and androgen receptors, and inhibits the action of testosterone and DHT and direct action suppressing ovarian androgen production. It can be used alone in the dose of 25–50 mg/day on cycle days 5–14 or combined with ethinylestradiol (EE) (CPA—2 mg + EE 20 μg/day on days 5–25) to provide cycle control in addition to amelioration of hyperandrogenic symptoms. Side effects—Headache, nausea, weight gain, decreased libido, fatigue, breast tenderness, and rarely hepatotoxicity.
- Antiandrogens should not be used without effective contraception due to the risk of teratogenicity (feminization of male infant) and to stop at least 6 months before pregnancy is planned.[62]
- Spironolactone and finasteride can be used as second-line treatments for the management of hirsutism in PCOS.

Combined hormonal OCP:

- Oral contraceptive pills with antiandrogenic progestins such as CPA, drospirenone, and desogestrel are used as the first-line agents for pharmacologic treatment of hirsutism in PCOS not willing to conceive.[82] OCPs act to reduce the androgen levels through these mechanisms:
  - Estrogen component increases hepatic SHBG production.
  - Suppression of LH secretion and thereby ovarian androgen production by progestogens
  - Competition for 5-α-reductase and androgen receptors by progestogens, thereby inhibiting the peripheral conversion of testosterone to DHT and binding of DHT to androgen receptors in the skin.
- Antiandrogenic progestogens such as CPA, chlormadinone acetate, desogestrel, and drospirenone can block the action of testosterone through competition on the androgen receptor at the tissue level.
- OCP containing CPA (2 mg CPA + 35 μg EE) and drospirenone (3 mg of drospirenone + 30 μg EE) and desogestrel (150 μg +30 μg EE) are more effective in reducing the growth of new terminal hair and acne formation. Further, drospirenone is a derivative of spironolactone (≈25 mg of spironolactone) and thus has direct antiandrogenic activity.[83]
- At least 6 months of medical therapy for hirsutism is necessary to see a therapeutic response.[62]

Dermatological interventions:

- Permanent methods of hair removal include electrolysis and photo epilation devices such as laser and intense-pulsed light. Temporary current hair removal methods include waxing, plucking, shaving, depilation, epilation, and bleaching.
- Topical treatment with eflornithine hydrochloride 1%, an inhibitor of ornithine decarboxylase, approved by US-FDA, is shown to be effective for decreasing the development of new unwanted facial hair.[84] However, it is expensive and needs to be used continuously to yield its desired effect.

Management of Acne

- Use of OCPs (containing CPA, drospirenone, or desogestrel as progestin component) as first-line therapy for the management of all types of acne lesions, in consultation with a dermatologist.
- Topical treatment with salicylic acid, benzoyl peroxide, clindamycin/benzoyl peroxide preparations, tretinoin, and clindamycin/tretinoin combinations can be used.

Management of Alopecia

- OCPs and androgen blockers are recommended as first-line therapy.

- Use of CPA + EE for 6–9 months demonstrated a marked improvement in androgenic alopecia.[85] Topical treatment of hair loss is with minoxidil, 2–5% twice daily.

Existing guidelines:

- The Endocrine Society clinical practice guidelines recommend the use of hormonal contraceptives and dermatological interventions as the first-line therapy for the management of hirsutism/acne in women with PCOS.[86] Further, the guidelines recommend screening guidelines for use of OCPs and OCPs containing CPA for more effective management of HA. Then, if at least 6 months of therapy with OCP has not significantly decreased the rate of hair growth, antiandrogens may be added.[86]
- However, when estrogen is contraindicated, drugs with an antiandrogen effect should be used in combination with effective contraceptives (nonhormonal methods or progesterone-only contraceptives).
- The AEPCOS recommends OCPs containing progestogens with a greater antiandrogen potential, such as cyproterone, chlormadinone, and drospirenone as the choice for treatment of hirsutism.[11]

Management of Menstrual Dysfunction

Combined Hormonal Oral Contraceptive Pills

- The approach to the management of menstrual dysfunction will depend on the type of menstrual dysfunction, life stage, medical history, and preferences of the woman concerned.
- OCP has a primary role in the management of AUB and in oligo/amenorrhea. In women who do not wish to conceive, OCP given cyclically will confer regular monthly withdrawal bleeds.
- *Rationale for use of OCP:*
  - The progestin component → LH secretion → ovarian androgen production. With a reduction in androgens, there is decreased substrate available for aromatization and overall decreased endogenous sex steroid production.
  - Estrogen component → hepatic SHBG production → in circulating bioavailable free testosterone levels.
  - The progestin component protects the endometrium from unopposed estrogen.
- The most widely prescribed OCPs contain EE at doses ranging from 20 to 35 μg and progestin with minimal androgenic activity.
- Although both second- and third-generation OCPs are equally effective in controlling menses, it is advisable to avoid OCPs with higher estrogen doses or those containing 19-nor-derived progestins.
- Increased risk of metabolic abnormalities, CV events and venous thromboembolism, worsening of IR due to OCPs in PCOS who are inherently at risk, particularly the obese ones.[62] However, in the absence of other risk factors, there is no evidence that PCOS are at increased risk of CVD compared with normal women.
- Overall, the benefits of OCPs outweigh the risks in most patients with PCOS.[62] However, all patients should be counseled on the potential risk of thrombotic events with the use of OCPs.
- Low-dose OCs are metabolically safe and ameliorate several CV risk markers.[87]
- OCs containing third-generation progestins as well as drospirenone and CPA have reduced metabolic side effects compared to OCs containing more androgenic progestins.[88]
- Absolute and relative contraindications to the use of OCP according to the WHO guideline to be followed.[89] Absolute contraindications include smoking (>15 cigarettes a day) over the age of 35, liver dysfunction, hypertension (>160/100 mm Hg), deep venous thrombosis, ischemic heart disease, stroke, and breast cancer.

Existing guidelines: The clinical practice guidelines from the Endocrine Society,[86] RCOG,[90] ACOG,[84] RCOG, ACOG, ASRM, and ESHRE[62] all recommend the use of OCPs as the first-line management for the amelioration of clinical and biochemical HA and menstrual irregularity in the absence of contraindications. However, the guidelines do not suggest any specific combination of compounds.

Alternatives to Oral Contraceptive Pills

Progestin therapy:

- Indicated in those women who are intolerant to estrogen-containing therapies or when contraindication to estrogen or multiple risk factors for CVD are present.
- Regular withdrawal of the endometrium with progestin, if administered on a regularly basis, without prolonged episodes of amenorrhea, will regulate menses and provide some protection against endometrial hyperplasia.[25]
- Given cyclically (micronized progesterone 100–200 mg daily or medroxyprogesterone acetate 10 mg daily for 10–14 days per month)[25]
- Those in need of contraception might be candidates for progestin-only contraceptives including long-acting injectables (depot medroxyprogesterone), etonogestrel-containing implants, or levonorgestrel-containing intrauterine systems. These methods provide effective protection against endometrial hyperplasia.
- Levonorgestrel-releasing intrauterine device (IUD): (1) for control of abnormal bleeding. The use of levonorgestrel IUD was found to be more effective than usual

medical treatment in reducing the effect of heavy menstrual bleeding on QoL;[91] (2) protects the endometrium from unopposed estrogens; and (3) provides contraception.

- Transdermal contraceptive patch contains:
  - Norelgestromin and 0.75 mg EE, weekly application, is also a treatment option. However, it may be associated with an increased risk for venous thromboembolism compared to OCPs.[25]
  - A transvaginal contraceptive ring releasing 15 μg EE and 120 μg etonogestrel per day over 3 consecutive weeks (monthly insertion) is yet another option.
- There is a paucity of data regarding the use of hormonal contraceptives other than OCPs in PCOS and the long-term risks and benefits remain largely unknown.[92]

Existing guidelines: The RCOG Green-top guidelines recommend in those oligomenorrheic or amenorrheic regular induction of withdrawal bleed at least every 3–4 months with cyclical gestogens for at least 12 days or OCPs or endometrial protection gained by exposure to gestogens by the IUD.[71]

Management of Infertility in PCOS

- About 74–80% of PCOS suffer from subfertility due to anovulation.[36,69]
- Women with PCOS desiring pregnancy should be evaluated for all other factors causing anovulation along with evaluation of the male partner.
- Management of infertility as per the Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop[77] is shown in **Table 8**.

Oral Ovulation Induction Agents

Clomiphene Citrate

- Clomiphene citrate (CC) is the first choice for OI in anovulatory PCOS.[93]
- Nonsteroidal selective estrogen receptor modulator (SERM) triphenylethylene derivative
- Racemic mixture of two stereoisomers: En (cis) clomiphene and zu (trans) clomiphene. Zu form exists in tissues for weeks and contributes to its metabolic life; En form is the more potent isomer and contributes to the ovulation-inducing action of CC.[94]

TABLE 8: Management of infertility—Thessaloniki ESHRE/ASRM PCOS Consensus Workshop.[77]

• First-line treatment for ovulation induction • Alternative agents	• Clomiphene citrate (CC) • Tamoxifen • Aromatase inhibitors (Letrozole)
Second-line intervention	• Exogenous gonadotropins • Laparoscopic ovarian drilling (LOD)
Third-line treatment	In vitro fertilization

- *Mechanism of action:* Binds to hypothalamic nuclear estrogen receptors → blocks the negative feedback mechanism of circulating estrogen → FSH and LH → follicular development.

Dosing and monitoring:

- *Starting dose*: 50 mg/day for 5 days from day 2/3 of the menstrual cycle; over-response, reduce to 25 mg, no ovulation—50 mg increments with the maximum dose of 150 mg/day. FDA recommends 750 mg/treatment cycle.[93]
- Selection of patients for treatment is based on age, BMI, normal baseline FSH levels, and assessment of other associated infertility factors.
- Monitoring by ultrasound is not mandatory, though monitoring of the first cycle would allow adjustment of the dose for the subsequent cycles.[93] ASRM recommends monitoring by the menstrual calendar, serum progesterone concentration, or urinary LH excretion to ensure its effectiveness in OI.[94]
- Human chorionic gonadotropin (hCG) triggers when the lead follicle is 18–22 mm, in those requiring intrauterine insemination (IUI) and in whom LH monitoring would be difficult or unreliable in the timing of intercourse.
- *Outcome:* [68,69,93]
  - Ovulation rate: 75–80%
  - Conception rate per cycle: 22–36%
  - Multiple pregnancy rate (MPR): 8%
  - Miscarriage rate: 10–20%
  - Live birth rate (following 6 months of CC): 20–29%.
- *Discrepancy between ovulation and PR:* Due to peripheral antiestrogenic action of CC on the endometrium, cervical mucus, decreased uterine blood flow, impaired endometrial placental protein 14 synthesis, probable detrimental effects on tubal transport, oocytes, and luteal phase defect.[93]
- *Duration of treatment:* Six ovulatory cycles and in the absence of pregnancy, second-line therapy to be considered.
- *CC resistance (ovulation failure):* Defined as failure to ovulate after receiving 150 mg of CC daily for 5 days per cycle, for at least three cycles, is seen in about 20–25% of cases.[93] Such patients are likely to be more obese, insulin resistant, and hyperandrogenic.
- *Options for CC resistance*:[93]
  - Use of insulin sensitizers concomitantly
  - Second line of management; either GT/LOD
  - Extended use of clomiphene: For 7 or more days in the dose of 100 mg/day, rarely 150 mg/day
  - Use of aromatase inhibitors (AIs)
  - Addition of glucocorticoids either dexamethasone 0.25–0.5 mg or prednisolone 5 mg
  - Pretreatment with OCPs.
- *Clomiphene citrate failure:* Those who ovulate but fail to conceive after three or more ovulatory cycles with CC. Failure to conceive after 3–4 successful CC-induced

ovulation cycles is an indication for further evaluation to exclude other contributing factors of infertility, particularly in women more than 35 years of age.[94]

- *Side effects:* Vasomotor flushes, mood swings, bloating, abdominal distension, breast tenderness, visual symptoms (scotomas, light sensitivity, blurred/double vision), dryness of the vagina, headache, and ovarian hyperstimulation.
- *Clomiphene and ovarian malignancy:* With six CC cycles, the risk will not exceed that of other women, but with more than 12 cycles in a women's lifetime, there was a threefold increase in ovarian cancer.[93] However, a pooled analysis of 8 case–control studies concluded that neither fertility drug nor use for more than 12 months was associated with invasive ovarian cancer.[94]
- *Contraindications*: Ovarian cyst, pregnancy, liver disease, and visual disorders
- *Congenital anomaly:* The possibility of an association between CC exposure and anomalies included spina bifida occulta, hypospadias, cloacal exstrophy, ventricular septum heart defects, Dandy–Walker syndrome, and omphalocele.[68]

Tamoxifen

- Selective estrogen receptor modulator acts as potent estrogen antagonist on breast, blood vessel, and some peripheral sites, but as a partial agonist in uterus, bone, liver, and pituitary.
- *Mechanism of action:* Being structurally similar to CC, the mechanism of action is similar to CC, but may also involve a direct action on the ovary and improve folliculogenesis.[95]
- *Dose*: About 20–40 mg/day from day 2/3 of the menstrual cycle for 5 days.
- Ovulation and PRs similar in both CC and tamoxifen. However, better ovulation and PRs were reported in a few studies, maybe because of a higher score of the endometrium, cervical mucus, and better functioning of the corpus luteum.[95]
- Tamoxifen has shown reasonably good results in CC failure cases with beneficial effects on bone mineral density and serum lipids.[95]
- *Side effects:* Hot flushes, vomiting, anorexia, AUB, and endometrial hyperplasia.

Aromatase Inhibitors

- *Letrozole (LE):* It is the most commonly used AI as an ovulation-inducing agent.
- *Mechanism of action:* (1) Inhibits aromatase enzyme at the granulosa cells, prevents the conversion of androgens into estrogens → release of hypothalamo-pituitary axis (H-P axis) from E2-negative feedback → FSH → follicular development. (2) Transient in intraovarian androgenic environment → follicular sensitivity to FSH. (3) Induces intrafollicular high IGF-1 concentrations, which synergize with the action of FSH.
- *Advantages of AIs for ovulation induction:* (1) No antiestrogenic effect on the endometrium or cervical mucus. (2) LE is rapidly eliminated due to its short half-life (45 hours), leading to late follicular rise in circulating estrogen, with a shorter FSH window (mimicking the physiological cycle) resulting in mono-ovulation.[96] (3) Reduces the risks of ovarian hyperstimulation and multiple pregnancies.
- *Dose*: About 2.5–5 mg/day, from day 3/4 of the cycle for 5 days. The use of higher doses (5 and 7.5 mg), although might cause a shorter stimulation period, adds no advantage over 2.5 mg in terms of PRs. Moreover, the higher dose of 7.5 mg causes persistence of aromatase inhibition resulting in thin endometrium by the time of ovulation.[96]
- *Ovulation rate:* 75%; PR: 17–20%.[96]
- *Side effects:* Minimal and transient generally due to hypoestrogenemia, gastrointestinal disturbances, asthenia, headache, and back pain.
- *Safety*: Although an abstract (Biljan, ASRM abstract, 2005) raised the concern for the potential of teratogenicity suggesting a higher risk (4.7%) of congenital cardiac and musculoskeletal malformations in newborns,[97] the methodology was criticized and a peer-reviewed paper did not result from the presented abstract. Subsequent publications found LE to be safe[98,99] and the incidence of major malformation was 2.5% in babies in the LE group, 2.9% in babies conceived naturally, and 3.9% in babies in CC.[98]
- *Anastrozole:* There have been few studies on the use of anastrozole as an OI agent. Used in the dosage of 1 mg daily from day 3 for 5 days.

Existing guidelines: ACOG recommends LE as the first line of drug for ovulation-induction in PCOS with BMI of >30 kg/m^2 because of increased live birth rate when compared with CC.[99]

CC or LE (when available and permissible) should be the first-line pharmacological therapy to improve fertility outcomes in PCOS, with no other infertility factors.[68] Endometrial receptivity during the implantation window of LE is superior to CC in PCOS women, which may be related to higher clinical pregnancy and ongoing PRs.

Gonadotropins

- *Indications:*
  - Clomiphene/tamoxifen/LE resistance
  - Clomiphene/tamoxifen/LE failure
  - Persistent LH hypersecretion
  - IUI cycles
  - Assisted reproductive technology (ART) cycles
- GTs can be used alone or in combination with CC, LE, or tamoxifen.

- Initial dose depends on the age, BMI, AMH, and previous response to GTs with subsequent adjustment of dose based on follicular response.
- GT usage requires close monitoring with ultrasound and, if required, correlated biochemically with E2, LH, and progesterone levels, more so in ART cycles.
- Induction of ovulation in timed intercourse and IUI cycles, the difficulty is in achieving the desired monofollicular ovulation, due to the extreme sensitivity of the polycystic ovary to GTs. This is not due to a difference in FSH threshold levels but probably, the cohort contains twice the number of available FSH-sensitive antral follicles, compared to the normal ovary.[99]
- Any dose of FSH overstepping the threshold of the polycystic ovary will result in multifollicular development.
- Maximum of six cycles only (no response—resistance)
- *GTs used for OI*: Use of urinary FSH, highly purified FSH, recombinant FSH, or human menopausal gonadotropin (hMG) showed no difference in terms of pregnancy outcome and risks of OHSS.[99]
- *Complications*: OHSS and multiple pregnancies
- *Outcomes*: PR 20–25% per cycle, cumulative PR 50–70%, MPR 10–30%, OHSS rate 2%[93]
- Regimens for use of GT to fulfill two essential requirements for a successful outcome: (1) To allow a slow rise of FSH to just above the FSH threshold level (which is high in PCOS) and (2) to avoid an explosive ovarian response because of the exquisite sensitivity of PCO to exogenous GT.[93]

Step-up regimens:

- *Conventional step-up protocol:*
  - Principle: Supraphysiological dose of FSH provokes initial development of a large cohort, rescuing those follicles destined for atresia.
  - The classical protocol used in the 1970s for PCOS, included stimulation with 150 IU of hMG (containing 75 U FSH and 75 U LH), which was increased every 3–5 days by 50% until an ovarian response occurred.[36]
  - Although here the ovulation rate is 70% and cumulative PR as high as 21–75%, there is a high incidence of OHSS of 7–14% and multiple PRs of 36%.[99]
- *Low-dose step-up protocol:*
  - Principle: Increasing FSH in a gradual step-wise fashion allows rescue of a limited number of follicles mirroring that of the normal hormonal cycle.
  - GT is started in the dose of 75 IU, the first increment being done on day 7 of stimulation either by 50% or 100%, depending on the follicular growth **(Fig. 6)**.
  - Once follicle growth is observed, the same FSH dose is maintained until the DF is achieved.
  - With this, one can reduce the risk of OHSS and multiple pregnancies.

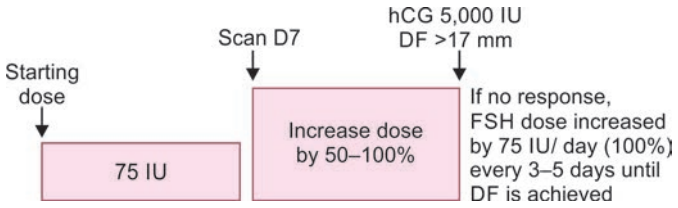

Fig. 6: Low-dose step-up protocol.
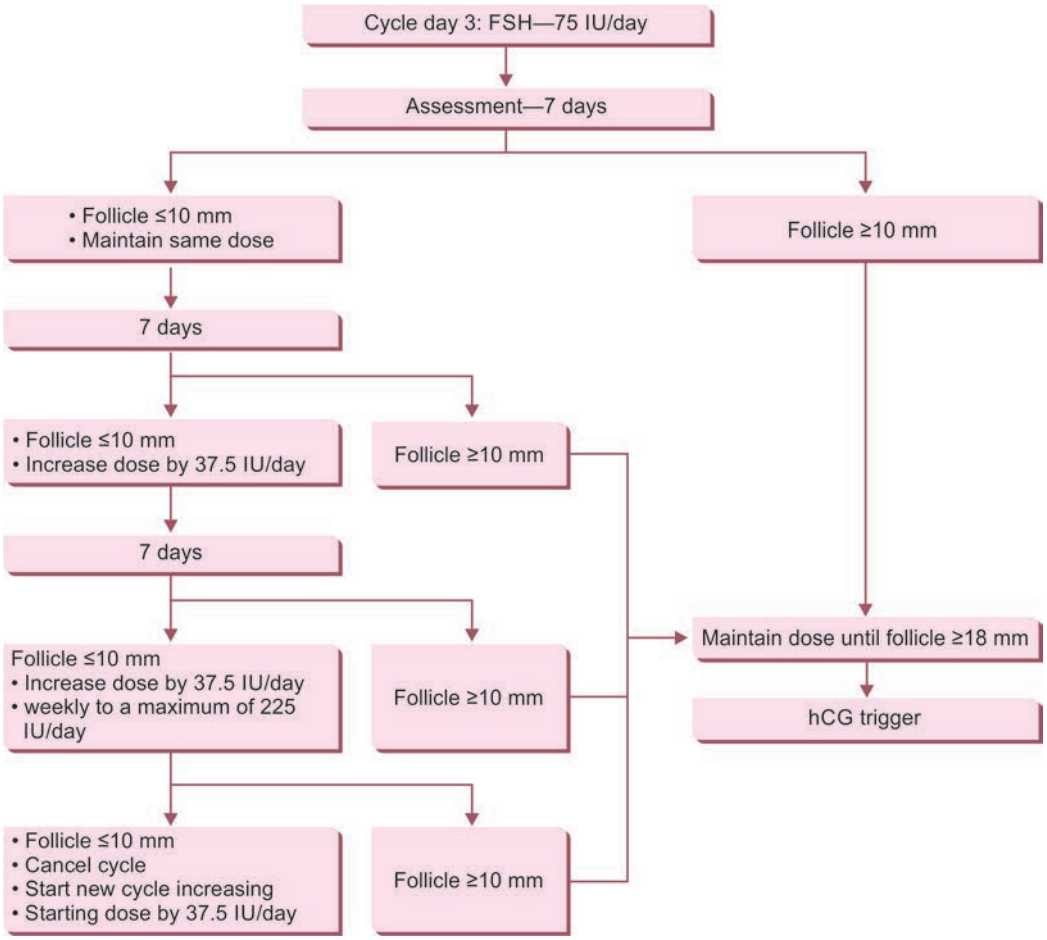
(DF: dominant follicle; FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin).

- *Chronic low-dose regimen:*
  - To further reduce the risk of ovarian hyper-responsiveness, the duration of the initial dose of FSH was extended (from 7 to 14 days) and the weekly dose increment was reduced (from 100% to 50% of the dose usually 37.5 IU) **(Flowchart 8)**.[100,101]
  - *Principle:* "Threshold theory", the attainment and maintenance of follicular development with exogenous FSH without exceeding the threshold requirement, aiming to achieve the development of a single DF.[102]
  - Safer in terms of monofollicular development.[101]
  - Avoids complications of OHSS and multiple pregnancies
  - *Drawback:* Long treatment cycles of 28–35 days.
  - Outcome:[101,102]
    - Mono-ovulatory cycles (70%)
    - PR: 20–40% per cycle
    - OHSS incidence: Very low (0.14%)
    - MPR: Less than 6% (88% twins).

Step-down regimen:

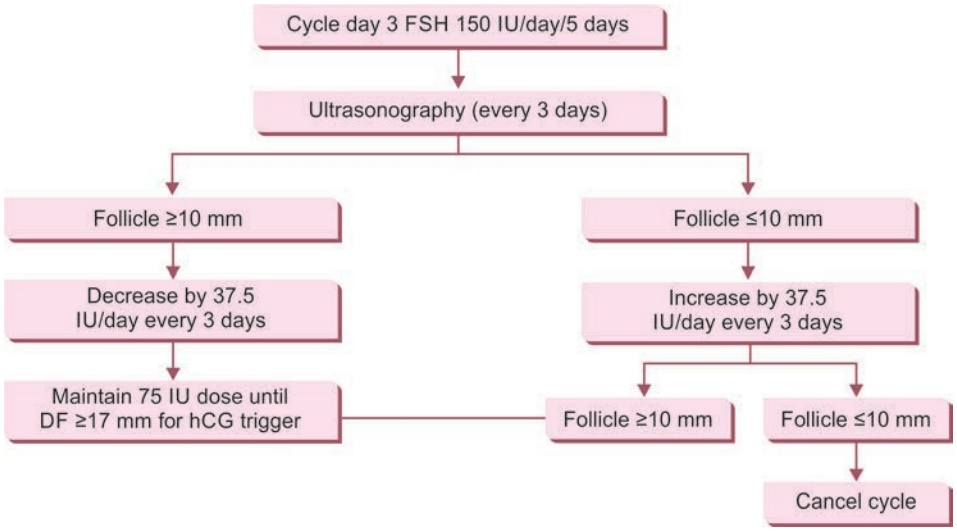
- Principle: To achieve FSH threshold through a loading dose of FSH, followed by subsequent stepwise reduction with the dominance of the follicle[103]
- Physiological as it mimics the natural intercycle FSH rise with a subsequent decrease in dependence of the developing DF to FSH than the smaller follicles, achieving monofollicular development
- In conventional step-down protocol in PCOS, FSH was started at the dose of 150 IU daily from day 2/3 of the cycle, decreasing the dose by 37.5 IU every 3 days till optimal follicular growth **(Flowchart 9)**.[102]
- In low-dose step-down, the starting dose is reduced to 100–112.5 IU/day, decreased by 25/37.5 IU every 3–5 days, respectively, decreasing to 75 IU, which is continued until hCG is administered to induce ovulation.[103]
- PR are comparable with those reported for step-up regimens. However, the French multicenter study demonstrated the superiority of the step-up regimen with regard to the rates of monofollicular development (88% of cycles), ovulation, and OHSS.[103]

Flowchart 8: Chronic low-dose step-up protocol.



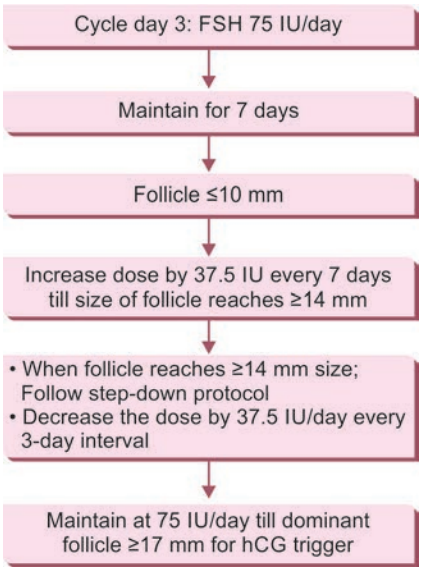
(FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin)
Source: Gardner DK, Wessman A (Eds).[101]

Flowchart 9: Step-down protocol.



(DF: dominant follicle; FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin)

Flowchart 10: Sequential protocol.



(FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin)

- Sequential protocol:
  - It combines an initial step-up GT administration followed by a step-down regimen after follicular selection.[104]
  - Reduces the risk of ovarian hyperstimulation by narrowing the follicular selection window due to atresia of the smaller follicles, with declining levels of FSH **(Flowchart 10)**[104]
- Combining GTs with GnRH analogs:
  - Hypersecretion of LH in PCOS may cause premature luteinization of the granulosa cells, premature oocyte maturation through inhibition of oocyte maturation inhibitor, and deleterious effects on granulosa cell steroidogenesis.[104]
  - To suppress LH hypersecretion, concomitant use of a GnRH agonist (GnRHa) is not justified, as this is associated with an increased risk of OHSS, additional inconvenience, cost, and multiple pregnancies.[77]
  - The benefit of LH suppression by GnRH antagonist during OI with GTs needs to be addressed by large-scale studies.[77]

Recommendations for gonadotropin: Anovulatory CC-resistant PCOS with no other infertility factors, where suitable to use GT, with consideration to provide a low-dose protocol and appropriate monitoring to minimize complications.[68]

Laparoscopic Ovarian Drilling

- The first description of laparoscopic drilling was by Gjonnaess in 1984 to reproduce the beneficial effects of the ancient ovarian wedge resection, performed by laparotomy, while avoiding its main complication, pelvic adhesions.[105]
- LOD is the creation of multiple ovarian punctures through the ovarian capsule, electrosurgical or with laser energy by a minimally invasive route, laparoscopically.
- Alternative routes for ovarian drilling are culdoscopy, transvaginal hydrolaparoscopy, and fertiloscopy, although uncommonly used.[106]
- *Indications:*[93]
  - Anovulatory CC/LE resistance
  - Anovulatory infertility in lean PCOS with raised serum LH (>10 IU/L) levels.
  - Anovulatory PCOS requires laparoscopic assessment of the pelvis.
  - Intensive monitoring is not feasible as in GT treatment or follow-up is difficult.
- Not to be done for nonfertility indications (irregular cycles, HA)[93]
- *How does LOD work*?
  - Exact mechanism is unknown. Probably, the destruction of androgen-producing stroma reduces the circulating androgens (testosterone, ASD, and DHEA).[106]
  - LOD may also result in modifications of ovarian–pituitary feedback relationships, releasing the ovary from some inhibitory process, thereby decreasing the LH levels.[106]
  - Destruction of small follicles (which are the source of AMH) leads to a fall in the serum AMH, thereby increasing the sensitivity of the follicles to circulating FSH resulting in ovulation.[107]
- *Predictors of success*: Higher likelihood of LOD success in those with young age, less than 3 years of infertility, elevated LH concentrations (>10 IU/L), lean PCOS, AMH ≤7.7 ng/mL, and no other associated infertility factors
- *Methods*:[108] (1) *Electrocautery:* insulated monopolar or bipolar electrode, preferably monopolar; (2) Laser energy [CO_2, argon, Nd: YAG (neodymium-doped yttrium aluminum garnet), KTP (potassium titanyl phosphate)]
- Armar's rule of 4:4 punctures/ovary with 40 W, 4 seconds, 4-mm depth, and 640 J/ovary (4 punctures × 4 seconds × 40 W = 640 J), fixed effective thermal dose.[108]
- However, an adjusted diathermy dose based on OV has been found to have a better reproductive outcome compared to the abovementioned fixed thermal dosage. The effective adjusted thermal dosage was found to be 60 J/cm^3 of ovarian tissue.[109]
- Ideally, the required number of punctures should be calculated by dividing the total individual ovarian dose based on OV by the dose delivered at each puncture point.[109]
- *Procedure:* Initially, the pelvis is examined, and a dye test is performed. The monopolar diathermy is set at 30 W, through cutting mode, the ovarian capsule is penetrated by an insulated monopolar electrode of

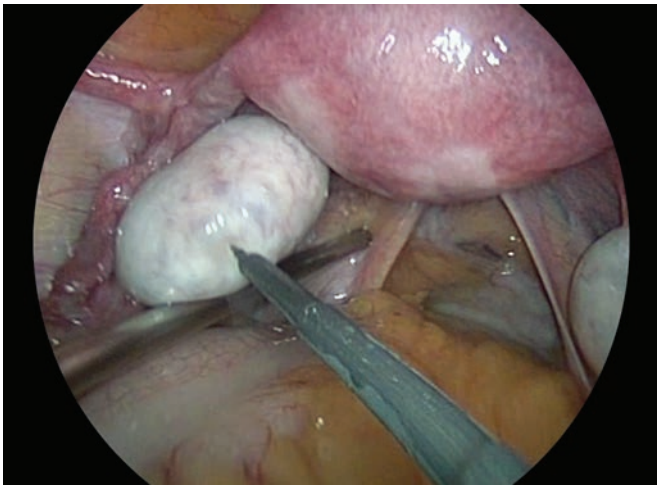


Fig. 7: Laparoscopic ovarian drilling.

1.5–2 mm in diameter with a conical tip. The denuded tip of the electrode is inserted perpendicular to the ovary, to a depth of 4–5 mm, and then the coagulation mode is activated for about 3–5 seconds **(Fig. 7)**. The instillation of 500–1,000 mL of isotonic solution into the pouch of Douglas cools the ovaries and prevents heat injury to the adjacent tissues, and thereby reducing the risk of adhesion formation. The procedure is ensured by the presence of appropriate hemostasis and a pelvic lavage.

- *Precautions to be taken in LOD:*
  - Away from the hilar area
  - Wash ovarian surface with crystalloid solution
  - Seven or more punctures per ovary discouraged—concern about excessive destruction of ovary without additional benefit[108]
  - Unilateral LOD is effective, less time-consuming, and probably with fewer complications.

Adhesions (10–20%), more with laser [(laser 41.5%, electrocautery 31%) (CO laser >Nd:YAG laser)[108]

- *Advantages of LOD over medical treatment:*
  - Correction of hormonal milieu ($^{-}$ androgens, $^{-}$ LH)
  - Assessment of tubal patency and pelvic pathology simultaneously
  - One-time procedure (safe and effective)
  - No intense monitoring is required.
  - Cost-effective
  - Monofolliculogenesis
  - No multiple pregnancies
  - No OHSS complications are rare (premature ovarian failure/adhesions)
  - CC-resistant PCOS may respond as LOD improves the sensitivity to GTs.
  - The beneficial effects of LOD on reproductive outcomes appear to be sustained for about 9 years.[110]
- *Complications:*
  - Complications of anesthesia
  - Establishment of surgical access
  - Bleeding from the drilling site
  - Laceration of utero-ovarian ligament
  - Deep desiccation of hilar vessels—ovarian failure
  - *Adhesions:* Mechanical infertility, more with laser.[111] Abdominal lavage with the use of an insulated needle for cautery may decrease its incidence.
  - Damage to ovarian reserve, and risk of premature ovarian failure with multiple punctures
- LOD is usually effective in generating ovulation in about 50% of anovulatory PCOS, and in the remainder, additional OI agents would be required.[69]
- *Outcome:*[106] Ovulation rate: 70–80%, spontaneous PR: 20–64%.

Recommendations

- Laparoscopic ovarian drilling could be second-line therapy in CC-resistance or first-line therapy, if laparoscopy is indicated for another reason in infertile PCOS.[68]
- Minimal effective intervention dose should be applied to achieve ovulation and minimize complications, with consideration given to increased perioperative risks in those overweight or obese.[68]

Evidence

The Cochrane database compared GTs with LOD in CC-resistant PCOS and concluded that no difference exists in miscarriage rates, the live birth rate per patient, long-term cost, and QoL. However, LOD was better than GTs in reducing MPR [odds ratio (OR): 0.13 (95% confidence interval (CI): 0.03–0.52) I2 = 0%, P = 0.004; five studies, 166 participants] and short-term cost (P <0.00001; two studies, 203 participants).[112]

Role of Intrauterine Insemination

- Ovulation induction with IUI in those with associated male factor infertility or any other associated risk factors and failure to conceive despite multiple successful inductions of ovulation
- Single IUI around the time of ovulation, at 36 ± 2 hours following hCG administration would provide a better cycle outcome compared to double insemination.[113]
- The clinical PRs per cycle: 16–20%; MPR (all protocols)—4–10%.[93]

Assisted Reproductive Technology in Polycystic Ovary Syndrome

- Anovulation is not an indication of in vitro fertilization (IVF).
- *Indications:*
  - Failure to conceive despite 6 ovulatory cycles with IUI
  - *Coexistent infertility factors:* Advanced maternal age, tubal factor infertility, severe endometriosis, male

factor infertility, need for preimplantation genetic screening/diagnosis (PGS/PGD)

- Relative GT resistance and increased GT consumption, may be related to obesity and IR.[114]
- Cycle cancellation is due to absent/limited ovarian response or OHSS.
- *Complications:* Hyper-response to GTs leading to the risk of OHSS. In IVF cycles, the incidence of moderate-to-severe OHSS is 3–8% which increases to 10–20% in high-risk PCOS population.[115]
- GnRH antagonist protocol should be the protocol of choice in PCOS, as it is associated with a shorter duration of stimulation, a lower total dose of GTs, and a significantly lower risk of moderate-to-severe OHSS.[116]
- *Individualized controlled stimulation (ICOS):* Dosage of GT based on age, BMI, AMH, and previous response to stimulation reduces the risk of OHSS in PCOS.[117]
- *Use of GTs:* With use of urinary or recombinant FSH, there was no significant difference in the number of oocytes retrieved, live birth rates, miscarriage, multiple pregnancy, or OHSS.[118]
- Trigger for follicular maturation: Use of GnRHa trigger instead of traditional hCG, which is feasible in a GnRH-antagonist protocol nearly eliminates the risk of OHSS.[119]
- *For prevention of OHSS, segmentation strategy*[120] *to be followed:* (1) *Segment A:* Optimization of ovarian stimulation, use of GnRH antagonist protocol with GnRHa trigger; (2) Segment B: Cryopreservation of all embryos by vitrification; (3) Segment C: Frozen embryo transfer in the subsequent cycle.
- However, the use of GnRHa as a trigger causes drastic luteolysis and is associated with luteal phase defect, presumably because of excessive negative steroid feedback resulting in suppressed pituitary LH release.[121] To circumvent this issue, there are two options: (1) intensified or modified luteal phase support in case of fresh transfer;[122] (2) cryopreservation of all oocytes/embryo by vitrification.
- Deferring fresh embryo transfer and following a freeze-all strategy would be beneficial due to these reasons: (1) To prevent early-onset OHSS; (2) To avoid the possibility of late-onset OHSS, in case of pregnancy by early embryonic hCG; (3) Impaired endometrial receptivity due to supraphysiologic steroid levels;[123] (4) To avoid embryo exposure to extremely high steroid levels, being embryo-toxic, following a high-ovarian response to ovarian stimulation.
- Performing single embryo transfer (SET) with blastocyst, the risk of multiple pregnancies and their complications are markedly reduced.[93]
- *IVF outcome:*
  - A greater number of oocytes were retrieved.[124]
  - Obese PCOS, independent of HI, was found to have an increased GT requirement and a lower oocyte yield.[124]
  - Impaired oocyte competence due to:
    - Abnormal follicular development[125] **(Fig. 3 and Flowchart 3)**
    - Altered granulosa cell–oocyte interactions, with impaired cytoplasmic and/or nuclear maturation of the oocyte due to paracrine dysregulation of growth factors[125] **(Flowchart 2)**
    - Premature granulosa cell luteinization due to HA and HI
  - An increased expression of TNF-α and epidermal growth factor receptors[125]
  - Reduced expression of GDF9 and BMP-15 mRNA in the cytoplasm of the oocytes[126]
  - Elevated follicular testosterone levels, especially in meiotically incompetent oocytes[125]
  - Increased follicular fluid homocysteine levels[76]
  - Nondisjunction and predivision of sister chromatids due to altered expression of key genes associated with chromosome alignment and segregation during mitosis and/or meiosis due to hyperandrogenemia[127]
  - Altered metabolic milieu throughout oogenesis, leading to reduced expression of genes encoding oxidative phosphorylation,[128] with increased pyruvate consumption due to impaired insulin signaling and glucose metabolism[129]
  - Lower fertilization and delayed cleavage kinetics from fertilization to 8-cell stage[130]
  - Poor embryo quality is due to poor quality oocytes and increased oxidative stress[128]
  - Endometrial dysfunction due to:
    - HA and HI cause suppression of uterine placental protein (PP14, also known as glycodelin), homeobox *A10 (HOXA10)* genes, insulin-like growth factor-binding protein 1 (IGFBP-1) and b3 integrins, and high plasma endothelin-1, all possibly impairing endometrial receptivity.[131]
    - Supraphysiological levels of E2
    - Inadequate endometrial blood flow[131]
- However, these features are not universal, and oocyte quality, fertilization, and implantation rates in women with PCOS may be normal.[92]
- It has been reported that the clinical pregnancy rate (CPR) following fresh embryo transfer in phenotypes A, B, C, and D was 32.5%, 26.4%, 36.8%, and 53.3%, respectively. Phenotypes A and B were associated with a decreased CPR compared with the control group, probably due to associated HA and chronic anovulation.[132]
- A randomized controlled clinical trial showed a statistically significant 7.3% absolute increase in live births following frozen embryo transfer and an increased

pregnancy loss in the fresh transfer group, which may involve the process of placentation as well as potential effects of aspects of PCOS on the endometrium or on the maternal response to pregnancy.[133]

Evidence

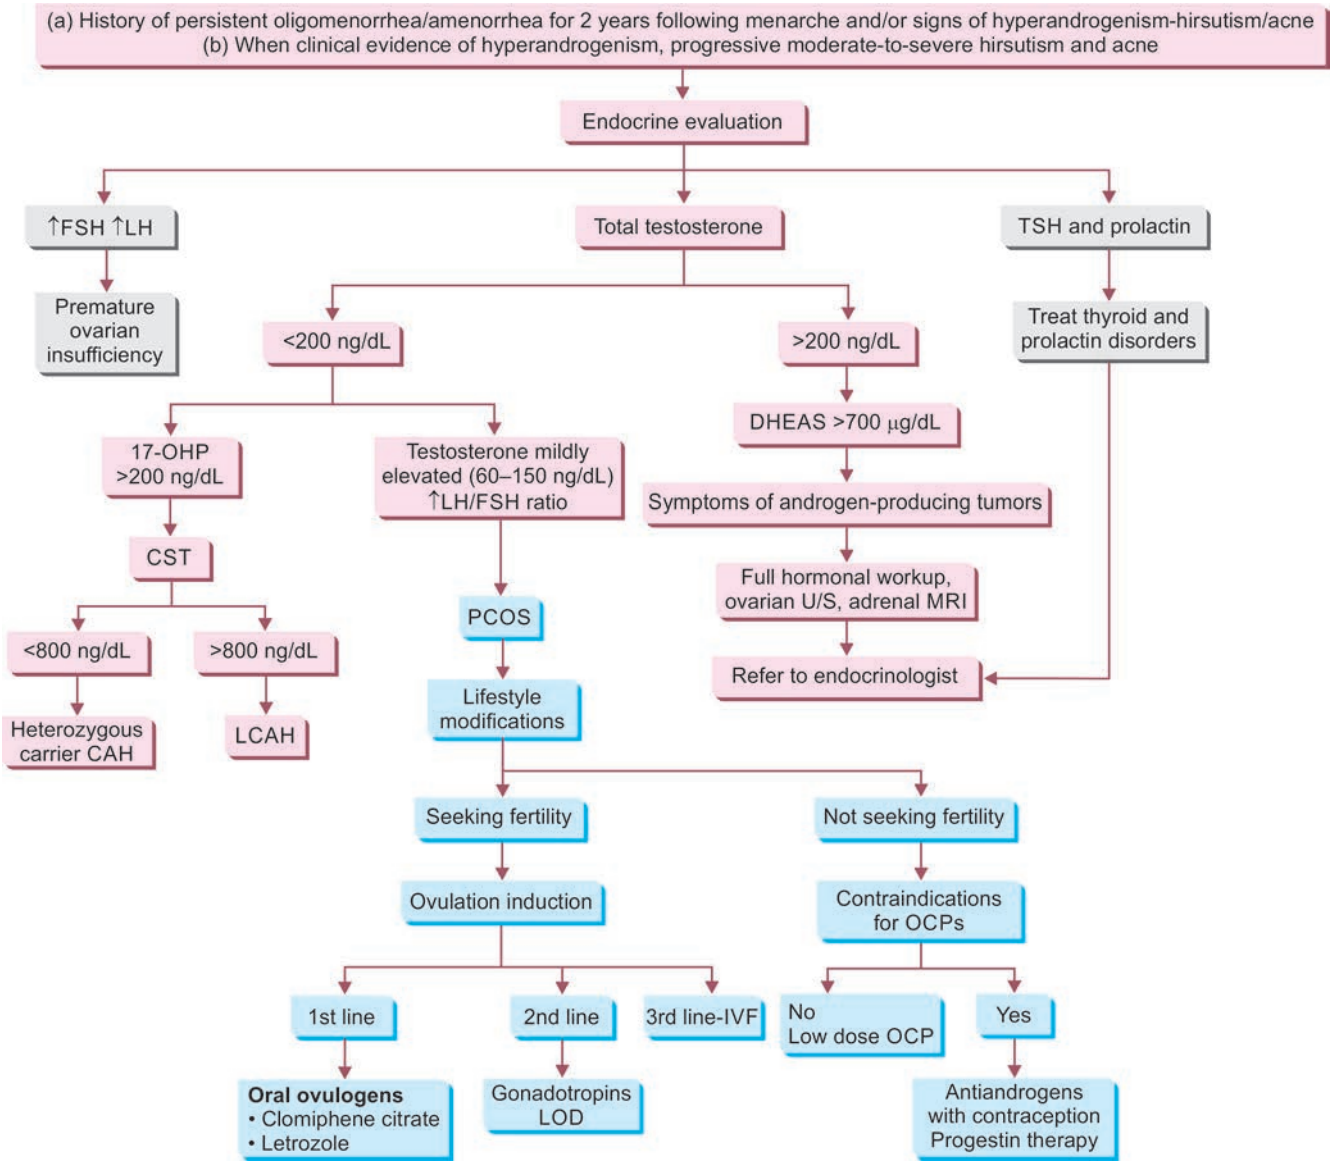
- Use of GnRH antagonist protocol in PCOS significantly lowers the incidence of OHSS (Cochrane analysis by Al-Inany).[116]
- GnRH agonists trigger for final follicular maturation seems to be safer than traditional hCG triggers due to the lower risk of OHSS (Cochrane 2015).[134]

SUMMARY OF EVALUATION AND MANAGEMENT OF PCOS (DEPICTED IN THE FORM OF FLOWCHART 11)

In Vitro Maturation

- Immature oocytes are retrieved transvaginally from antral follicles measuring 2–12 mm in diameter, either unstimulated or minimally stimulated ovaries and matured in vitro for 24–48 hours before fertilization.
- *Clinical protocol:*[135]
  - Priming with FSH and hCG has been shown to improve the maturity, fertilization, and implantation rates.

Flowchart 11: Evaluation and management of PCOS.



(CAH: congenital adrenal hyperplasia; CST: corticotropin stimulation test; DHEAS: dehydroepiandrosterone sulfate; FSH; follicle-stimulating hormone; LCAH: late-onset congenital adrenal hyperplasia; LH: luteinizing hormone; LOD: laparoscopic ovarian drilling; OCP: oral contraceptive pill)

- Unstimulated follicles are mobile and technically difficult to aspirate. A newly designed in vitro maturation (IVM) needle, composed of two needles, one for puncturing (21 G) and one for holding (17 G), facilitates easier puncture of small follicles.
- Aspiration pressure of 180 mm Hg yielded a higher retrieval rate compared to 300 mm Hg.
- Use heparinized media for flushing and rinsing the needle.
- Retrieved cumulus oophorus complexes (COCs) were cultured in IVM medium for 24–26 hours, and later assessed for maturity after denudation of cumulus cells.
- *Mode of fertilization:* Intracytoplasmic sperm injection (ICSI) is better than IVF.

- *Advantages:* Avoids/minimal use of GTs, patient-friendly, cost-effective, less monitoring, and avoids OHSS
- *Disadvantages:*
  - IVM when compared with conventional IVF, yields significantly fewer mature oocytes (7.8 vs. 12.0) and embryos (6.1 vs. 9.3), respectively.[136]
  - Lower CPRs per cycle in comparison to IVF (IVM 32.4% vs. IVF 45.8%) and lower live birth rate (IVM 23.5% vs. IVF 40.7%).[137]
  - The possible causes for lower implantation and CPRs:[136,137] (1) Reduced oocyte development potential (suboptimal culture conditions or defective oocytes due to inadequate cytoplasmic maturation); (2) Higher frequency of abnormal meiotic spindles and chromosomal alignment; (3) Nuclear, cytoplasmic asynchrony; (4) Failure of embryonic gene expression; and (5) Asynchronous endometrium or reduced endometrial receptivity
  - Concerns of epigenetic disorders in the offsprings.

Evidence

- This technique first offered in PCOS as an alternative to conventional IVF for the prevention of OHSS cannot be recommended now because of poor results and as GnRH antagonist with agonist-trigger protocols effectively prevent OHSS.[136]
- In a Cochrane systematic review, Siristatidis et al. concluded that no randomized controlled trials (RCTs) exist upon which to base practice recommendations regarding IVM before IVF or ICSI in PCOS. IVM as a treatment has yet to be adopted as a routine clinical entity, and may remain a research interest.[138]

ADJUVANTS TO IMPROVE METABOLIC AND REPRODUCTIVE FUNCTION

Insulin Sensitizing Agents

Metformin

- Metformin is an oral biguanide that lowers blood glucose levels in hyperglycemic individuals with T2DM but has no effect on glucose levels in normal subjects.[31]
- *Mechanism of action:*[31,139]
  - Inhibits hepatic glucose production
  - Improves insulin-stimulated peripheral glucose uptake by the liver, skeletal muscle, and adipose tissue
  - Reduces absorption of glucose uptake from the gastrointestinal tract
  - Reduces substrate availability for gluconeogenesis by lowering serum lipid levels
- *Pharmacokinetics:* Bioavailability of 50–60%, mean plasma elimination half-life of 4.0–8.7 hours, excreted renally
- *Dosage:* Orally in the dose of 500 mg/day and then increased gradually every week up to a total dose of 1,500 mg/day, after confirming normal renal and liver function tests
- Category B drug in pregnancy.
- *Side-effects:* Dose-dependent includes diarrhea (53%), nausea/vomiting (25.5%), flatulence (12.1%), asthenia (9.2%), indigestion (7.1%), abdominal discomfort (6.4%), headache (5.7%), and lactic acidosis (rare and fatal, but almost all patients who develop acidosis have impaired renal function).
- *Contraindications:* Renal disease, creatinine >1.4 mg/dL, cardiac failure, acute or chronic metabolic acidosis, sepsis, active liver disease alcoholism, should be stopped before intravenous contrast use and before surgery.
- *Advantages:*
  - Metformin has been shown to increase the frequency of ovulation in PCOS, although this impact may be mediated partly by weight loss, because of a slight anorectic effect and with some evidence of benefit on parameters of the MebS.[31]
  - Metformin has been observed to reduce serum testosterone concentration and free androgen index.[140]
  - Usage of metformin for 12 weeks prior to IVF, reduces the risk of moderate-to-severe OHSS by ameliorating the expression of VEGF.[141]
  - Alleviation of HA and IR at the ovarian level may improve folliculogenesis, the developmental potential of the embryo, and therefore the CPR.[140]
  - Metformin in combination with CC had better ovulation rates versus CC or metformin alone (60.4% vs. 49.0% vs. 29.0%) as shown by Legro et al. in a multicentric RCT.[142]
- *Uses:*
  - Adjunct in CC-resistant cases
  - In PCOS with glucose intolerance and T2DM
  - Obese PCOS for weight loss along with lifestyle modifications[143]
  - Adjuvants in IVF cycles may enhance ongoing PRs and reduce the incidence of OHSS.[144]

Evidence:
ASRM 2017 recommendations:[31]

- Metformin alone versus placebo increases the ovulation rate in PCOS (Grade A).
- Metformin in combination with CC improves ovulation and CPRs but does not improve live birth rates compared with CC alone (Grade A).
- Insufficient evidence to recommend metformin during pregnancy to reduce the chance of miscarriage (Grade C).

Cochrane: Recent Cochrane published in 2017 has concluded that metformin may improve menstrual frequency and ovulation rate, which may result in a marginal improvement in live birth rate when compared with placebo. Further, combined therapy with metformin and CC in CC resistance, in both obese and nonobese patients, improved clinical pregnancy and ovulation rates versus CC alone, although it did not improve live birth rates. Insufficient evidence to show any beneficial effect of metformin on multiple pregnancy and OHSS rates.[145]

Thiazolidinediones

- They are peroxisome proliferator-activated receptor gamma (PPAR-γ) agonists, approved for the treatment of T2D.
- They decrease IR at the periphery and liver and increase insulin-dependent glucose disposal. Because of this improvement in IR, they have been used in the treatment of PCOS with modest improvement in menstrual patterns.[146]
- Actively metabolized by the liver; half-life 3–7 hours.
- Rosiglitazone and pioglitazone are the two prescribed drugs, as they are relatively free of liver toxicity; however monitoring of liver function every 2 months is recommended.[146,147]
- Troglitazone, though has been shown to improve ovulation and PRs has been withdrawn from the market, due to its hepatotoxic effect.[147]
- Rosiglitazone: Initial dose of 4 mg/day; increased to 8 mg/day after 8–12 weeks. Pioglitazone: Used in the dose of 15–30 mg once a day.
- Side-effects: Gastrointestinal, hepatic effects, weight gain, edema, congestive heart failure, and bladder cancer risk with pioglitazone.
- Contraindications: Hypersensitivity to drugs, pregnancy, lactation, heart failure, and liver failure.
- FDA category C drugs, owing to the potential for fetal growth restriction.[146] Hence, must be discontinued as soon as pregnancy is established.

Inositol

- Myo-inositol is an insulin sensitizer. MI acts at the level of the ovary to reduce hyperandrogenemia, regularizes the cycle with spontaneous ovulation, improves ovarian response, induces nuclear and cytoplasmic maturation, thereby improving oocyte competence.[35,147]
- DCI acts at the level of the periphery to reduce IR, improves glucose metabolism, improves lipid profile, and thereby reduces CV and metabolic complications.[35]
- Hence, administration of both MI and DCI, in the physiological plasma ratio (40:1), ensures better clinical results.[147]
- Dose: 2–4 g/day

Vitamin D

- There is controversy regarding the efficacy of vitamin D3 supplementation to improve the various features of the syndrome.
- However, vitamin D supplementation has shown beneficial effects on IR, HA, follicular maturation, menstrual regularity, and ovulation.[47] It might also exert a protective effect against the inflammatory action of AGEs by increasing circulating soluble sRAGE.[44]
- Given orally in the form of vitamin D2 or D3 at a dose of 1,000–2,000 units/day or 50,000 units/week depending on the severity of deficiency to achieve a serum level of 25-hydroxyvitamin D more than 20 ng/mL
- Adverse effects are related to hypercalcemia which includes headache, nausea, vomiting, dizziness, loss of appetite, and dry mouth.
- Supplementation with vitamin D3 (400 IU/day) and calcium (1,000 mg/day) for 3 months can reduce the androgens, with a positive effect on follicle maturation and menstrual disorders.[47]

L-Methylfolate

- It is a natural and active form of folic acid, helps DNA synthesis, and reduces homocysteine levels and thereby improving endothelial function, preventing CV risk factors.[47]
- Dose: 1–5 mg/day for 3 months
- Also, high follicular fluid levels of homocysteine, an amino acid whose metabolism is facilitated by folic acid and other B vitamins, are negatively associated with embryo quality.[148] Thus, higher serum concentrations of folate and vitamin B12 were found to be associated with lower follicular fluid homocysteine levels, resulting in better fertilization and clinical pregnancy.[149]

Antioxidants

N-Acetyl cysteine (NAC):

- *N*-acetyl cysteine, the precursor of glutathione, is an antioxidant.
- It has effects on insulin receptor activity and insulin secretion, thereby increasing glucose utility.[150]

- Decreases total cholesterol, LDL, homocysteine, and oxidative stress and increases HDL levels.
- Antiapoptotic activity and aids healthy cervical secretions.
- Combination of NAC and CC enhances ovulation and PR in CC-resistant PCOS.[150]
- Dose: 600 mg twice a day for 6 weeks
- Melatonin: Melatonin administration reduces intrafollicular oxidative damage, prevents DNA damage, and lipid peroxidation and acts as a free radical scavenger, reducing ROS, thereby improving follicular growth and maturation, ovulation, oocyte quality, fertilization rates, and PRs. However, there needs more clarity regarding the benefit of adding melatonin in all PCOS.[151]
- L-Carnitine: Administration of 3 g/day over 8–12 weeks reduces IR, with improvement in lipid profile. In CC-resistant cases, the use of L-Carnitine throughout the cycle was shown to improve the ovulation and PR.[152]
- Omega-3 fatty acids: In the dose of 4 g/day for 8 weeks reduces IR, total cholesterol (TC), triglycerides, LDL, TC/HDL, LDL/HDL ratios, and MDA levels.[46]
- Soybeans: Soy phytoestrogen (Genistein) in the dose of 18 mg/day for 3 months reduces oxidative lipid damage, decreases triglycerides, low-density lipoprotein, LDL/HDL ratio, and testosterone levels. Useful for CV and metabolic disorders prevention in PCOS.[46]
- Coenzyme Q10: As an adjuvant to oral ovulatory agents in CC-resistant PCOS[153]
- Zinc: 50 mg of zinc or 220 mg/day of zinc sulfate supplementation for 8 weeks reduces IR, total cholesterol, LDL, triglyceride, and testosterone levels, resulting in beneficial effects on metabolic risk factors.[46]
- Chromium picolinate: In the dose of 200–1,000 μg for 4–6 months improved IR, fasting insulin level, and body weight; induced ovulation and regular menstrual cycles in obese PCOS[154]
- Selenium: 200 mg/day decreases serum insulin and triglycerides[46]
- Multiple micronutrients (vitamins, L-arginine, glutathione) and minerals (iron, Zn, magnesium) supplementation in PCOS undergoing OI reduces the ROS levels and maintains the cellular oxidant–antioxidant balance trace and thereby improves the reproductive outcome.

Corticosteroids

- Indication: PCOS with high DHEAS levels, which is seen in about 20–33% and in CC-resistant cases along with CC.[33]
- Mechanism of action: (A) Decrease in adrenal androgen secretion; (B) Indirect action, serum GH, serum IGF-1 → follicular fluid IGF-1 concentrations, thereby facilitating development of follicles; (C) Improves ovarian response to GTs
- Dose: Dexamethasone 0.25–0.5 mg/day; prednisone 5 mg/day from day 2 to 6 or for 10 days or throughout the follicular phase or from the mid-luteal phase of the previous cycle.
- Addition of 2 mg of dexamethasone in CC-resistant cases from days 5 to 14 was shown to be associated with a higher ovulation rate and cumulative PR.[155] However, prolonged use should be discouraged.

Oral Contraceptive Pill Pretreatment

It causes suppression of the HPO axis, and reduces LH and androgen levels, thereby improving folliculogenesis.[156] However, pretreatment with OCP results in more days of GT therapy and a higher amount of GTs.[157]

Statins

- Statin includes simvastatin and atorvastatin
- Selective inhibitor of the enzyme hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase, decreases the production of cholesterol, the precursor to sex steroids, and thus, improves HA by decreasing ASD and testosterone biosynthesis.[146]
- Metabolized rapidly by the liver; half-life of 2 hours
- Improves lipid profile, decreases systemic inflammation (C-reactive protein), endothelial inflammation, and homocysteine levels[158]
- *Side-effects:* Myopathy, liver dysfunction, rhabdomyolysis, impairment of glucose metabolism, and teratogenicity
- It is a *category* X drug. Hence effective contraception is essential and not recommended as an adjunct to OI.
- Can be considered for the treatment of dyslipidemias in PCOS who are not trying to conceive[146]

Glucagon-like Peptide 1 Receptor Agonists

- Glucagon-like peptide 1 (GLP1) augments insulin secretion in response to oral glucose intake, inhibits glucagon secretion, slows gastric emptying, and reduces appetite and food intake.[146]
- Includes exenitide and liraglutide
- Liraglutide is long-acting and US-FDA approved.
- *Side-effects:* Nausea, vomiting, diarrhea, headache, risk of pancreatitis, possible increased risk of thyroid tumors with liraglutide
- Combination treatment of liraglutide with metformin for 12 weeks facilitates weight loss in PCOS.[146]
- Category C drug
- Although, these agents are promising for the treatment of IR and obesity in PCOS, larger studies are needed.[146]

POLYCYSTIC OVARY SYNDROME IN ADOLESCENTS

- During puberty, the normal physiologic IR in response to growth hormone, which peaks at this time, may aggravate the symptoms and phenotypic expression of PCOS **(Fig. 8)**.[25]

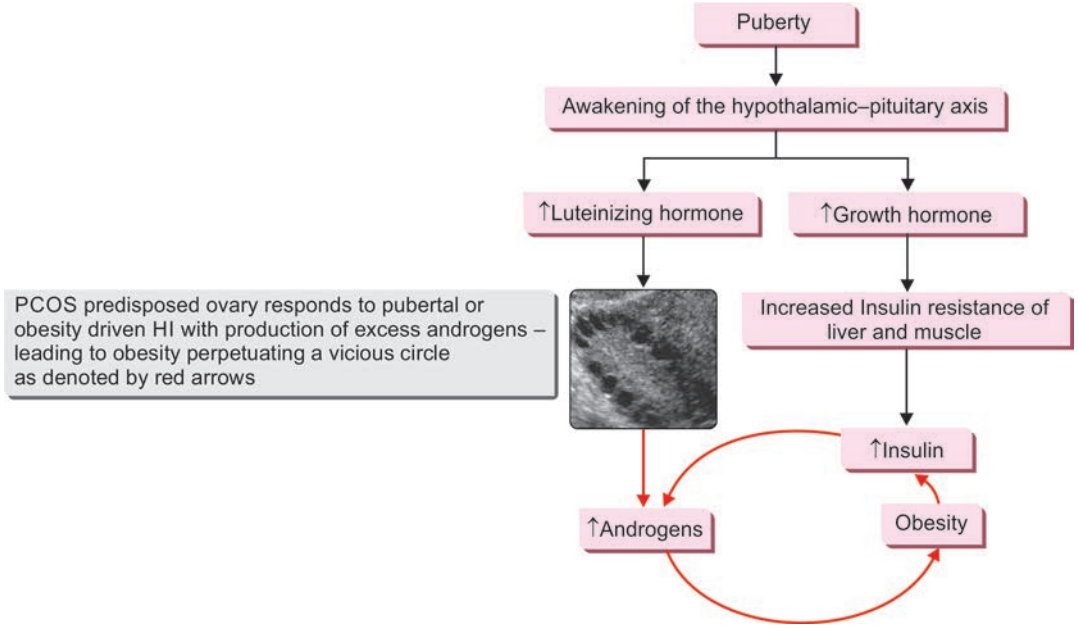


Fig. 8: Pathophysiology of PCOS in Puberty.

- Rapid weight gain in small for gestational age (SGA) girls and sustained adiposity in large for gestational age (LGA) girls accelerate the prepubertal appearance of PCOS **(Fig. 2)**.[25]
- Difficulties in diagnosing PCOS in adolescents, as several features suggestive of PCOS, may be transitory findings during the evolution of normal puberty to adulthood.[23,159]
  - A relatively higher rate of cycles being irregular and anovulatory during this period. About 85% of menstrual cycles are anovulatory during the first year following menarche, 59% in the third year, and 25% in the sixth year.
  - As acne and hirsutism are common during adolescence, there exist difficulties in interpreting clinical and biochemical evidence of HA.
  - PCOM on transabdominal sonography (TAS) has to be differentiated from multicystic ovaries, which is a normal variant feature of physiologic puberty. Hence ovary volume of more than 10 cm^3 is being considered a better marker for diagnosing PCOS in adolescents.
- Taking into account these problems, in an attempt to overcome the possibility of erroneous diagnoses, the diagnostic criteria differ in adolescents from those used for women of reproductive age **(Table 9)**.[75,159]
- *Evaluation for PCOS in adolescents:*
  - When persistent oligomenorrhea/amenorrhea for 2 years after menarche and/or primary amenorrhea by 16 years
  - When clinical evidence of HA, progressive moderate-to-severe hirsutism, and acne resistant to topical treatment
- Amenorrhea is defined when there are intervals between periods exceeding 199 days, whereas in oligomenorrheic patients the intercycle interval varies between 35 and 199 days.[75]
- Signs and symptoms of the disorder may appear in puberty, but may not be diagnosed until well into adulthood.
- Oligomenorrhea in adolescents does not require active treatment usually, but simple reassurance that with time, cycles will become regular. However, a regular follow-up to ensure that this does happen, if not further evaluation would be required.
- There has been evidence to show that low SHBG levels, HA and HI in the early teen years, predict subsequent development of class 3 obesity and MebS by mid-third decade.[23]

TABLE 9: Diagnostic criteria for PCOS in adolescents.

Parameter	*ESHRE/ASRM 2012*[62]	*Endocrine Society 2013*[86]
Criteria	1. Clinical or biochemical hyperandrogenism[a] 2. Oligo-/anovulation[b] 3. Polycystic ovarian morphology[c]	1. Clinical or biochemical hyperandrogenism[a] 2. Persistent oligo-anovulation[b]
Limitation	Three of three criteria required with exclusion of other etiologies	Two of two criteria required with exclusion of other etiologies

Note:
[a]Increased serum androgens and/or progressive hirsutism.
[b]Oligo-/amenorrhea for at least 2 years, or primary amenorrhea by the age of 16 years.
[c]Ovarian volume >10 cm^3

(ASRM: American Society for Reproductive Medicine, ESHRE: European Society for Human Reproduction and Embryology)

- A large study showed that about 26–35.3% of adolescents were at risk for MebS. Hence, screening for metabolic abnormalities in all adolescent PCOS, independent of body weight is required.[160] Menstrual irregularity and high free testosterone levels were associated with high MebS risk (OR: 3.00), the risk increased substantially with overweight or obesity.[160]
- *Screening test for IGT:* 2-hour OGTT with 75-g glucose load, interpreted using ADA guidelines. Although the most appropriate screening interval is not defined, the conversion from IGT to T2DM can occur within 5 years.[72]
- Although, routine ovarian imaging is not indicated for the diagnosis of PCOS in adolescents, TAS may be performed in those with high testosterone levels or rapidly progressive hirsutism or virilization to evaluate for malignancy.

The diagnostic value of serum AMH concentrations has also been studied since ultrasound is often unreliable to detect PCOM in this population. However, serum AMH concentrations were found to be a questionable surrogate marker of PCOM in adolescents.

- *Management:* Multidisciplinary approach, involving dietary and lifestyle modifications, symptomatic management of reproductive, metabolic, and cosmetic manifestations of the syndrome as discussed earlier
- Evaluation and management in adolescents is shown in **Table 10**.
- Lifestyle modification and OCPs significantly reduce androgens and increase SHBG in obese PCOS adolescents **(Table 11)**.
- There have been limited studies on the use of metformin in adolescents. Metformin, in combination with lifestyle modification and OCP, reduces central adiposity, reduces HA by increasing the levels of SHBG, reduces IR, and normalizes menstrual cycles. Also, indicated in those with glucose intolerance. However, it is not clear, as to for long it needs to be continued to result in long-term benefits and whether improvement in CV outcomes would occur, for which further larger longitudinal studies are required.[161]

TABLE 10: Diagnosis and management of adolescent PCOS.

Presentation	• Irregular menses more than 2 years post-menarche • Evidence of clinical androgen excess
Diagnosis	• A thorough medical history and physical examination • FSH, LH, prolactin, TSH, 17-OHP, total and free testosterone, SHBG, lipid profile and a random blood glucose level • If obese, OGTT • If unclear, define patient as at risk for PCOS but not definitive and reassess • TAS in indicated cases
Associated metabolic risk factors	Assess for hypertension (using the appropriate age- and height-percentile reference values), dyslipidemia, and impaired glucose metabolism
Hirsutism or severe acne	• Anti-androgens + OCP • OCPs containing CPA
Menstrual dysfunction	• OCPs • Progestin therapy
Obesity, glucose intolerance or diabetes, dyslipidemia	• Lifestyle modifications—diet and exercises • Metformin therapy

(CPA: cyproterone acetate; FSH: follicle-stimulating hormone; LH: luteinizing hormone; OCP: oral contraceptive pill; OGTT: oral glucose tolerance test; 17-OHP: 17-Hydroxyprogesterone; TSH: thyroid-stimulating hormone)

Recommendations by The Amsterdam ESHRE/ASRM-Sponsored 3rd PCOS Consensus Workshop Group[73]

- Adolescents at risk (e.g., obese, hirsute, irregular menses) should be identified, but be cautious of overdiagnosing PCOS.
- Individual PCOS manifestations in adolescents (e.g., obesity, hirsutism, and irregular menses) should be treated.
- OCPs—either containing or not containing an antiandrogen—may be safely used, following the contraindications to administration. Lipid patterns should be evaluated before and after a few months of treatment.

POLYCYSTIC OVARY SYNDROME AND PREGNANCY

- PCOS women may be at increased risk for adverse pregnancy outcomes, which may be exacerbated by obesity and/or IR. (Level B)[62]
- *Preconception management:* Folic acid supplementation, cessation of smoking, weight reduction, if obese and optimal control of sugars should be advised.[77] Assessment of serum homocysteine levels in those who have had repeated miscarriages.[76]
- Although data in relation to the risk of miscarriage in PCOS is conflicting, an increased risk of miscarriage has been observed (24–36% in PCOS vs. 15–18% in non-PCOS) due to:[36,162]
  - Obesity
  - Defective folliculogenesis
  - Developmental incompetence of the oocytes
  - Hyperandrogenemia
  - IR
  - Increased PAI-1
  - Hyperhomocysteinemia

TABLE 11: Lifestyle modification for polycystic ovary syndrome.

Intensity and measure[01]	*Description*	*Activities of daily living*
Light: 1.6–3† METs 40–55%* HRmax	• Aerobic activity that does not cause noticeable changes in breathing rate • An intensity that can be sustained for at least 60 minutes	Casual walking, cycling <8 km/h (5 mph), stretching, light weight training, dancing slowly, leisurely sports (playing catch) golf (using cart), light yard/house work
Moderate: 3–6† METs 55–70%* HRmax	• Aerobic activity that can be conducted whilst having an uninterrupted conversation • An intensity that may last between 30 and 60 minutes	Brisk walking (5–7 km/h, 3–4.5 mph), walking uphill, hiking, cycling (8–15 km/h, 5–9 mph), low impact or aqua aerobics, yoga gymnastics, weight training, moderate dancing, aerobic machines (stair climber, elliptical, stationary bike)—most competitive tennis, volleyball, badminton, recreational swimming, golf—carrying clubs, intense house/yard work or occupations with extended standing or walking
Vigorous: 6–9† METs 70–90%* HRmax	• Aerobic activity where an uninterrupted conversation generally cannot be maintained • Intensity that may last up to 30 minutes	Race walking, jogging/running, mountain climbing, cycling (>16 km/h, 10 mph), high impact aerobics, karate or similar, circuit weight training, vigorous dancing and aerobic machines, competitive basketball, netball, soccer, football, rugby, hockey, swimming, water jogging, downhill or cross country skiing, nonmotorized lawn mowing, occupations with heavy lifting or rapid movement

*Predicted maximal heart rate (HRmax) = 208 – [0.7 × AGE (years)]
†Metabolic equivalent (MET) where 1 MET is the O/kg body weight/min required to sustain ones resting metabolic rate (3.5 mL/kg/min)

  - Altered serum leptin levels:
    - Endometrial glycodelin and IGFBP-I
- Decreased uterine vascularity and increased uterine vascular resistance.
- Recurrent miscarriage is found to be higher in PCOS (36–56%), in comparison to the general population (20–23%).[163]
- There is also a higher incidence of pregnancy complications such as gestational diabetes (40–50%), gestational hypertensive disorders (5%), and neonatal complications [(small-for-gestational-age babies (10–15%) and neonatal intensive care units admissions)], even in singleton pregnancies.[164,165]
- Pregnancy-related complications are greater in type A and B phenotypes due to impaired early decidual trophoblastic invasion and/or remodeling of spiral vessels and placentational defects.[166]
- Obese PCOS will have the additional risk of obstetric complications, such as shoulder dystocia and postpartum thromboembolism.[166]
- Metformin therapy lowers HI and may have a beneficial effect in reducing miscarriage rates and the risk of gestational diabetes.[167] Data supports their safety when used during pregnancy, with no major birth defects and no effect on social or motor development in infants followed up at 3 and 6 months of age.[167]
- *Evidence:* There is no evidence that the use of metformin either before conception or during pregnancy decreases pregnancy complications and improves the live birth rates (Level A).[167]
- Endometrial receptivity during the implantation window of LE is superior to CC in PCOS women, which may be related to higher clinical pregnancy and ongoing PRs. Endometrial FI examined by 3-D power Doppler, and integrin αvβ3 in uterine secretion during the implantation window, could be preferable noninvasive predictor markers for pregnancy.[168]

POLYCYSTIC OVARY SYNDROME AND MENOPAUSE

- With age, many of the manifestations, including hirsutism, oligomenorrhea, testosterone levels, ovarian size, and morphology, may improve.[62]
- Diagnosis in postmenopausal first is based on the previous history of menstrual dysfunction (oligomenorrhea) and presence of HA during the reproductive period with PCOM, as formulated by the Endocrine Society (2013).[160]
- PCOS women will have a larger cohort of primary follicles than age-matched control women before menopause.
- Hirsutism, alopecia, and AUB are the presenting complaints of postmenopausal women with PCOS.
- Menopausal PCOS women have a higher incidence of obesity, hypertension, diabetes, CV complications, and stroke.
- Continuous unopposed estrogen-mediated endometrial proliferation leads to endometrial hyperplasia and carcinoma, with obesity and diabetes adding to the risk.
- It has been found the odds of PCOS developing endometrial carcinoma are almost three times higher (approximately 9%), as shown in a systematic review and

meta-analysis.[168] Further, in PCOS <50 years, there is a fourfold increased risk of developing endometrial cancer (EC).[169,170] When adjusted for BMI, this risk was reduced by half. Well-differentiated, endometrioid adenocarcinoma (a subtype of type-1 EC) is the most common.

- Women with PCOS may experience menopause on average 2 years later than healthy control women due to prolonged reproductive function as well as an increased ovarian reserve.[75]
- Although retrospective data suggest that they have higher rates of stroke and CVD, with mortality occurring at a similar rate and presumably at the same age, as in the general population, prospective data suggest they have increased CVD event rates and decreased survival.[75]

KEY POINTS

- Polycystic ovary syndrome is the most prevalent cause of anovulatory infertility accounting for 80–90% of WHO group 2, hypothalamic-pituitary-ovarian dysfunction.
- PCOS is an endocrine, metabolic, and chronic inflammatory disorder, with hyperandrogenemia, IR, and obesity being the key factors that influence the expression and symptoms of the condition.
- HA, like chronic anovulation, is a hallmark of PCOS, and its origin appears to be multifactorial; the evolution and severity of its phenotypic expression result from the impact of environmental influences (both pre- and postnatal) on genetic and epigenetic factors in utero.
- First-line therapy for all PCOS women is lifestyle modifications targeting weight loss in those obese and overweight and prevention of weight gain in lean women.
- CC or LE should be the first-line pharmacological therapy to improve fertility outcomes in PCOS, with no other infertility factors.
- Recommended second-line intervention should first-line fail to result in pregnancy is either exogenous GTs or LOD.
- Induction of ovulation great care must be taken to avoid multiple follicle development and its adverse consequences—OHSS and multiple pregnancy particularly with GTs.
- Metformin use in PCOS should be restricted to women with glucose intolerance and in combination with CC improves ovulation and CPRs but does not improve live birth rates.
- Screening by OGTT (75 g, 0- and 2-hour values) should be performed in the following conditions: obesity, women with a family history of T2D or GDM, HA with anovulation, and acanthosis nigricans.
- Women with PCOS have an estimated 2.2, 2.5, and 4-fold increased prevalence of metabolic dysfunctions, IGT, and T2DM, respectively in both BMI and non-BMI-matched studies.
- MebS is a cluster of risk factors, predisposing to both CVD and T2DM.
- PCOS with a BMI >30 kg/m^2, high-risk ethnic South Asian women with a BMI >25 kg/m^2, dyslipidemia, overt vascular or renal disease, or family history of T2DM are at risk of metabolic dysfunction.
- Recommended CVD risk assessment at any age: assessment for BP, glucose, lipid profile (cholesterol, triglycerides, HDL, and LDL), waist circumference, physical activity, nutrition, smoking, and psychosocial stress.
- During pregnancy, PCOS women should be followed closely as they may be at increased risk for the development of GDM, gestational hypertension, and neonatal complications, even in singleton pregnancies. This may be exacerbated by obesity and/or IR.
- Women with PCOS have a 2.7–2.9-fold increased risk for endometrial carcinoma. Most ECs are well differentiated and have good prognosis.

CHAPTER 40

Assessment of Ovarian Reserve

Padma Rekha Jirge

INTRODUCTION

Ovarian reserve is the quantity and quality of the primordial follicle pool and is an important factor in determining the fertility potential of an individual.[1] Age-related decline in ovarian reserve has long been documented, noted as early as mid-twentieth century.[2] Two factors that necessitate the need for elaborate assessment of ovarian reserve are: wide variation in the age-related decline in fertility and absence of any clinical pointers for declining ovarian reserve, as majority of women continues to have regular menstrual cycles during this phase. It is believed that there is an accelerated decline in the follicle numbers when the critical figure reaches 25,000 and fertility remains for a relatively short period beyond this stage.[3,4] Hence, estimation of ovarian reserve would assist in making informed decisions about fertility, need for any active management, and fast tracking toward in vitro fertilization (IVF).

An ideal ovarian reserve test (ORT) should be easy to perform, easily reproducible, noninvasive and accurately measure the quantity and hence quality of the follicular pool; and predict the chances of pregnancy.[5] Over a period of time various static and dynamic tests have been introduced into clinical practice for evaluation of ovarian reserve. It has so far not been possible to estimate the primordial follicle pool and hence various indirect measures are used. These include direct ovarian assessment, including certain secretions from the ovarian follicles, various measurements of the ovaries, or indirect measurements of certain hormones, which reflect a declining ovarian follicular pool.

OVARIAN RESERVE TESTS

Ovarian reserve tests have been developed primarily with an aim to predict the ovarian response in IVF. However, it is not clear whether the decline in oocyte quality is dependent on chronological age or the changing hormonal environment with declining numbers of oocytes.[6] A list of these tests has been summarized in **Table 1**.

BIOLOGICAL AGE

Biological age remains the most important predictor of reproductive potential of an individual.[1] Fecundity is known to decline with maternal age and this is evident from ages as early as late 20s.[7-9] Despite wide variation within population and amongst different ethnicities, it is known that ovarian reserve declines rapidly after 37 years of age.[7,10,11] In those undergoing IVF, most of the embryos are found to be aneuploid by the age of 44 years.[12] It is interesting to note that even women with polycystic ovarian syndrome (PCOS) with high ovarian reserve do not appear to have an extended window of fertility.[13] However, it is generally believed that in women younger than 35 years of age despite poor ovarian response, risk of pregnancy loss with IVF cycles does not increase, due to euploid nature of most of the embryos obtained.[14] As there is a wide spectrum of response encountered in women undergoing IVF from normal to hyper-response, biological age alone cannot be used as

TABLE 1: Ovarian reserve tests.

Ovarian reserve tests	*Categories*	*Tests*
Biological	Biological age	–
Biochemical	• Static	• Baseline serum FSH (day 2–4) • Baseline serum estradiol • Serum inhibin B • AMH
	• Dynamic tests	• CCCT • EFFORT • GAST
Biophysical	Ultrasonological evaluation	• AFC • Ovarian volume • Ovarian Doppler
Histological	Ovarian biopsy	–

(AFC: antral follicle count; AMH: anti-Müllerian hormone; CCCT: clomiphene citrate challenge test; EFFORT: exogenous follicle-stimulating hormone ovarian reserve test; FSH: follicle-stimulating hormone; GAST: gonadotropin-releasing hormone agonist stimulation test)

a marker of ovarian reserve and hence efforts continue to identify a single or a set of markers of ovarian reserve to predict the ovarian response.

BASAL SERUM FOLLICLE-STIMULATING HORMONE

Basal follicle-stimulating hormone (FSH) has been the most widely used ORT to assess ovarian reserve for the past three decades. It is measured in the morning hours on days 2–4 of the cycle.[15] The measurement of FSH is easy and it is an inexpensive test. However, it has diurnal, intra- and intercycle variability.[16,17] Increasing levels of FSH occur due to progressive follicular depletion. There is no universally accepted cutoff value for FSH to predict poor ovarian response. However, most of the IVF clinics consider 10–12 IU/L as the upper limit of normal range. In women with regular menstrual cycles, FSH can predict poor ovarian response only at very high levels and consequently helpful to only a small number of women as a screening test for poor ovarian reserve. Considering that decline in ovarian reserve begins several years earlier to any elevation in serum FSH levels, a normal value cannot rule out a poor ovarian response.[18,19] In addition, significance of elevated basal FSH levels in young infertile women with regular menstrual cycles is unclear.[20,21] Hence, in the current clinical scenario with availability of more robust ovarian reserve markers, FSH cannot be used alone to predict ovarian reserve.

SERUM ESTRADIOL

The role of estradiol as an ORT has remained controversial. It is known that an elevated serum estradiol level may mask abnormal FSH levels and the ovarian reserve may be wrongly considered as normal.[22] Hence, addition of serum estradiol values on days 2–4 of the cycle with FSH values is considered to reflect ovarian reserve more precisely. Elevated basal estradiol in itself (>80 pg/mL) is considered as predictor of poor response.[23] However, a meta-analysis concluded that basal estradiol does not add to the predictive value of other ORTs and hence it should not be used in routine clinical practice as an ORT.[19]

SERUM INHIBIN B

Inhibin B is a glycoprotein produced in the granulosa cells of ovarian follicles. It is noted that serum inhibin B level of <45 pg/mL predicts poor response to ovarian stimulation for IVF.[23] Inhibin B was the first ORT used to predict hyper-response in IVF.[24] However, unreliability of the assays and availability of more robust markers of ovarian reserve such as anti-Müllerian hormone (AMH), to predict both ovarian response in IVF and occurrence of pregnancy, have limited the use of inhibin B as an ORT in recent years.[25,26]

SERUM ANTI-MÜLLERIAN HORMONE

Anti-Müllerian hormone is a dimeric glycoprotein exclusively produced by granulosa cells of preantral (primary and secondary) and small antral follicles (AFs) in the ovary.[27,28] AMH is produced by the granulosa cells of the follicles following their transition from primordial pool to the primary stage and continues till the follicles reach antral stage with diameters of 2–6 mm.[28-30] These small antral follicles reflect the size of the primordial pool. As the size of the follicular pool declines with age, AMH production diminishes and becomes undetectable at menopause.[31] It is considered as a regulator of follicular recruitment and with declining AMH levels, there is an accelerated recruitment of follicles from the primordial pool.[28]

Anti-Müllerian hormone exhibits certain advantages over other ovarian reserve markers:

- It exhibits little intra- and intercycle variability and hence can be measured on any day of the menstrual cycle.[32,33]
- It is the earliest marker to show decline in ovarian reserve. Levels below 1.26 ng/mL are considered to indicate poor ovarian response to ovarian stimulation. At levels of 0.5–1.26 ng/mL, AMH indicates perimenopausal transition within 3–5 years. Women with levels within this range still have a favorable outcome with IVF if the treatment is not delayed.[34]
- It is a very sensitive marker to predict hyper-response as well.[35]
- Serum AMH levels strongly correlate with antral follicle count (AFC) measured by transvaginal ultrasonography (TVS).[36]
- Age-related population nomograms are available for AMH[37,38] and this provides an opportunity to counsel young women with low AMH regarding prioritizing conception or for oocyte cryopreservation.[39]
- AMH has a unique place in that it may be applicable as a screening test in a general subfertile population.[39]
- AMH is the only ovarian reserve marker found to be reliable in assessing the residual ovarian reserve in young cancer survivors who have received gonadotoxic therapy previously.[40]
- Whether AMH can predict the occurrence of pregnancy is less clear. However, recent evidence suggests that AMH may be a better predictor of occurrence of pregnancy in young poor responders than age alone.[41]

Anti-Müllerian hormone assay technique has evolved over the past decade as well. From the initial enzyme-linked immunosorbent assay (ELISA), semiautomated assays, we now have fully automated assays. Original diagnostic systems lab (DSL) assay is considered as the benchmark for AMH assays. However, the fully automated assays have reduced the time consumed for performing the assay and made international comparison feasible.[42]

A comparison of three different ELISA assays and the two new automated assays have revealed certain important facts. All the three commercially available ELISA assays—Gen II (Beckman Coulter), EIA AMH/MIS (Immunotech, Beckman Coulter), and Ultrasensitive AL-105i (Anshlab) perform similarly.

The two new fully automated immunoassays are Access Dxi automatic analyzer (B13127, Beckman Coulter) and Cobas e instrument (Roche Diagnostics). Gen II and Cobas e assays use bovine AMH as calibrator whereas others use recombinant human anti-Müllerian hormone (rhAMH) as the calibrator. It is seen that even though all the assays have similar specificity of 91.7%, Cobas e has the highest sensitivity of 73.5% similar to Gen II assay.[43] As there is a shift toward use of fully automated assays in the recent years and as AMH is the most important deciding factor in individualizing the protocols and dosing, it is of importance to note that AMH values measured by Access assay are on an average 10% higher than that by Cobas e assay. This has led to concerns regarding incorrect dosing in up to 29% of women when Access assay used for AMH estimation.[44] However, current clinical experience is reassuring and suggest that the such differences little affect the calibration of FSH dose for ovarian stimulation.[45]

DYNAMIC TESTS

Three dynamic tests have been used in the past to assess ovarian reserve:[46]

1. *Clomiphene citrate challenge test (CCCT):* This involves estimating basal FSH level on day 3 followed by administration of 100 mg of clomiphene from day 5 to day 9 and estimation of FSH level on day 10. Either an abnormally high basal FSH or an abnormally high value of cumulative FSH (day 3 + day 10) is considered as evidence of poor ovarian reserve.
2. *Exogenous follicle-stimulating hormone ovarian reserve test (EFFORT):* This test involves estimation of basal FSH and estradiol on day 3 of the cycle followed by administration of 300 IU FSH on the same day. Serum estradiol concentration is rechecked 24 hours later. It was found to be of value in predicting hyper-response but has a high false positive rate.
3. *Gonadotropin-releasing hormone agonist stimulation test (GAST):* This test involves estimation of day 2 serum estradiol followed by administration of gonadotropin-releasing hormone agonist (GnRH-a) (triptorelin 100 μg) subcutaneously. The test is repeated 24 hours later and an elevation in estradiol is considered to indicate good ovarian reserve. It has been used in the past to identify poor responders.

The dynamic tests are time consuming, expensive, and are inferior to the more robust markers such as AMH and AFC.[46]

ANTRAL FOLLICLE COUNT

Antral follicles are all the small follicles seen in the ovary measuring 2–10 mm in diameter. The AFC is measured in the early follicular phase (day 2–4) using TVS with a 7.5 MHz probe. Two perpendicular measurements are taken of each of the follicles and the mean value is considered the diameter of the follicle. The follicles in both ovaries are added for the total AFC.[47] An AFC of 8–16 is considered to predict normal ovarian response in IVF whereas those below 8 are considered to predict poor ovarian response. An AFC of >16 is highly predictive of hyper-response. AFs of 2–6 mm and 2–9 mm are both considered to reflect AFC. However, the number of AFs of 2–6 mm diameter decline with age whereas those of 7–9 mm diameter remain constant and hence the former appears to be a more reliable marker of ovarian reserve.[48] There appears to be limited intercycle variability; however, interobserver variability in young women may be high. Use of 3D ultrasound does not have any advantage over 2D ultrasound in the assessment of ovarian reserve.[49]

Antral follicle count has a strong correlation to AMH and has similar sensitivity and specificity to predict both poor and hyper-response.[36] Current evidence does not support its ability to predict occurrence of pregnancy.[41]

OVARIAN VOLUME

Ovarian volume is measured by TVS using the formula for an ellipsoid. Even though increased ovarian volume is an important diagnostic criterion for PCOS, it does not add to the predictive value of AFC while assessing ovarian reserve.[50,51]

OVARIAN DOPPLER ASSESSMENT

Even though attempts have been made to utilize ovarian Doppler for assessing ovarian reserve, its role is currently limited to assessing perifollicular flow during ovarian stimulation with a view to select oocytes with best potential to achieve pregnancy.[52]

OVARIAN BIOPSY

Biopsy of ovarian cortex obtained during laparoscopy or laparotomy, have shown declining follicular density with age. However, the follicles are not uniformly distributed in the cortex and hence the biopsy may not represent the true follicular density.[53] In addition, any such invasive procedure has no place in the current clinical scenario in the presence of ovarian reserve markers such as AMH and AFC.

DISCUSSION

Historically, ORTs were thought to reflect oocyte quantity and were developed to provide prognostic information for IVF cycles.[1] Despite decades of research, controversy

TABLE 2: Role of ovarian reserve testing under various clinical scenarios.

ORT	*Role*
Prior to IVF	To individualize protocol and dosing; counseling regarding hyper- or poor response and their consequences
Subfertile women	To identify those with poor ovarian reserve and early recourse to IVF
General population	Informed decision regarding social egg freezing or prioritize conception
Young cancer survivors	To assess residual ovarian function and offer suitable fertility treatment

(IVF: in vitro fertilization; ORT: ovarian reserve test)

remains as to whether ORTs can also provide insight into oocyte quality and estimate an ovarian age. Over a period of four decades, various forms of ORTs have become available for clinical use.[54]

Table 2 highlights the role of ovarian reserve testing in various clinical situations commonly encountered. The primary role of any ovarian test has been prediction of ovarian response to ovarian stimulation in IVF. It is well understood that ovarian reserve declines with age. But clinical experience has also shown that there is a wide variation amongst young women of reproductive age in the rate of decline in ovarian reserve. Hence, the initial efforts were directed toward identifying poor responders. Basal FSH, estradiol, and various dynamic tests have been used to achieve this purpose,[18,19,23,46] and they are all found to have limited value in clinical use. However, AMH and AFC are the two markers of ovarian reserve found to have highest predictive value for not only for poor response but also for hyper-response.[35] They have made it possible to individualize the IVF protocols based on the ovarian reserve to improve both safety and efficacy of IVF.[55]

In the recent years, efforts have been directed at identifying poor responders in young women with infertility early enough and offer fast-tracking of treatment to maximize the chances of conception for such women with their own eggs. AMH is found to be the marker that declines earliest with age; and addition of AFC may not improve the predictive value.[34,36] AMH has also allowed exploration of an association between poor ovarian reserve and genetic factors such as *BRCA* mutations or environmental toxins such as bisphenol A and phthalate.[56,57]

Even though there is general consensus that ORTs predict the quantity of follicles reliably, there is controversy regarding their ability to predict the quality of oocytes and hence the occurrence of pregnancy. Age is generally considered the best measure of oocyte quality and young women with reduced quantity of oocytes still have a good pregnancy outcome.[14] However, recent evidence has challenged this view and low AMH and AFC in addition to predicting ovarian response may also be indicative of poor oocyte quality.[58-60]

Over the past two decades, there is a steady increase in the survival of children and young adults treated for various malignancies. This has also brought into focus the fertility issues in such young population treated previously with gonadotoxic chemotherapy and/or radiotherapy. AMH is found to be the only marker, which reflects the damage to the follicular pool during and immediately after such treatment and recovery of and residual ovarian reserve following treatment.[40] It plays an important role in decision-making process for suitable treatment in such young women who have not been offered or found ineligible for fertility preservation prior to cancer therapy.

One of the most important growing concerns in the field of reproductive medicine is the increasing global trend toward delaying pregnancy. This increases the need for usage donor oocytes in women with very poor ovarian reserve and those with advanced maternal age. AMH has been used to assess ovarian reserve in those who wish to delay fertility as it is known to be the earliest marker to show decline in ovarian reserve.[37-39] This helps in informed counseling of young women wishing to delay childbearing either for oocyte cryopreservation or to prioritize fertility based on the situation and individual's wish.

CONCLUSION

Ovarian reserve tests play an important role in the evaluation of infertile women. AMH and AFC have the best predictive value for ovarian reserve compared to all other markers. Age is considered to be most important factor in predicting the occurrence of pregnancy. However, recent evidence suggests that AMH and AFC may have better predictive value for euploid pregnancy in young women compared to age alone. AMH, in addition, is proven to be a good screening test for general population wishing to delay fertility and also to identify poor responders in the subfertile population to expedite and fast-track the treatment. The role of FSH in the current scenario for evaluation of ovarian reserve is limited.

CHAPTER 41

Endometriosis

Nandita Palshetkar, Rohan Palshetkar, Erika Patel

INTRODUCTION

Endometriosis is a long-term, recurrent, and debilitating disease experienced by 5–10% women. It remains an everlasting challenge to the healthcare providers, one of the important reasons being a delay in its diagnosis.[1]

Endometriosis affects 1 in 10 women of reproductive age worldwide. The prevalence of endometriosis as reported is between 2% and 10% in the normal women, 20–50%[2,3] in the infertile population, and >60%[4] in women with chronic pelvic pain and dysmenorrhea. Maximum incidence is seen in the age group of 25–30 years.

Endometriosis is characterized classically by the presence of endometrial glands and stroma outside the endometrial cavity in ectopic locations like the pelvic peritoneum, ovaries, and retrocervical septum.[5,6]

The monthly fecundity rate (MFR) in a normal couple in the reproductive age group is around 30% in the first three cycles and <4% after 1 year. In endometriosis, MFR is reduced to 2–10% per month. Even minimal endometriosis may present with severe infertility.[7,8]

PATHOGENESIS OF ENDOMETRIOSIS

Flowchart 1 describes the pathogenesis of endometriosis.

PATHOGENESIS OF ENDOMETRIOSIS CAUSING INFERTILITY

Whether endometriosis causes subfertility or whether it is an incidental finding in subfertile women remains a controversial issue.

Various mechanisms are known to cause fertility impairment, which are discussed here.

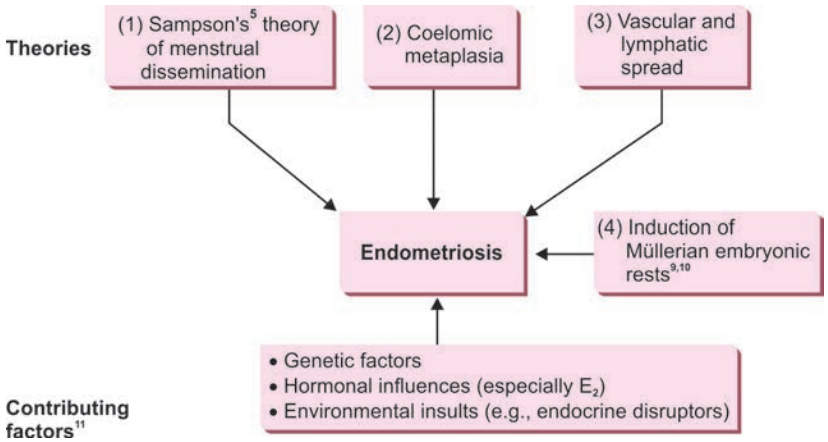
Ovulatory Dysfunction

- Abnormal folliculogenesis
- Slow follicle growth with a decreased dominant follicle size
- Poor oocyte quality
- Decreased fertilization rate
- Low-grade embryo formation
- Reduced implantation
- Luteal phase defect (LPD)
- Luteinized unruptured follicle (LUF) syndrome.

Bacterial Contamination Hypothesis

Diagrammatic presentation of the lipopolysaccharide (LPS)/toll-like receptor-4 (TLR4) cascade in the bacterial contamination hypothesis of endometriosis is shown in **Figure 1**.

Flowchart 1: Pathogenesis of endometriosis.



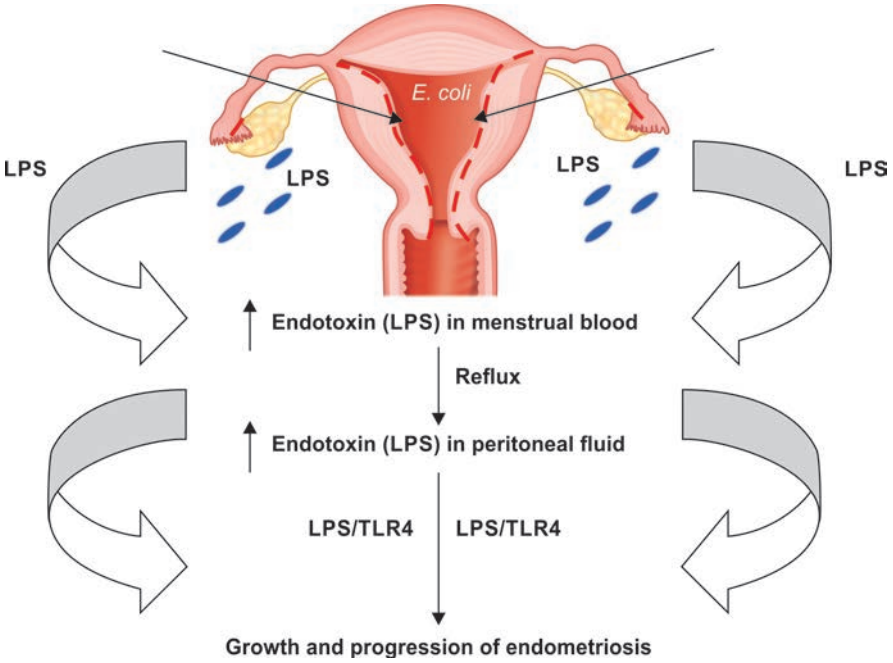


Fig. 1: Bacterial contamination hypothesis.
(*E. coli*: *Escherichia coli*; LPS: lipopolysaccharide; TLR: toll-like receptor)

The constant release of LPS from *Escherichia coli* (*E. coli*) contamination of the menstrual blood causes a higher endotoxin (LPS) concentration in the menstrual blood and consequently higher levels of endotoxin in the peritoneal fluid (PF) due to the retrograde flow of menstrual blood into the pelvis. Peritoneal macrophages, eutopic and ectopic endometrial epithelial cells, and epithelial stromal cells express TLR4, a receptor for LPS. The LPS/TLR4 complex induces pelvic inflammation and promotes the growth and progression of endometriosis via intracellular adaptor molecules and nuclear factor kappa-light-chain-enhancer of activated B-cells activation.[11]

Inflammation in the PF and at the follicular level is described in **Table 1.**

TABLE 1: Inflammation in peritoneal and follicular fluid.

In the peritoneal fluid (PF)	*In the follicular fluid*
↓	↓
• Increased cytokines (IL-1 beta, IL-6, TNF alpha, IL-10) promote adhesion • Decreased vascular endothelial growth factor (VEGF)[12] promotes follicular growth and vascularization • Increased matrix metalloproteinases (MMPs) promote invasion • Increased chemokines like IL-8, MCP, RANTES-1 which attract increased numbers of immune cells, thus increasing proliferation and angiogenesis	• Increased IL-6 which inhibits aromatase enzyme. This decreases estrogen (E2) causing subfertility[13] • Decreased VEGF thus hampering embryo quality and implantation rate[14]

(IL: interleukin; MCP: monocyte chemotactic peptide; RANTES: regulated on activation, normal T-cell expressed and secreted; TNF: tumor necrosis factor)

Oxidative Stress and Endometriosis

In women with endometriosis, expression of enzyme xanthine oxidase, which produces reactive oxygen species (ROS), is increased.[15] Also, large amounts of ROS are produced by macrophages and polymorphonuclear (PMN) leukocytes in PF and endometrial cells as well as apoptotic endometrioma cells.

Reactive oxygen species and elevated ROS produce oxidative stress, which has the following effects:

- Oocyte degeneration and apoptosis by damaging the meiotic spindle.
- Lipid peroxidation causing increased membrane and cell death.[16]
- Increased fragmentation at the time of intracytoplasmic sperm injection (ICSI).[16]
- Local inflammation resulting in increased cytokines, which in turn promote endometriosis.[17]
- Increased deoxyribonucleic acid (DNA) damage of the oocyte, sperm, and embryo thus adversely affecting the fertilization rate, implantation rate, and increasing the miscarriage rate.[18]
- Nitric oxide (NO) is a free radical which regulates apoptosis. Low levels of NO are crucial in ovarian function and implantation. However, increased amounts of NO and nitric oxide synthase (NOS) are seen in the endometrium of women having endometriosis.[19,20] Following effects of high levels of NO are seen:

- Deleterious effect on oviduct function and sperm motility
- Toxic to embryos
- Inhibits implantation.

[Corollary: In in vitro fertilization (IVF), contact of gametes with toxic peritoneal and oviductal factors (NO and ROS) is avoided, which increases pregnancy rate (PR)]

Endometriosis and Sperm Function

As discussed above, increased ROS production by activated macrophages can induce DNA fragmentation, lipid peroxidation in turn increasing membrane permeability, loss of membrane integrity, and enzyme inactivating the sperm.[16]

Also, severe ROS can negatively affect the acrosome reaction and sperm-oocyte fusion.[21]

In endometriosis, not only the sperm motility is affected, but also the tubal ampulla binds sperm more tightly, resulting in reduced quantity of free sperms available to travel through the lumen for fertilization.[22]

Endometriosis and Fertilization

There is reduced fertilization in endometriosis due to:[23-25]

- Poor oocyte quality
- Normal follicular fluid (FF) induces acrosome reaction and binding of sperms to zona pellucida (ZP). The PF and FF in endometriosis inhibit the Sperm—zona binding.[26-28]

Endometriosis and Implantation

Normally, during the window of implantation (WOI), the cellular adhesion molecule αVβ3 integrin expression is increased. But in endometriosis, the expression of αVβ3 is reduced or absent, thus decreasing the endometrial receptivity and hampering implantation.[29,30]

Also, delayed histologic maturation and biochemical disturbances may affect the endometrial receptivity.[29]

In a Nutshell

Factors causing infertility in endometriosis:

- Ovulatory dysfunction
- Immunological alterations
- Peritoneal factors
- Sperm inactivation—phagocytosis by macrophages
- Interference with implantation—endometrial dysfunction
- Interference with coital function—dyspareunia
- Mechanical factors:
  - Anatomical distortion of tubes
  - Altered tubal motility
  - Interference with ovum pickup
  - Peritubal adhesions.

The adverse effect of pelvic endometriosis on uterine cavity is seen not only before conception but even after, resulting in deep placentation and subsequently predisposing the woman to preeclampsia and antepartum hemorrhage in pregnancy.[31]

CLINICAL FEATURES[32]

The Guideline Development Group (GDG) recommends that the diagnosis of endometriosis should be considered in women with any of the following:

- Gynecological symptoms such as dysmenorrhea, chronic pelvic pain, deep dyspareunia, infertility, and fatigue.
- Nongynecological cyclical symptoms such as dyschezia, dysuria, hematuria, shoulder pain, or rectal bleeding in a woman of reproductive age.

DIAGNOSIS OF ENDOMETRIOSIS

Clinical examination must be performed in all women suspected to have endometriosis, although vaginal examination may not be appropriate for adolescents and women without any prior sexual intercourse. In some cases, rectal examination may be helpful, especially when rectal endometriosis or ovarian endometrioma is suspected.

When painful induration and/or rectovaginal wall nodules are felt and nodules are visible in the posterior vaginal fornix on clinical examination, the diagnosis of deep endometriosis may be considered **(Figs. 2 and 3)**.[33]

When adnexal masses are detected on clinical examination, the diagnosis of ovarian endometriosis may be strongly considered.

Sometimes even in presence of endometriosis, the clinical examination is normal.[34] Transvaginal sonography is a very good modality to diagnose or exclude ovarian endometrioma[35] and rectal endometriosis, but in the latter, a highly experienced operator is required.[1] Typical and atypical ultrasonography (USG) features of endometrioma are shown in **Table 2**.

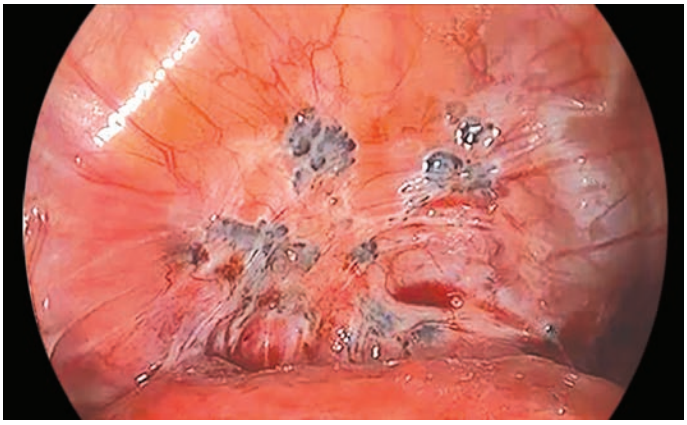

Fig. 2: Left ovarian cyst with endometriotic nodules in the pouch of Douglas with adhesions.

A monolateral, unilocular image <5 cm in the ovary, without septa or papillae with very sparse vascularization independent of its content's density, has very little possibility of being malignant. **Table 3** shows differential diagnosis of endometriotic cyst.

- Doppler ultrasound is of great help in the differential diagnosis, as most endometriomas show the typical peripheral vascularization, whereas others show the "hilus sign" described by Kurjak, which is the presence of vessels between the cyst capsule and the ovarian parenchyma.
- Three-dimensional USG to diagnose rectovaginal endometriosis is not a well established tool. Magnetic resonance imaging (MRI) is useful in diagnosis of extraovarian endometriosis.[36]
- Biomarkers in the endometrial tissue/follicles or menstrual blood and/or cancer antigen-125 (CA-125) should not be used to diagnose endometriosis.[37]

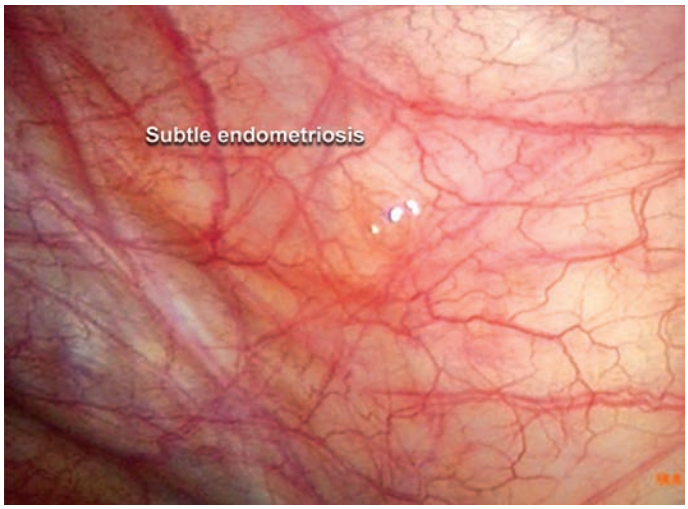

Fig. 3: Subtle endometriosis in the ovarian fossa.

TABLE 2: Typical and atypical ultrasonography (USG) features of endometrioma.

Typical USG features of endometrioma	*Atypical features of endometriomas*
• Oval mass • Hypoechoic content • Hyperechogenic wall • Absence of papillae	• Septae • Inhomogeneous content • Irregular internal wall • Papillary projections

Laparoscopy along with histological confirmation of endometriotic glands and/or stroma used to be the gold standard for diagnosis. However, according to the new European Society of Human Reproduction and Embryology (ESHRE) 2022 guidelines, laparoscopy is no longer the diagnostic gold standard and it is now only recommended in patients with negative imaging results and/or where empirical treatment was unsuccessful or inappropriate.

STAGING

Laparoscopy is essential for the definitive diagnosis of endometriosis. The American Society for Reproductive Medicine (ASRM) classification system is the most widely accepted staging system,[38] but unfortunately no staging system correlates adequately with the pregnancy chances following treatment **(Fig. 4)**.

MANAGEMENT OPTIONS

- Medical
- Surgical
- Combined medical and surgical
- Superovulation-intrauterine insemination (SO-IUI)/IVF/ICSI
- Oocyte freezing.

Medical Treatment

Currently all the available treatment options for endometriosis are suppressive rather than curative. So, there is temporary relief of symptoms during the treatment and on discontinuation, recurrence is the rule. The most common indication for medical treatment is pain. The current treatment options for endometriosis-associated pain are contraceptive in nature by blocking the hypothalamic-pituitary-ovarian (HPO) axis.

A systematic review of 25 trials[39] showed that in subfertile women with endometriosis who wanted to conceive, there was no benefit of using ovulation suppression.

In women with endometriosis associated with pain, nonsteroidal anti-inflammatory drugs (NSAIDs) appear to be the only medical option. In a systematic review of three clinical trials,[40] pretreatment with a gonadotropin-releasing hormone (GnRH) agonist for 3–6 months before IVF/ICSI in endometriosis improved the clinical pregnancy rate (CPR) fourfold.

TABLE 3: Differential diagnosis of endometriotic cyst.

Gonadotropin-releasing Hormone Agonists

Refer **Table 6**.

Extrapelvic and Deep Infiltrating Endometriosis

Deep infiltrating endometriosis (DIE) involves the utero-sacral ligaments, rectovaginal septum, bowel, ureters, or urinary bladder. GnRH agonists are usually the first-line agents as they suppress ovarian hormone production and inhibit the growth of ectopic endometrial growth.[54]

TABLE 4: Medical treatment options for endometriosis.

Medical therapy[41]	
FDA approved therapies: • Three GnRH agonists: – Leuprolide – Goserelin – Nafarelin • Two progestins: – Depot medroxyprogesterone acetate 150 mg IM every 3 months. This may cause decrease in bone density with long-term use – Norethindrone acetate (oral) is the only oral progestin approved by the FDA. Dose—5 mg/day orally for 2 weeks, then increased by 2.5 mg/day every 2 weeks till 15 mg is reached for total 6–9 months • Danazol: – Antiestrogenic with weak androgen agonistic properties – Causes anovulation and suppression of menses by inhibiting gonadotropins, immunomodulatory action, and inhibition of cell proliferation – Category X drug	*Non-FDA approved therapies:* • Ovulation suppressing agents: – Combined hormonal contraceptives usually recommended as first-line therapy in adolescents with endometriosis and in those without contraindication to hormonal treatment – Progestins: - Oral medroxyprogesterone acetate 20–30 mg/day for 6 months - Dienogest (2 mg/day) – GnRH antagonists: - Cetrorelix acetate 3 mg subcutaneous weekly over a 8 weeks period - Elagolix (oral) • Anti-inflammatory agents: – *NSAIDs:* According to a Cochrane review[42] although NSAIDs are used as a first-line treatment in suspected endometriosis, there is little evidence for significant reduction in pain. No one NSAID is more effective than the other. Along with OCPs, usually given as first-line therapy[43] – *COX-2 inhibitors (Rofecoxib):* Inhibits PG synthesis—withdrawn from US market due to cardiovascular risk – *Peroxisome proliferator-activated receptor gamma (PPAR-γ) agonists (rosiglitazone and pioglitazone)* – *Pentoxifylline:* Not commonly used – *Antioxidants:* Role is speculative • Agents acting on endometriotic deposits directly: – Aromatase inhibitors (inhibition of estrogen formation in ovarian granulosa cells and also in endometriotic deposits) - Letrozole, anastrozole—concern is formation of functional cysts due to superovulation – Levonorgestrel intrauterine device (LNG-IUD) – Progesterone receptor antagonists/selective progesterone receptor modulators - Mifepristone – Selective estrogen receptor modulator (SERM)—raloxifene – Statins–e.g., simvastatin • Immunomodulators—e.g., infliximab, etanercept • Angiogenesis inhibitors—cabergoline, quinagolide • Gestrinone • Valproic acid • Melatonin • Phytoestrogens—isoflavones

(FDA: Food and Drug Administration; GnRH: gonadotropin-releasing hormone; NSAIDs: nonsteroidal anti-inflammatory drugs; OCP: oral contraceptive pills; PG: prostaglandin)

TABLE 5: Dienogest (DNG).

Type	***Fourth generation selective progestin steroid***
Route	Oral
MOA	Anovulation, antiproliferation, and inhibition of cytokine secretion from endometrial stromal cells
Additional effects	Antiandrogenic. Profound local effects on local endometriotic implants with minimal impact on metabolic parameters
Dose	2 mg daily is usually recommended
Comparison with other drugs	• When compared with norethisterone acetate (NETA) at 2.5 mg, DNG at 2 mg gave comparable symptomatic relief and health-related quality of life (QOL).[44] Due to high cost of DNG, it can be given in patients who do not tolerate NETA • In a recent systematic review of eight RCTs, comparing DNG with GnRH agonist which included 1,273 women with symptomatic endometriosis, DNG was superior to placebo but equivalent to GnRH agonists in controlling pain symptom in endometriosis[45]
Pharmacokinetics	Oral absorption rapid with 90% bioavailability, exclusively bound to albumin (90%), t1/2 10 hours, metabolism in liver[46]
Uses	In superficial and deep infiltrating endometriosis with or without visceral involvement
Safety profile	• Side effects though not common are mild to moderate—headache, breast discomfort, depressed mood, acne, nausea, vaginal bleeding • In a pooled analysis from four European RCTs, DNG at 2 mg dose was well tolerated and safe for up to 65 weeks[47]

(GnRH: gonadotropin-releasing hormone; MOA: mechanism of action; RCT: randomized controlled trial)

TABLE 6: Gonadotropin-releasing hormone agonists.

Route	***Intramuscular, subcutaneous or intranasal***	
Drug available	• Leuprolide acetate (parenteral) • Nafarelin acetate (intranasal) • Goserelin acetate (subcutaneous) • Triptorelin	
Manufacturing	Substitution of L-amino acid by D-amino acid at position 6 of the native GnRH, thus making it resistant to degradation and giving a longer half-life	
MOA	Administration of GnRH agonist ↓ Initial pituitary flare (FSH and LH) This may exacerbate endometriosis symptoms. This can be blunted by aromatase inhibitors for first 7–10 days of treatment or giving GnRH agonist in the luteal phase of the cycle[48] ↓ Downregulation of pituitary GnRH receptor ↓ Decrease in FSH and LH ↓ Ovarian suppression → ↓ ↓ E_2 and P. Within 1 month of GnRH use, the E_2 levels will be in the menopausal range	
Effects	Direct effects on endometriotic implants	
Efficacy	Second- or third-line medical treatment after COCs and progestin for endometriosis associated pain. Pain relief is between 50% and 90%. Combined surgical and medical treatment with GnRH agonists have the lowest recurrence rate and highest cure rate[49-51]	
Add back HT	• GnRH agonist therapy can lead to hypoestrogenic side effects like hot flushes, mood swings, vaginal dryness, decreased libido, bone loss, and headache. Therefore, add-back HT is used to treat these side effects and prevent any long-term sequelae. Only progesterone or a combination of estrogen/progesterone may be used. This does not affect the efficacy of GnRH agonist • Most commonly used is NETA 5 mg daily as add-back agent and is approved by the US-FDA • Typically, GnRH agonist is used for 3–6 months and could be extended to 1 year • Add-back therapy should be started along with GnRH-a therapy as this will reduce the vasomotor symptoms and bone density. According to "estrogen threshold hypothesis", E2 concentration of 30–45 pg/mL is required to maintain bone density • Also patients must be instructed to take adequate calcium and vitamin D along with HT • In those who cannot use HT as add-back they may benefit from herbal remedies, selective serotonin reuptake inhibitors (SSRIs), and serotonin/norepinephrine reuptake inhibitors • Alternatively, dose of GnRH agonist may be reduced or interval between doses may be increased[52,53]	
Doses	Leuprolide acetate	3.75 mg once a month or 11.25 mg every 3 months
	Nafarelin acetate	1 spray (200 µg) in the morning and evening. Total 400 µg/day for 6 months
	Goserelin acetate	3.6 mg every 4 weeks for 6 months in ≥18 years women
	Triptorelin	3.75 mg every 4 weeks

(COCs: combined oral contraceptives; E2: estrogen; FDA: Food and Drug Administration; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; HT: hormone therapy; LH: luteinizing hormone; MOA: mechanism of action; NETA: norethisterone acetate)

Surgical Treatment

Surgery may be the first-line management in:[55]

- Highly symptomatic women
- Those with a normal ovarian reserve
- Unilateral and large cysts
- Those suspicious of malignancy.

After an initial surgery for infertility, performing any additional surgery will not increase the fecundability and such patients should be better subjected to assisted reproductive technology (ART).

Combined Medical and Surgical Treatment

Although theoretically beneficial, there is no evidence to support that combined medical and surgical therapy improves fertility. On the contrary, it may unnecessarily delay any further fertility therapy.

Assisted Reproductive Technology

Certain patient profiles may benefit from proceeding directly to IVF which are:

- Asymptomatic women
- Women with advanced reproductive age

- Bilateral endometriomas
- Prior surgical treatment as surgery may have a detrimental effect on the ovarian reserve and delay the initiation of treatment.

Endometriosis and Assisted Reproductive Technology

- There is almost up to 30% reduction in PR with controlled ovarian hyperstimulation (COH)-IUI in minimal/mild endometriosis.
- The GDG recommends ART in women with endometriosis when associated with tubal factor or male factor infertility and/or when other treatments have failed.
- Also, ART can be offered after surgery for endometriosis as controlled ovarian stimulation for IVF/ICSI does not increase the recurrence rate.[56]
- In a Cochrane review by Sallam et al. (2006), administration of GnRH agonist 3–6 months before ART in women with endometriosis increases the odds of clinical pregnancy by more than fourfold.[40]
- According to the new ESHRE 2022 guidelines, the extended administration of GnRH agonist prior to ART treatment to improve live birth rate (LBR) in infertile women with endometriosis (ultralong protocol) is no longer recommended due to unclear benefits.
- The Endometriosis Fertility Index (EFI) was added as a step in the treatment as it can support decision-making for the most appropriate option to achieve pregnancy after surgery.
- It is important to note that in women with endometriosis:
  - The ovarian response to COH is not decreased.
  - Stimulation protocol could be ultralong GnRH agonist or the GnRH antagonist protocol. Frozen embryo transfer may be performed after GnRH agonist depot suppression for 2 months.
  - There is no increase in size or rupture of endometriomas with COH.[57]
  - During oocyte retrieval, if one encounters endometrioma, avoid puncture and aspiration. Antibiotic prophylaxis may be used, but the risk of pelvic infection/abscess is low.[32]
  - There is no evidence to performing surgical excision in cases of deep nodular endometriosis prior to ART to improve PRs. Pain relief may be the only reason for their surgical removal.
  - There is no increase in the recurrence rate of endometriosis with ART.[32]

TREATMENT OF ENDOMETRIOSIS ASSOCIATED INFERTILITY

It is always important to weigh the risks against the benefits of surgery in endometriosis as here, the surgical procedure may neither be able to restore the pelvic anatomy completely nor it may inhibit the inflammatory process.

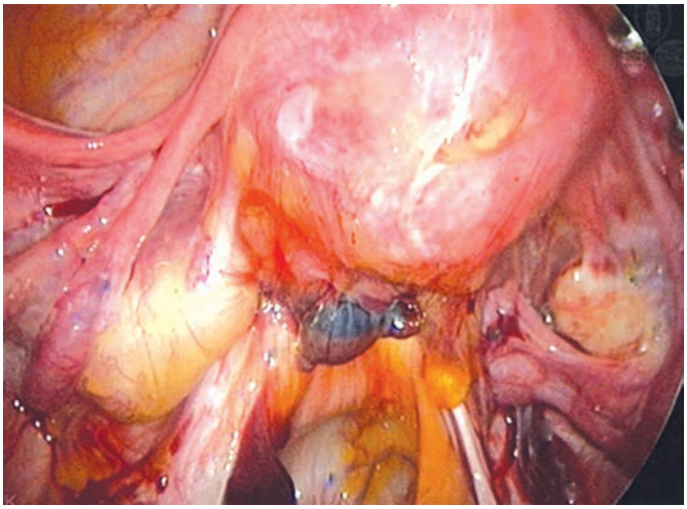

Fig. 5: Adhesions and endometriotic lesions between the bladder and anterior uterine surface.

American Fertility Society/American Society for Reproductive Medicine Stage I/II Endometriosis

In women <35 years of age with stage I/II endometriosis-associated infertility, expectant management or SO-IUI may be considered first-line therapy. In women >35 years, aggressive management like SO-IUI or ART may be considered.[58]

According to the ESHRE guidelines, in order to increase ongoing pregnancy rates (OPRs), one must perform operative laparoscopy [ablation or excision of endometriotic lesions, adhesiolysis rather than just performing diagnostic laparoscopy since there is an increase in LBR **(Fig. 5)** and OPR] [odd ratio (OR) 1.64; 95% confidence interval (CI) = 1.05–2.57].[32,59]

Also, instead of monopolar electrocoagulation, one may use CO_2 laser vaporization of endometriosis as it is associated with increased cumulative spontaneous PRs.[32,60] In minimal/mild endometriosis, COH-IUI increases LBR as compared to expectant management and increases the PR instead of only IUI.

Also, COH-IUI may be performed within 6 months after operative laparoscopy as PRs will be similar to that achieved in unexplained infertility.[32,61]

American Fertility Society/American Society for Reproductive Medicine Stage III/IV Endometriosis

There are no randomized controlled trials (RCTs) or meta-analysis to compare PRs after surgery and after expectant management in women with moderate to severe endometriosis. According to the ESHRE guidelines, it is a level B recommendation to consider operative laparoscopy rather than expectant management to increase spontaneous PRs.[32,62]

Women with stage III/IV endometriosis who do not conceive after conservative surgery or of advanced reproductive age must proceed with IVF/ICSI.[58]

Prognostic Tool for Pregnancy

The EFI was developed as a tool to predict PRs in patients with surgically documented endometriosis who attempt non-IVF conception **(Fig. 6)**.[63]

ENDOMETRIOSIS FERTILITY INDEX (EFI) SURGERY FORM

LEAST FUNCTION (LF) SCORE AT CONCLUSION OF SURGERY

Score	Description		Left	Right
4 =	Normal	Fallopian tube		
3 =	Mild dysfunction			
2 =	Moderate dysfunction	Fimbria		
1 =	Severe dysfunction			
0 =	Absent or nonfunctional	Ovary		

To calculate the LF score, add together the lowest score for the left side and the lowest score for the right side. If an ovary is absent on one side, the LF score is obtained by doubling the lowest score on the side with the ovary

Lowest score: Left [ ] + Right [ ] = LF Score [ ]

ENDOMETRIOSIS FERTILITY INDEX (EFI)

Historical factors			Surgical factors		
Factor	**Description**	**Points**	**Factor**	**Description**	**Points**
Age			LF Score	[ ]	
	If age is ≤35 years	2		If LF score = 7 to 8 (high score)	3
	If age is 36 to 39 years	1		If LF score = 4 to 6 (moderate score)	2
	If age is ≥40 years	0		If LF score = 1 to 3 (low score)	0
Years infertile			AFS Endometriosis score		
	If years infertile is ≤3	2		If AFS endometriosis lesion score is <16	1
	If years infertile is >3	0		If AFS endometriosis lesion score is ≥16	0
Prior pregnancy			AFS Total score		
	If there is a history of a prior pregnancy	1		If AFS total score is <71	1
	If there is no history of prior pregnancy	0		If AFS total score is ≥71	0

OVARIAN ENDOMETRIOMA[64,65]

Endometrioma is a pseudocyst originating from the ectopic endometrial tissue in the ovary and progresses by invaginating into the ovarian cortex.[66] It may be symptomatic or asymptomatic and is found in 17–44% of women with endometriosis. It can be diagnosed reliably by transvaginal USG **(Fig. 7)**.

Current medical treatment does not resolve an endometrioma. Also, surgical removal will diminish the ovarian reserve which has been seen in a systematic review.[67]

Risks and Benefits of Surgical Therapy of Endometrioma versus Expectant Management

Surgery[32]

Advantages:

- Facilitates access to oocyte retrieval
- Symptom relief
- Rules out malignancy
- Minimizes risk of cyst complications.

Disadvantages:

- Reduction of ovarian reserve and chances of ovarian failure as in 13% patients, normal tissue may be destroyed[68]
- Increased gonadotropin requirement
- Surgical risks
- Postoperative adhesions
- Recurrence.

Expectant Management

Advantages:

- No surgical risk
- Increased oocyte retrieval
- Ovarian reserve maintained
- May require comparatively lower dose of gonadotropins
- No delay in starting ART.

Fig. 7: An endometriotic cyst in the right ovary with drainage of chocolate-colored endometriotic fluid.

Disadvantages:

- Pain
- Small chance of pelvic infection following oocyte retrieval
- No tissue available for histopathological diagnosis
- Cyst rupture
- Difficulties in accessing the ovaries at the time of oocyte retrieval
- Contamination of FF
- Accelerated progression of the disease.

In a systematic review by Laursen et al.[69] where surgery versus conservative management of endometriomas in subfertile women was studied, very low quality evidence suggested no difference in the odds ratio of live birth between women who underwent surgery for endometriomas before IVF/ICSI compared with conservative management. They recommended to consider conservative treatment if subfertility was the only indication.

Brief surgical steps are as follows:

- Proper inspection of pelvis and upper abdomen
- Three laparoscopic working ports
- Peritoneal washings only in case of suspicious lesion or ascites
- Adhesiolysis after careful identification of ureter to prevent its damage
- A combined technique of both excision and ablation may be used to prevent ovarian tissue removal and bleeding.

Excision involves opening the endometriotic cyst with either scissors, electrosurgical, or laser. The cyst is opened and drained. The plane of cleavage between the cyst wall and ovarian tissue is then identified. Then the cyst wall is excised or stripped away by applying traction and counter traction with two grasping forceps. The edges may be sutured with suture ends being placed inside or inverted by minimal bipolar coagulation.[70]

A study by Donnez et al.[71] showed that combined technique of excision and laser ablation without suture is good for preserving ovarian reserve.

Endometrioma treated surgically have a high recurrence rate and using this option for women undergoing IVF has been challenged.[72] It has been reported that due to the technical difficulty involved in removal of endometriomas as they are usually adherent to the normal ovarian tissue, tissue rim containing primordial follicles is removed in >50% endometriomas.[73] This results in diminished ovarian reserve after its surgical removal.

The ESHRE guidelines state that there is no evidence that cystectomy before starting ART has any improvement in the PR.[32,74]

The GDG recommends cystectomy before ART or endometriomas >3 cm in size only to improve endometriosis associated pain and improving accessibility to the follicles for oocyte retrieval.

Also, the clinician must counsel the woman adequately about the risk of premature ovarian failure and the possible risk of loss of ovary after surgery. A cautioned decision must be taken if a woman has any previous ovarian surgery.

In a systematic review and meta-analysis which included 33 studies, women with an endometrioma undergoing IVF/ICSI had a similar LBR (OR 0.98; 95% CI = 0.71, 1.36) and a similar CPR (OR 1.17; 95% CI = 0.87, 1.58) but a higher cancellation rate compared to those without the disease. Surgical treatment of endometrioma did not affect the outcome of IVF/ICSI as compared to those without surgical management.[75]

Also a systematic review and meta-analysis by Tsoumpou et al.[65] concluded that surgical treatment of endometriomas did not have any significant effect on IVF PRs and also no effect on response to ovarian stimulation compared to expectant management.

Recurrent Disease

- In order for the treatment to be successful in curbing endometriosis, it must target to suppress endogenous estrogen synthesis which propagates endometriosis.[76]
- Rx → Suppression of ovulation
  ↓
  Amenorrhea
  ↓
  Hypoestrogenic environment
  ↓
  Inhibition of ectopic endometrial growth
  ↓
  Thus preventing disease progression.
- Hormone therapy acts by the above mechanism. Once hormone therapy is stopped there will be recurrence of symptoms due to growth of endometrial implants.
- The recurrence rate of endometriosis after medical or surgical therapy is up to 45% after 5 years, the rate reaching up to 56% in women <21 years.[77]
- Therefore, long-term therapy may be needed for this, frequently used are dienogest (DNG) and GnRH agonist with add back therapy.

ADOLESCENT ENDOMETRIOSIS

Early-onset endometriosis (EOE) starting around menarche or early adolescence may at times be severe, requiring early diagnosis, and proper treatment. Its origin may be different from its adult variant and is attributed to the neonatal uterine bleeding (NUB).[78]

Pathogenesis

Origin of Early-onset Endometriosis

In a small proportion of neonates
↓
Progesterone withdrawal bleeding occurs
↓
Secondary to the NUB is the reflux and seeding of endometrial stem and progenitor cells in the pelvic cavity. In a neonate, they quickly attach themselves to the peritoneum.[79]
↓
These may remain dormant for years and may get activated around the time of thelarche by factors known to develop endometriosis.
↓
This may then progress to highly angiogenic implants, recurrent ectopic bleeding, and endometrioma formation.

The above hypothesis provides explanation for the occurrence of endometriosis in the premenarcheal girl and severe endometriosis like ovarian endometrioma in an adolescent.

Clinical Features

The diagnosis in adolescents is usually delayed due to the nonspecific nature of symptoms, failure to give importance to these symptoms, and reluctance on the part of the clinician to subject an adolescent for invasive testing like laparoscopy. In adolescents, dysmenorrhea is a serious problem. An adolescent may present with severe primary dysmenorrhea usually resistant to NSAIDs and hormonal contraceptive pill. The younger the girls present at the time of diagnosis, more severe is the disease. It has been estimated that endometriosis or uterine anomalies may be seen in 10% adolescents with severe dysmenorrhea.[80] Symptoms include dysmenorrhea (most common), menorrhagia, abnormal or irregular uterine bleeding, and gastrointestinal and genitourinary symptoms.

Five practical ways to an early diagnosis in adolescents was suggested by Zannoni et al.,[81] which are as follows:

1. The pain should never be underestimated.
2. Endometriosis must always be considered as a possible cause of severe cyclical pain.
3. Detailed history must be obtained before performing clinical evaluation of USG.
4. Pain must be treated with hormonal therapies (combined oral contraceptive or progesterone-only pill) and analgesics (acetaminophen and NSAIDs).
5. Frequent follow-up visits must be planned for evaluating the patient.

Treatment

Medical/Surgical

Medical treatment: Same drugs are used in both adults and adolescents. Drugs commonly used are NSAIDs, combined estrogen-progesterone oral contraceptive pill, progesterone-only tablet [norethisterone acetate 15 mg/day

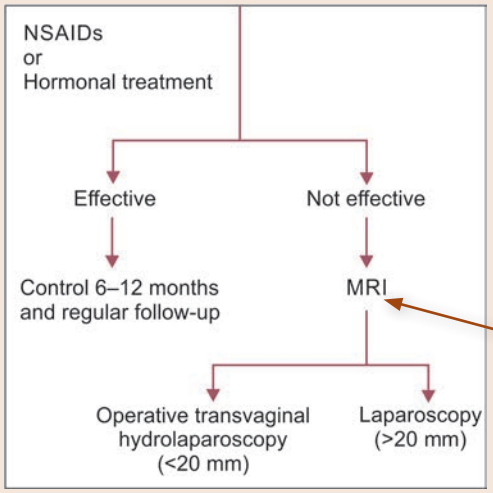
TABLE 7: Stepwise approach in managing adolescent endometriosis.

History ↓

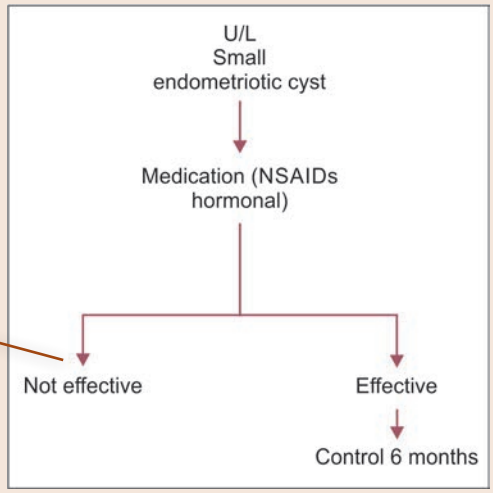
- History of neonatal uterine bleeding
- Maternal history of uteroplacental ischemia
- Onset of menarche
- Cycle length
- Uterine anomaly

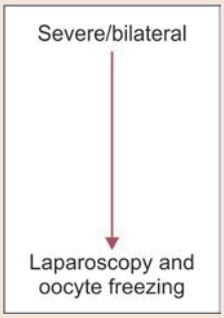
Ultrasonography (USG)

USG negative



USG positive





(NSAIDs: nonsteroidal anti-inflammatory drugs; MRI: magnetic resonance imaging; U/L: unilateral)

or medroxyprogesterone acetate (MPA) 50 mg/day] or MPA depot 150 mg intramuscular (IM) 3 monthly. Recent introduction of tablet DNG 2 mg/day in women >18 years is also a good option.82 GnRH agonists with add-back therapy to overcome hypoestrogenic side effects may also be considered.

If an adolescent's dysmenorrhea does not improve within 6 months of treatment with NSAIDs and oral contraceptive pill, laparoscopy is indicated to look for endometriosis.[83]

Surgical treatment: Surgical therapy in adolescents is like a double-edged sword. It may not only increase the risk of premature ovarian failure, but it itself may promote the development of endometriosis.84 Therefore, medical therapy forms a first-line therapy thus holding a special importance in treating adolescents.

Stepwise approach in managing adolescent endometriosis has been proposed, which is shown in **Table 7**.[78]

What is of paramount importance in adolescents is early diagnosis as endometriosis in these young women has a tendency to progress, endangering their reproductive potential.

ENDOMETRIOSIS AND CANCER

The ESHRE 2022 guidelines recommend that clinicians should inform women with endometriosis requesting information on their risk of developing cancer that endometriosis is not associated with a significantly higher risk of cancer overall.[85] Although endometriosis is associated with a higher risk of ovarian, breast, and thyroid cancers in particular, the increase in absolute risk compared with women in the general population is low.

In a systematic review by Kvaskoff et al., 2020, it was seen that the risk of ovarian cancer is 1.2% higher in women with endometriosis compared to all women and the risk of breast cancer and thyroid cancer by 0.5%.[86]

KEY POINTS

- Endometriosis is quite a common disease in women with infertility.
- Early diagnosis and appropriate management is crucial in managing early-onset endometriosis.
- One must consider the diagnosis of endometriosis even when the clinical examination is normal in the presence of symptoms.
- An adnexal mass with diffuse low-level internal echoes and absence of neoplastic features is highly suggestive of an endometrioma.
- While formulating a treatment plan for a particular patient, all factors like age, duration of infertility, symptoms, and stage of endometriosis must be considered.
- In infertile women having endometriosis, hormonal treatment like contraceptives, progestins, GnRH analogs, or danazol for suppressing ovarian function must not be prescribed to improve fertility.

- In minimal/mild endometriosis, medical management does not improve spontaneous PRs, but surgery is beneficial.
- The presence of an endometrioma does not appear to adversely affect IVF outcomes, and their surgical excision does not appear to improve IVF outcomes.
- There is no evidence that endometriosis causes cancer, nor there is an overall increase, but in these women incidence of some cancers like that of ovary and non-Hodgkin's lymphoma is slightly more.
- As compared to no management, ART improves the PRs.
- Women with endometriosis may benefit from a combination of medical, surgical, and ART therapy. Individualization of care is important.

CHAPTER 42

Endoscopy in Infertility

Nutan Jain, Tania G Singh, Vandana Jain, Shayari Jain

INTRODUCTION

Infertility is an emerging problem and affects one in eight patients. These significant proportions of patients tend to have structural or pathological causes. These factors that cause subfertility can be potentially treated by surgery. Data shows that in infertile woman, routine examinations and diagnostic procedures are of less use for the evaluation of pelvic pathology. Exploration of the peritoneal cavity and visualization of genital organs is important to diagnose any of the female pelvic pathologies especially in infertile patients. It also helps to evaluate any pelvic pain of non-specific etiology. Hysteroscopy and laparoscopic surgery have revolutionized gynecological surgery and are considered to be the gold standard in diagnosing tubal pathology and other intra-abdominal causes of infertility. It helps in providing a panoramic and magnified view of the pelvic and abdominal organs. It also gives the opportunity to perform extensive surgery in the same setting. This chapter aims to emphasize the management of infertility by advanced hysterolaparoscopy.

Indications for hysteroscopy-laparoscopy in infertility are manifold:

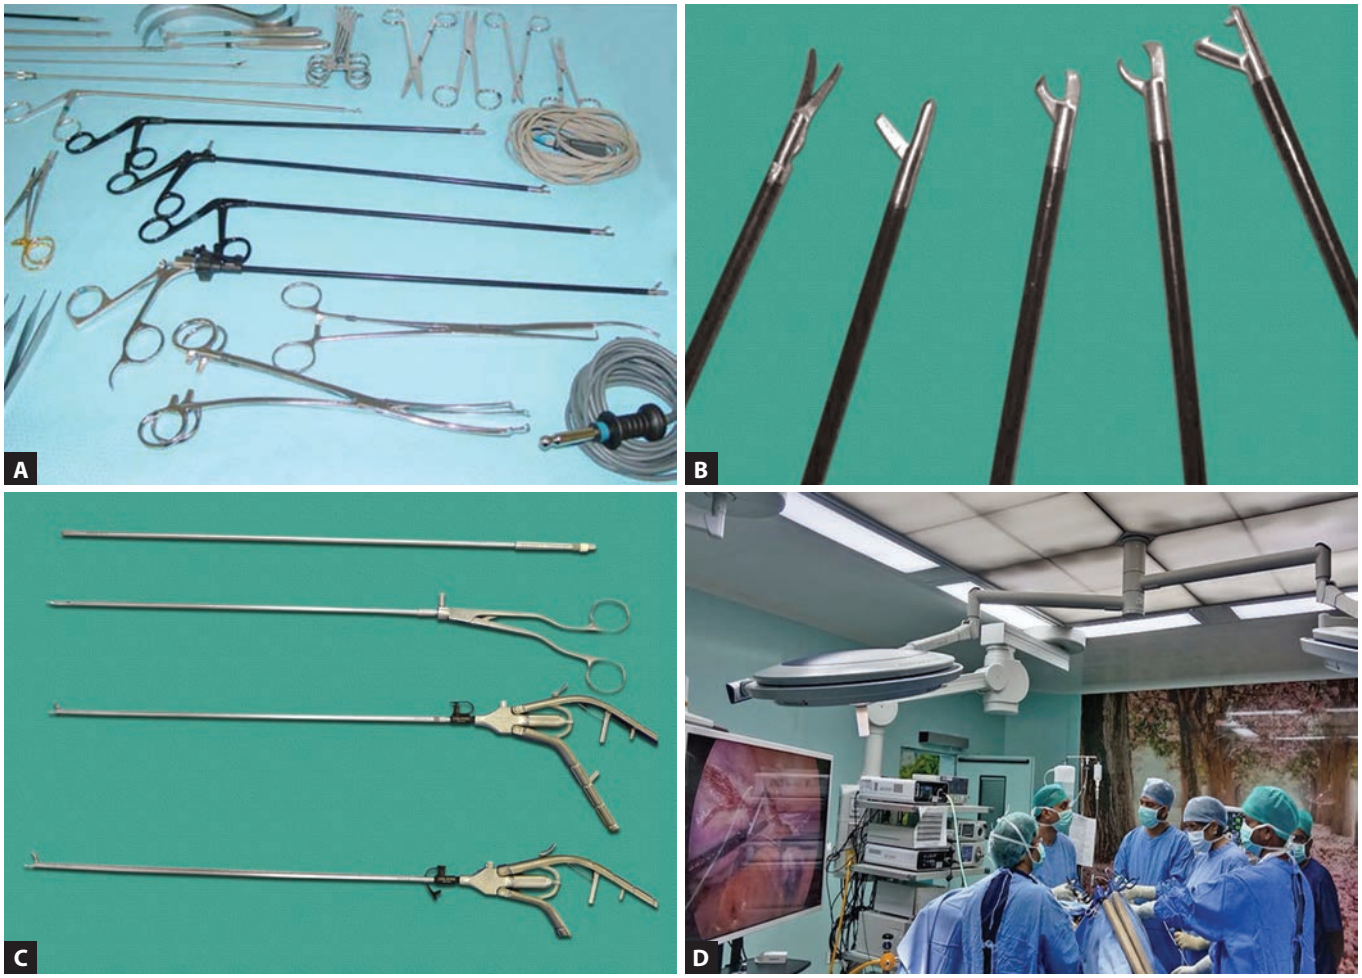
- Woman aged >25 years, married for 3 years with unprotected coitus
- Unexplained infertility
- Known pelvic factors:
  - Abnormal/suspicious hysterosalpingography (HSG)
  - Blocked tubes
  - Tubo-ovarian adhesions
  - Myoma
  - Endometriosis
  - Polycystic ovarian disease
  - Suspected/known Müllerian anomalies
  - Routinely before in vitro fertilization (IVF).

EQUIPMENT

- Veress needle
- Trocar and cannula
- Endoscope in 5 mm and 10 mm sizes and video camera
- Insufflation system
- Xenon cold light source
- Graspers
- Scissors
- Suction/irrigation system
- Electrosurgical equipment
- Harmonic scalpel
- Forceps
- Needle holder
- Uterine manipulator
- Morcellator
- Loop applicator
- Clip applicator
- Myoma screw
- Port closure needle (**Figs. 1A to D**).

LAPAROSCOPIC SURGERY ON UTERUS MYOMECTOMY

Fibroids are the most common pelvic tumors arising from the uterine smooth muscles. They are benign in nature. 70% of women are at risk of having them by the age of 45 years. However, most of these fibroids are small and do not produce any symptoms. Data analysis shows that they mainly are symptomatic in 25% of white and 50% of black women. Myomas can cause infertility as they lead to distortion of the endometrial cavity, defective implantation, pose a problem in sperm ascent, and embryo transport. They interfere with focal endometrial vascularity and cause endometrial inflammation. According to the statistics, removal of submucosal fibroids improves fertility, but removal of subserosal myomas has no role in improving fertility of the patient.[1] Great uncertainties exist about the relationship between intramural fibroids and fertility.[2] Benecke et al., have suggested that intramural fibroids should be removed, if they are close to the endometrium (<1 cm) and larger than 20 mm.[3] Semm and Mettler introduced laparoscopic myomectomy in 1980 for subserosal fibroids.[4] Minimal



Figs. 1A to D: Basic laparoscopic instruments and setup.

access surgery since then is on a rising trend for treatment of uterine fibroids. The two main challenges associated with laparoscopic myomectomy are:

1. Control of bleeding during enucleation of myoma
2. Good closure technique to reduce postoperative adhesions.

Patient Selection Criteria

According to the old concepts, patient selection was dependent on number, size of myomas, and the uterine size. The limits were three myomas and a diameter of 8 cm or a uterus corresponding in size to 16 weeks gestation and a myoma measuring 12 cm, but now a days patient selection largely depends on the surgical expertise and backup operating staff and team.

Preoperative Use of GnRH Analogs

Preoperative use of gonadotropin-releasing hormone (GnRH) analogs should be avoided:

- delay in the diagnosis of leiomyosarcoma
- increase in hyalinization phenomena
- obliteration of the myoma-myometrium interphase
- difficulty in localizing the cleavage planes
- prolongation of duration of surgery
- increased rate of conversion to open surgery.

Procedure

Laparoscopic myomectomy requires a baseline preoperative evaluation. The patient should undergo routine blood investigations and transvaginal sonography to assess the uterine size. Mapping of fibroids using magnetic resonance imaging (MRI) is also done in order to specify the exact location of each myoma. Laparoscopy is performed under general anesthesia. Nitrous oxide is avoided as it causes bowel distension, which may hamper the operative field. Port placement is done according to surgeon's choice and expertise. After port insertion, the uterus is visualized. On peritoneal entry all pelvic and abdominal structures are inspected and if any pathology presents, it should be noted. Pitressin (8-arginine vasopressin), a derivative of vasopressin, is injected at the concentration of 20 units diluted in 400 mL normal saline between the serosa and pseudo capsule of myoma for hydro dissection and to obtain a bloodless field. Its duration of action is 20–30 minutes and dose can be repeated after 20–25 minutes, if required. It should be metabolized before the end of surgery. It is advisable

to always inform the anesthetist before giving Pitressin, since strict vital monitoring is required. Complications like bradycardia, hypertension, and cardiovascular collapse have been reported. Hence, intravascular injection should be avoided and careful monitoring of vitals should be done. If there is persistent hypertension then nitroglycerine (NTG) infusion should be started. Anticholinergic (glycopyrrolate 0.2 mg IV) can be given before induction since it has protective role against bradycardia induced by vasopressin. Diluted NTG is also kept ready at hand for the same purpose. The radial pulse should be monitored continuously by palpation. 15% rise in blood pressure (systolic and diastolic) is tolerable, above this NTG is required. NTG (0.5 mg) when given intravenously causes fall in blood pressure within 2 minutes. If the blood pressure continues to rise, further NTG (0.5 mg) intravenously can be given.

Hysteroscopy should be performed before taking the incision on the myoma.

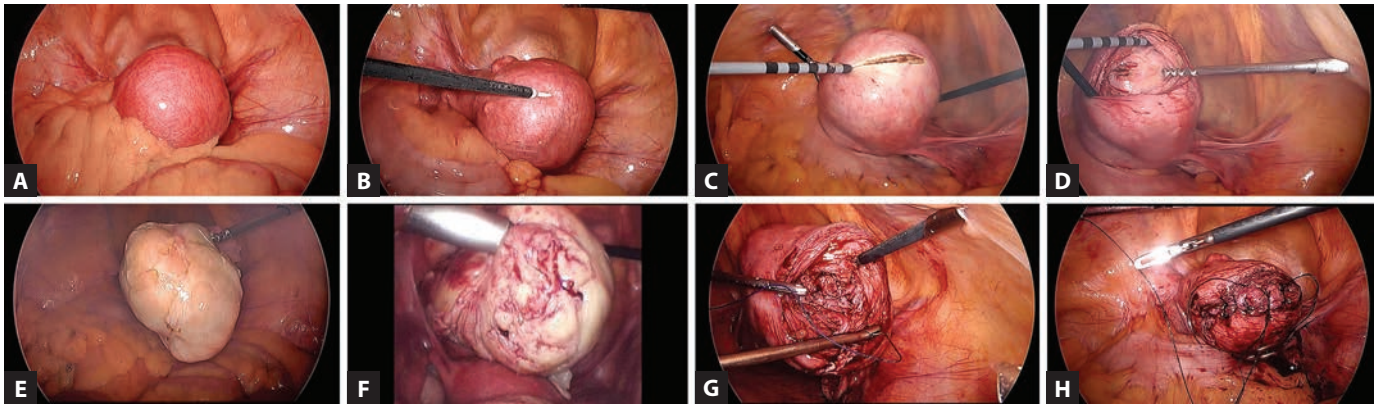
The harmonic scalpel is used and a transverse incision is given on the prominent part of the fibroid. The incision should not extend to the cornual ends. Transverse incision is preferred as it minimizes cutting of the radial arteries supplying the bulk of the uterus; however, oblique incision can also be given as it is easier to suture an oblique incision. The pseudo capsule and the myoma are separated by sharp dissection (*The Onion-Peel Appearance*) using harmonic scalpel. Application of myoma screw helps in traction and easy removal. Traction and counter traction help in easy enucleation of the myoma from its bed. It is preferred to do minimal bipolar coagulation of myoma bed after enucleation of the fibroid.

Suturing Myoma Bed—the Most Important and Determinant Step

Suturing of the myoma bed is done in multiple layers. The suture used is No. 1-0 vicryl. The taper cut needle is used with the length of the suture being 45–50 cm. The angle knot is taken by passing the suture from the upper and lower edges of the myoma bed, and an intracorporeal, tight, surgeon's knot is secured. From this point, continuous, nonlocking suturing is done, using needle holders in both hands, for a better grip. First, the layer of deep myometrium is completed and the same suture is used to take the second layer of superficial myometrium. The third layer of serosa is taken up using "one and half technique". In one and half technique of suturing innovated by us, a deep stitch is taken including the myometrium and then after going back a superficial stitch is taken in the serosa and no raw surface is left for formation of adhesions. A complete reconstruction is done with a single knot on the myoma bed giving the uterus its original shape. In order to prevent hematoma formation, it is advisable to take adequate tissue in every bite. Each suture should be at an equal distance thereby obliterating the dead space. In recent years, a new class of suture material, barbed suture has been introduced into the surgeon's armamentarium. Currently, there are two commercially available barbed suture products: the Quill™ SRS bidirectional barbed suture product line (Angiotech Pharmaceuticals, Inc., Vancouver, BC, Canada) and the V-Loc™ Absorbable Wound Closure Device product line (Covidien, Mansfield, MA). These synthetic sutures eschew the traditional sutures in favor of barbs that serve to anchor the sutures to tissue without knots. Reapproximation of the myometrium after removal of myomas requires a suture material that adequately addresses the need for a prolonged wound disruptive-force reduction, hemostasis, and minimal tissue reactivity. Traditionally, this suture has been made of either polyglycolic acid or polydioxanone. However, as noted earlier, braided sutures cause more tissue abrasion and inflammation than monofilaments and the transition from open to closed procedures has introduced the difficulty of laparoscopic suturing but when considerations for blood loss and hemostasis are added, the need for faster, more secure suture lines becomes readily apparent. To this end, barbed suture materials are an ideal solution. Their synthetic, monofilament configurations should minimize local inflammation and their absorption profiles and tissue pull-through strengths are well within the parameters needed for reduction of disruptive forces. Further, because barbed sutures allow for only minimal tissue recoiling, closing spaces such as myoma defects is easier with each subsequent suture pass exposed to less tension than the previous bite. The use of barbed suture reduces time of closure and blood loss significantly.[5] One of the serious complications from the use of barbed suture in surgery is bowel obstruction. Kindinger et al., 2012 reported a case of small bowel entanglement and obstruction involving an unraveled V-Loc suture 4 weeks following a laparoscopic myomectomy.[6] This complication could be avoided, if there is no exposure of the "free" barbed suture in the peritoneal cavity either through leaving no redundant suture material by cutting the suture flushed with the myometrium or to use the convention suture for repair of the seromuscular layer of the myometrium. Copious irrigation and lavage are done to obtain hemostasis. In the bag, morcellation is done to remove the myomas. It is important to remove all the myomatous fragments because leaving even a small piece of myoma can lead to the formation of "parasitic or wandering myoma", which can cause intestinal obstruction following formation of adhesions. About 2 L of ringer's lactate are left for hydroflotation. The patient is ambulated about within 6 hours of surgery, allowed orally and can be discharged after 24 hours **(Figs. 2A to H)**.

Jain's Backyard Theory for Broad Ligament and Cervical Fibroids

We have devised a novel way of taking care of the risk of injury to ureters when tackling broad ligament fibroids.



Figs. 2A to H: (A) Initial appearance of fundal myoma; (B) Blanched look of myoma after injecting diluted vasopressin; (C) Transverse incision given over the most bulging part of myoma with harmonic angiotensin-converting enzyme (ACE); (D) Showing onion-peel appearance. (E) Complete enucleation of myoma; (F) Morcellation of myoma (myoma brought close to the sleeve of morcellator); (G) Suturing of myoma and (H) Myoma bed sutured by continuous curve needle suturing.

Keeping in mind the risk of injury to ureter, especially in broad ligament and cervical myomas, we start with using 400 mL of diluted vasopressin to aid in hydrodissection. This helps in reducing the blood loss and getting the correct plane, especially in cases of broad ligament fibroids that attain large sizes. According to our "Backyard Theory", we prefer to give incision on the anterior aspect of the broad ligament myoma and even in posterior myomas, irrespective of its location. In such cases, an assistant pushes the posteriorly bulged myoma anteriorly with the help of a grasper. Myoma becomes prominent anteriorly and incision can be given on anterior aspect and enucleate the myoma with screw or spiral. Our technique has never failed us, thus now adhering to this "Backyard Theory" broad ligament and cervical myomas do not pose any challenges for us. They are taken up easily with a lot of vasopressin and anterior incision keeps ureters and the uterine arteries secured in their location just like we are operating in a living room and the rest of the stuff in the backyard does not bother us. In this endeavor, the myoma is brought out anteriorly and the ureter remains posteriorly and never comes across in field of surgery.

Degenerated Fibroid—A Diagnostic Challenge

Fibroids usually have a characteristic sonographic appearance. Degenerating fibroids can have variable patterns and pose a diagnostic challenge. Uterine leiomyoma with extensive cystic degeneration can masquerade as an ovarian tumor. Degeneration can be fatty, hyaline, calcified, cystic, and red degeneration. Nowadays a new entity has come up in which degeneration is due to medical management of fibroids (ulipristal, mifepristone, and GnRH analogues). Surgical management of these fibroids is a challenge as there is difficulty in finding the plane of cleavage, difficulty in traction making the myoma difficult to be held by a myoma screw or tenaculum. These fibroids are enucleated by using only scissors without using bipolar or harmonic angiotensin-converting enzyme (ACE).

Removal of Myoma

- Motorized (electromechanical) morcellator (Rotocut G1 morcellator, Karl Storz, Germany): Inserted in the abdomen with the help of trocar and cannula, usually via a 15 mm sleeve and in bag morcellation is done. This port site through which the morcellator is introduced requires closure, which is done with a port closure needle. This site also needs rectus sheath closure.
- By posterior colpotomy: A colpotomy incision can be made over, CCL vaginal extractor is placed in the vagina and the myoma can be removed by grasping with a 10 mm claw forceps, which is inserted through it. Incision is then sutured by endosuturing.
- By mini lap incision.

Future Pregnancy Rates

The pregnancy rates are 60–65% with no antepartum or intrapartum complications with multiple layer closure and of which several patients delivered vaginally. It should be mentioned in operation notes, if endometrial cavity has been opened and hence it is better to deliver these patients by cesarean section.

Advantages of Laparoscopic Myomectomy over Open Myomectomy

- Decrease postoperative pain
- Shorter hospital stay
- Early recovery
- Reduced febrile morbidity
- Decreased incidence of postoperative adhesion formation
- Cosmetically better

- Reduced fistula formation ileus, thromboembolic complications.

Rupture Uterus—A Grave Complication

Risk factors for uterine rupture after laparoscopic myomectomy can be:

- Hematoma formation.
- Deformed scar as a result of intraoperative thermal damage.
- Poor healing of wound due to improper approximation of the incision edges.

Risk of uterine rupture can be reduced by taking proper precautions during the surgery like reduced use of thermal devices and closure of myoma bed in multiple layers.

LAPAROSCOPIC TUBAL SURGERY

Surgeries for Tubal Infertility

Disease or damage to fallopian tube accounts for 25–35% of reported cases of infertility. A spectrum of severity of tubal disease exists from peritubal adhesions through damaged fimbriae and distorted anatomy to tubal occlusion, hydrosalpinges, and abnormal tubal mucosa. In tubal infertility, following factors have an important role:

- Role of the tubal mucosa.
- Tubal wall thickness.
- The mobility of the tube and ovary
- Any infective foci

Infections govern the results of tubal surgeries.

Surgery for Proximal Tubal Disease

Proximal tubal blockage accounts for 10–25% of tubal disease. It can be due to:

- Obstruction resulting from plugs of mucus and amorphous debris.
- Spasm of the intratubal ostium.
- Occlusion from fibrosis due to salpingitis isthmica nodosa (SIN), pelvic inflammatory disease (PID), or endometriosis.

A meta-analysis of studies suggests that 85% patients had bilateral proximal tubal occlusion (PTO) and half of the patients conceived after tubal cannulation.[7]

The meta-analysis also concluded that hysteroscopic cannulation has increased the pregnancy rates, although tubal patency rates are similar with fluoroscopic, and hysteroscopic techniques. Patients in which IVF is not advisable and there is failure of tubal cannulation, tubal microsurgery can be considered.

Surgical Approach to Distal Tubal Disease

Tubal repair or salpingectomy is performed based on intraoperative findings. It includes hydrosalpinges and fimbriae phimosis. Hydrosalpinges and fimbriae agglutination due to adhesions result in a narrow-phimotic tubal opening.

Both conditions can be due to:

- PID
- Peritonitis of any cause
- Previous surgery leading to tubal damage.

Good prognosis is associated with patients who have:

- Limited flimsy adnexal adhesions
- Mildly dilated (<3 cm) tubes with thin and pliable walls.
- A lush endosalpinx with preservation of mucosal folds.[8]

Salpingostomy improves the chances of conception in older woman. It is also considered a better option in those suffering from male factor infertility. It improves the success rate of IVF in patients suffering from mild hydrosalpinx. Women with both proximal and distal tube occlusions are generally not advised salpingostomy. Salpingectomy followed by IVF remains the mainstay of treatment for patients with severe hydrosalpinx. Postoperative reocclusions may occur necessitating an additional surgical procedure.

Alternatives include laparoscopic clipping of tubes and hysteroscopic occlusion of ostia; however, best results are achieved with salpingectomy followed by IVF.

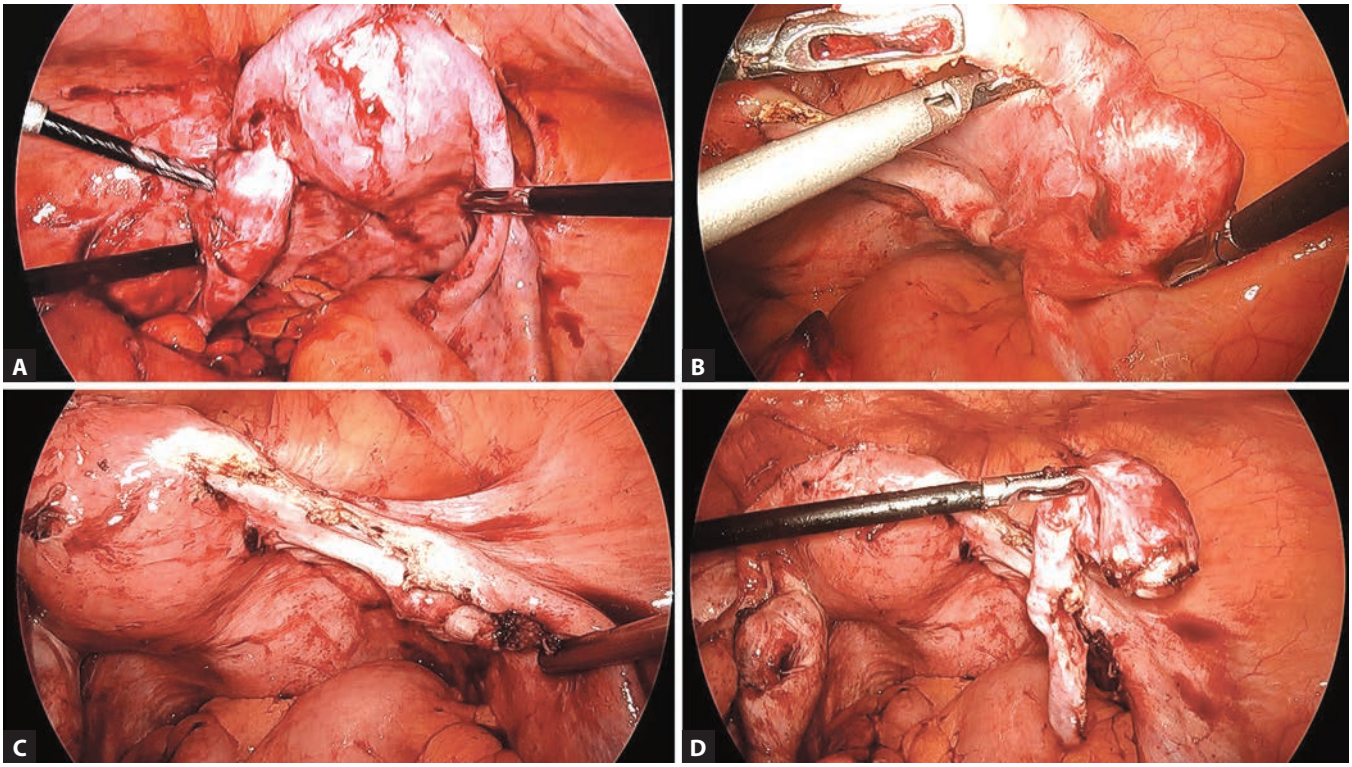
Management of Hydrosalpinx

Hydrosalpinges refers to dilatation of fallopian tubes due to prior pelvic infection. According to the consensus the hydrosalpinx fluid reduces the success rate of ART. Hydrosalpinx fluid impairs implantation and decreases the endometrium receptivity. Two meta-analysis[9,10] of these studies noted that the pregnancy and delivery rates were approximately 50% lower and that the spontaneous abortion rate was higher in the presence of hydrosalpinges. The pregnancy rates were higher in patients who underwent laparoscopic salpingectomy before undergoing IVF **(Figs. 3A to D)**. In patients with sonographically diagnosed hydrosalpinges, salpingectomy is preferred to salpingostomy.[11]

Salpingoscopy

Salpingoscopy has become a very useful means of diagnosing diseased fallopian tubes. The mucosa of the ampullary segment, in normal cases, consisted of 3–5 major mucosal folds with secondary folds arising from them along with running vessels and several minor folds interspaced among them. The density of the mucosal folds increases toward the fimbriae end. Salpingoscopic mucosal appearance was graded according to Brosens and Puttemans classification (1989) as follows:

- Grade I: Normal mucosal folds (both major and minor)
- Grade II: The major folds are separated and flattened, but otherwise normal/dye staining of mucosa/minimal flattening
- Grade III: Focal adhesions between mucosal folds and variable flattening



Figs. 3A to D: (A) Bilateral hydrosalpinx; (B) Salpingectomy with use of harmonic; (C) Uterus after salpingectomy; (D) Specimen of hydrosalpinx.

- Grade IV: Extensive adhesions between mucosal folds and disseminated flat areas
- Grade V: Complete loss of mucosal fold pattern.[12]

Nevertheless, salpingoscopy **(Figs. 4A to J)** is not routinely performed during laparoscopy. Salpingoscopy is a tedious process since it requires the use of a second telescope and additional devices. On the contrary, salpingoscopy is commonly practiced while performing fertiloscopy. Fertiloscopy is a simple technique. It requires stabilization of fimbria with grasping forceps introduced in the operative channel. A small telescope is used, which is pushed gently in the fimbria, which then enters the ampulla and reaches the isthmus-ampullary junction. It is important to continuously irrigate the tube throughout the procedure. A tap located on the sheath allows for inflow adjustment. Excessive pressure is avoided in the ampulla. The 30-degree lens enables us to examine each portion of the ampulla just by rotating the telescope on its axis. Any pathology in the ampulla is noted and corrected on a priority basis before performing any assisted reproductive technology (ART) procedure.

Tubotubal Reanastomosis by Laparoscopic Microsurgery

Tubal sterilization is currently the most popular form of birth control in India and is an everyday procedure. It is an important part of our National Family Planning Program. But due to unforeseen reasons, women may seek for reversal of sterilization. Nowadays, laparoscopic microsurgery is considered as the gold standard—derived from solid research and unchallenged dogma. Only surgeons who are very facile with laparoscopic suturing and who have extensive training in conventional tubal microsurgery should attempt this procedure.

Evolution of Microsurgery

Swolin in 1967 introduced microsurgery in the field of infertility for adhesiolysis and neosalpingostomy. After the introduction of microsuturing, the first series of microsurgical reversal of sterilization was published by Winston[13] (1977) and Gomel[14] (1977).

Why laparoscopic surgery and not open microsurgery?

Laparotomy itself exposes to:

- Desiccation
- Foreign body introduction.

In open laparotomy, adhesions and posterior pelvic organ lesions make the access difficult thereby making mobilization of the organs a must. Microsurgery can only be performed after the adnexa is elevated macro surgically.

- Restricted depth of field
- Small field of view
- Less scope of microsurgery via laparotomy in cases of cul-de-sac obliteration and severe pelvic sidewall endometriosis.

Source: Watrelot A, Grudzinskas JG. Fertiloscopy. State of the Art Atlas of Endoscopic Surgery in Infertility and Gynecology, 1st edition. New Delhi: Jaypee Brothers Medical Publishers (P) Ltd; 2004. pp. 239-53.

Indications for Laparoscopic Tubal Anastomosis

- Reversal of sterilization
- Mid tubal block secondary to pathology
- Tubal occlusion secondary to ectopic pregnancy treatment
- Salpingitis isthmica nodosa
- Failed tubal cannulation for proximal block
- Failed previous macrosurgical sterilization reversal
- Tubal transposition for unicornuate uterus, discrepant tubo-ovarian anatomy.

Contraindications

- Final tubal length is less than 4 cm
- Significant tubo-ovarian adhesions
- Stage 3–4 endometriosis
- And/or there is more than a mild male factor.

Instruments Used

- Three-chip camera with digital enhancement
- High-resolution monitor
- Ultramicro instruments
- 6-0 vicryl suture and needles.

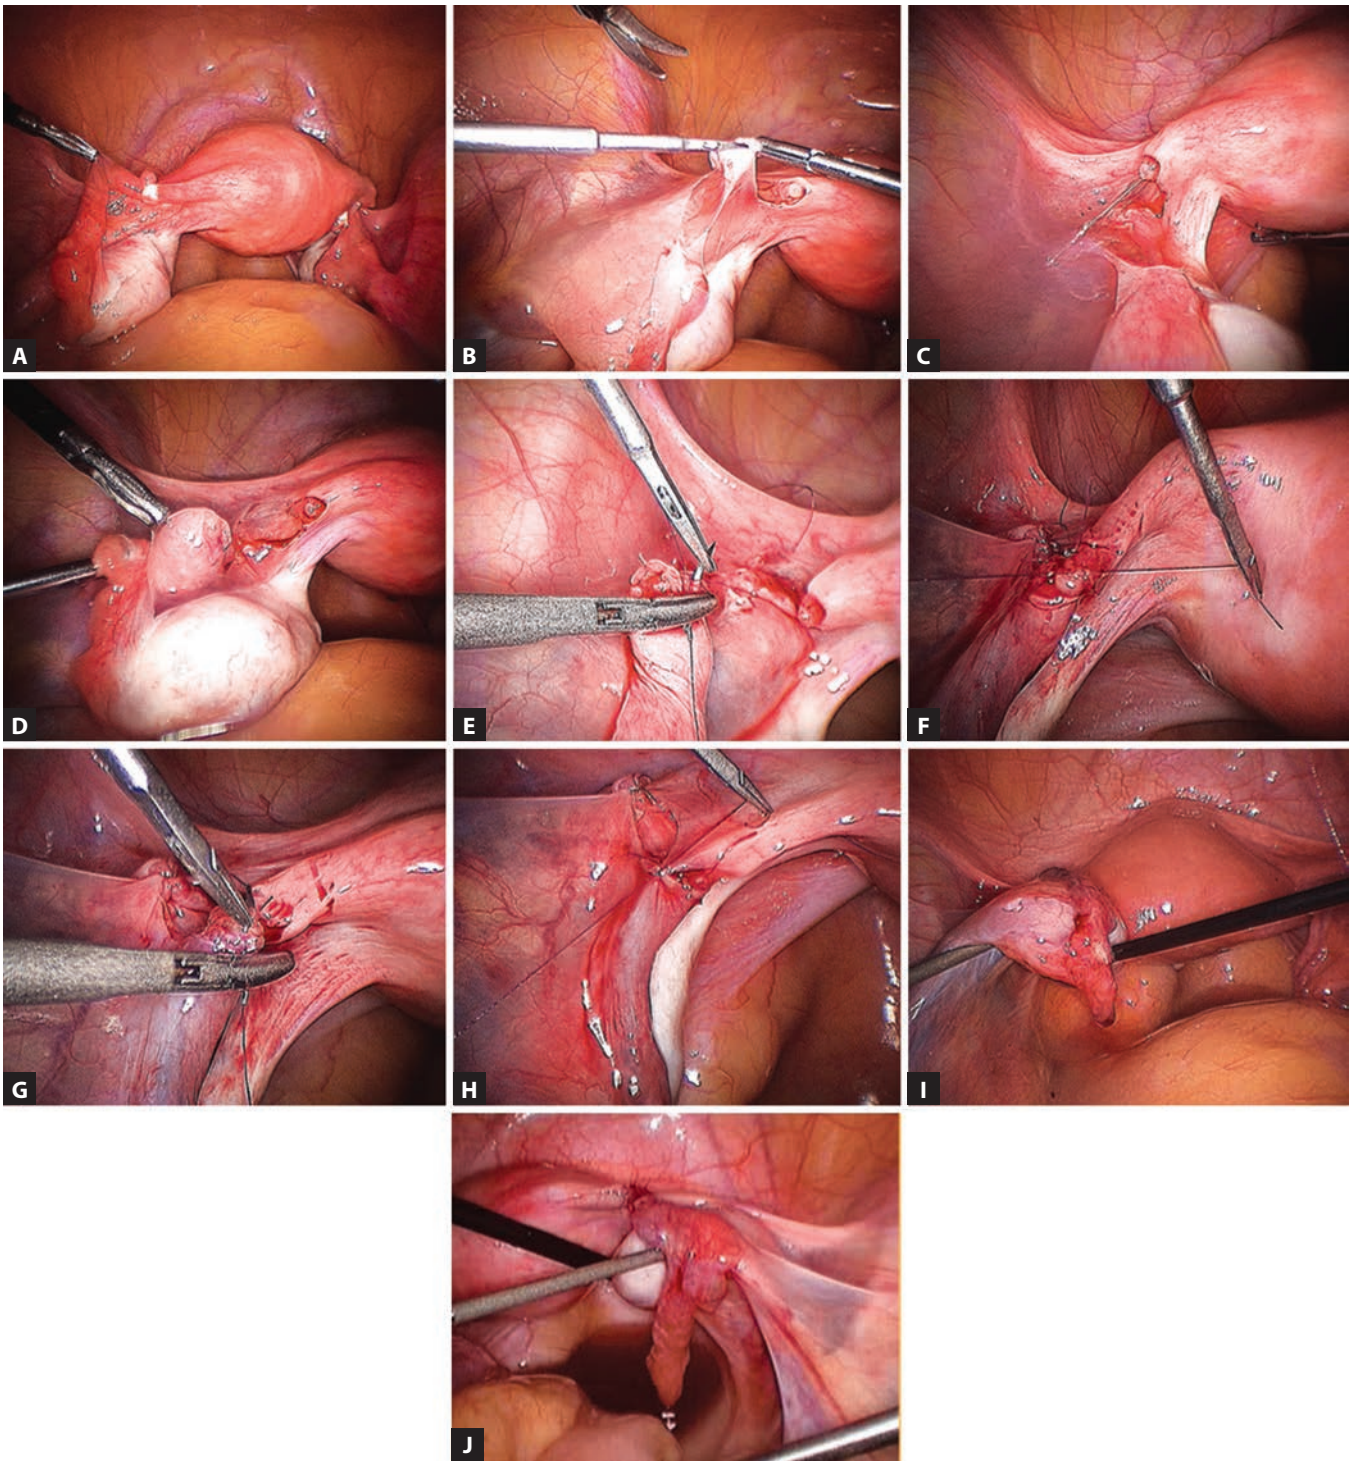
Procedure

It is done under general anesthesia and requires port placement. Tube on one side is held with atraumatic grasper. Diluted vasopressin is injected in mesosalpinx at the site of previous tubal ligation. With sharp scissors, the proximal and then the distal segments are cut. Scissors are always kept at right angles. Check the patency of both proximal segment (from uterine end) and distal segment (from fimbriae end). Take a bite at 6 O'clock position in proximal segment using 6–0 Vicryl in tubal muscularis and take inside out from 6 O'clock position in distal segment, so that knot is tied later. Take a mesosalpingeal suture beneath it to serve as a base for it, and then tie the knot of muscularis. Tubes come nicely together. Then a second suture is to be taken at 12 O'clock position in distal and then in proximal segment. The 6 O'clock and the 12 O'clock are the key sutures. Next, take two anchoring sutures at 3 O'clock and 9 O'clock positions. Thorough suction, irrigation, and lavage are done. Then take sutures through serosa-to-serosa. Again, check the tubal patency at the end of the procedure. Following points are to be kept in mind **(Figs. 5A to J)**:

- The 6 O'clock suture is tied after suture in mesosalpinx because 6 O'clock segment of the tube is then easily visualized and accuracy of stitch improves a lot.
- Preparation of the distal stump is the most important determinant of success. It is vital to avoid too large aperture.
- With proline, avoid entering the mucosa. With Vicryl, can be entered intraluminally.
- All principles of microsurgery, i.e.:
  - Closed internal environment
  - No tissue drying
  - Minimal tissue handling
  - Magnified vision.

Pregnancy Rates after Tubal Anastomosis

Woman's age plays an important role while considering tubal anastomosis as it is the most important prognostic factor. In women younger than 40 years of age, the cumulative rates of intrauterine pregnancy in 2 years are 70%, compared with more than 90% after microsurgical reversal of tubal sterilization.[15]



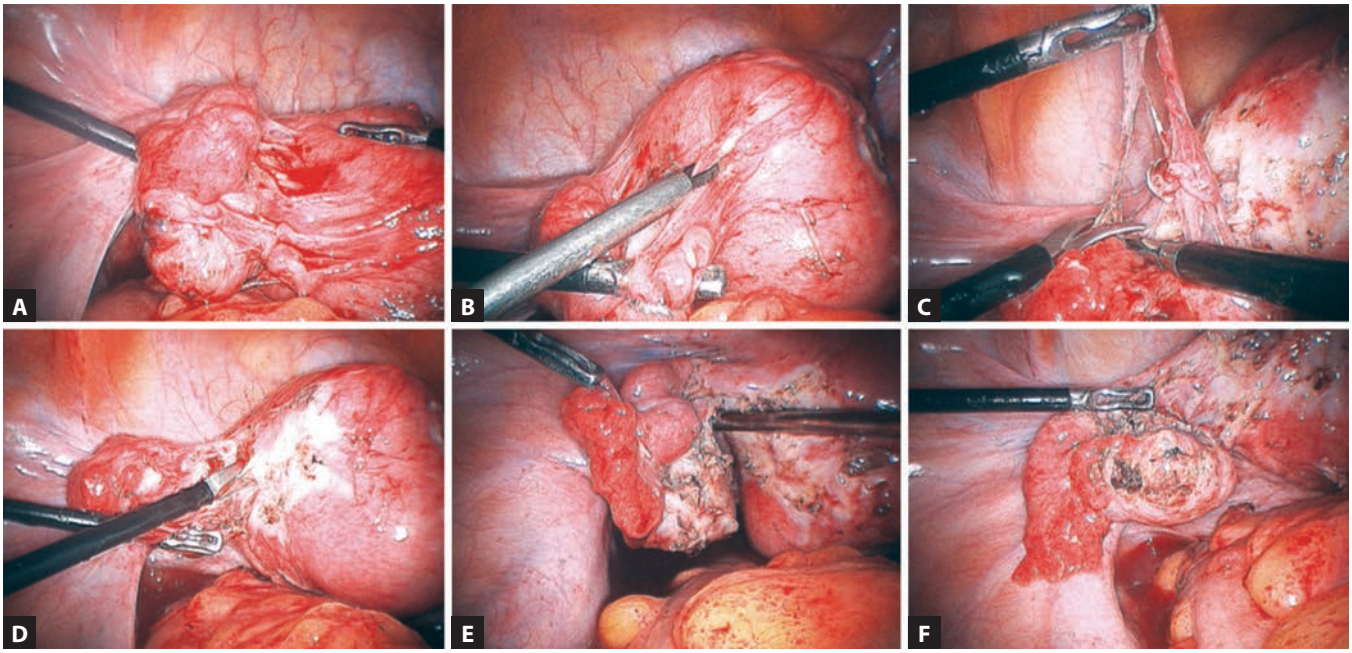
Figs. 5A to J: (A) Bilateral tubes with Falope rings; (B) Cutting and sectioning of Falope ring after injecting diluted vasopressin; (C) Patency of proximal end of tube; (D) Patency of distal end of tube; (E) Needle passed through 6 O'clock position; (F) 6 O'clock suture tied; (G) Passing suture through 12 O'clock position; (H) Serosal suture tied; (I) Left tube-free spill noted after anastomosis; (J) Right tube-free spill noted after anastomosis.

Salpingo-ovariolysis

Tubo-ovarian adhesions are commonly found in isthmic portions of the fallopian tubes. In the ampullary segment the adhesions are dense causing severe fimbriae stenosis.

Procedure

The thumb rule to achieve adhesiolysis **(Figs. 6A to F)** is to start by keeping close to the uterus initially. Adhesiolysis is achieved using scissors, thermal cauterization, or laser. Caution should be taken while dissecting between the ovary



Figs. 6A to F: (A) Dense tubo-ovarian adhesion; (B) Micro-bipolar being used for prophylactic coagulation before sectioning the adhesion; (C) Adhesion put on a stretch and divided; (D) A sharp scissor used for division of adhesion; (E) Normal tubo-ovarian relationships restored with good fimbrial end noted and free spill of dye seen; (F) Normal tubo-ovarian relationship.

and fimbriae.[16] It should be done in continuation with tubo-ovarian adhesiolysis. The cleavage plane is generally easier to find posteriorly. Hemorrhage due to external tubal artery damage is common during adhesiolysis as adhesions can easily be confused with the end of mesosalpinx. Therefore, a neosalpingostomy is mandatory prior to adhesiolysis.

Neosalpingostomy

Neosalpingostomy is a procedure, which involves recreation of new ostia. It is mainly done in cases of hydrosalpinx or complete tubal occlusions with fimbrial adhesions. In cases of mild disease that are characterized by hydrosalpinges having a diameter less than 15 mm with few associated adhesions and recognizable fimbriae, pregnancy rates approach 80%. In contrast, severe disease, characterized by larger hydrosalpinges exceeding 30 mm in diameter with dense adhesions and no visible fimbriae, cumulative pregnancy rates are poor 10–15%. The extent of adhesions, macroscopic appearance of the endosalpingeal mucosa and tubal wall thickness also correlate with operative success.

Procedure (Figs. 7A to F)

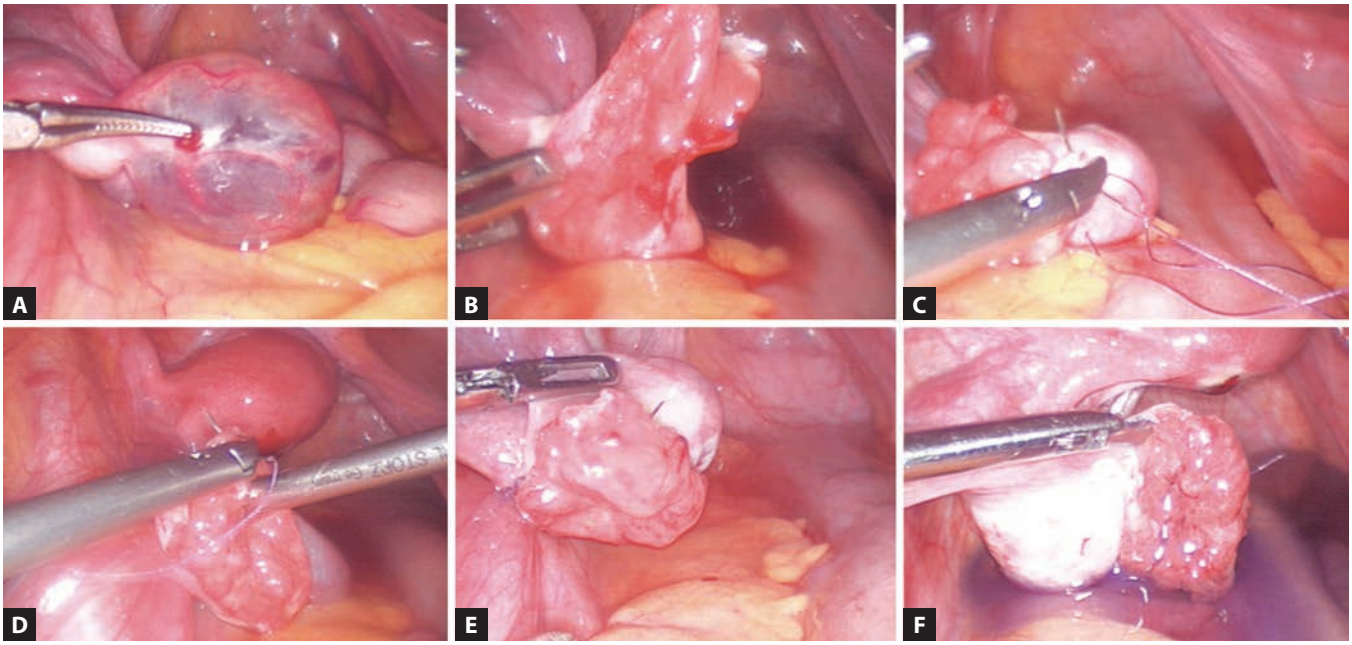
After adhesiolysis and freeing of tubes, chromopertubation is done under high pressure to distend the hydrosalpinx. Bruhat's maneuver is carried out.[17] The most important point is to determine the opening point on the former ostium or else the incision should be made at the center of the hydrosalpinx. Periampullary portion of the tube is held with atraumatic forceps and presented to the laparoscopic scissors or CO_2 laser. A pinhole incision is made and enlarged in a star pattern over the four quadrants of hydrosalpinx. The opening is widened by pulling the peritoneum in opposite directions using atraumatic forceps. The avascular zones must be left intact. Microbleeding is managed by bipolar coagulation with continuous irrigation.

Fimbrioplasty

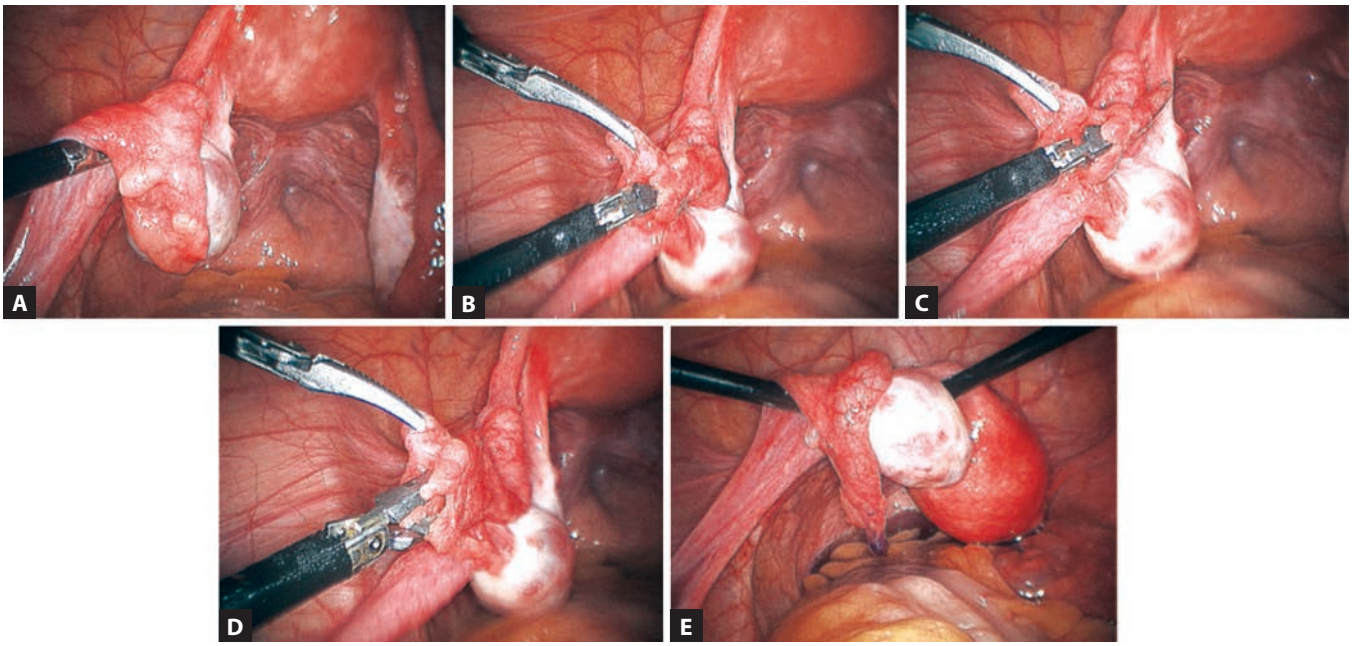
Fimbrioplasty is the procedure that involves reconstruction of fimbriae in a partially or completely occluded oviduct. Periadnexal adhesions are common in such cases and can be managed by doing salpingo-ovariolysis first. Agglutination of the fimbriae leads to stenosis giving a phimotic appearance to the terminal end. Complete occlusion can also occur in cases where the agglutinated fimbrial end gets covered with a fibrous layer. Therefore, the agglutinated fimbria should be completely exposed after excision of this fibrous layer. The excision can be done using laser energy or laparoscopic scissors.

Procedure (Figs. 8A to E)

Fimbrial deagglutination is achieved by using a closed 5 mm-curved atraumatic grasper, which is introduced into the fallopian tube through the phimotic end. The jaws of the grasper are opened within the tube and the forceps withdrawn with the jaws in the open position. This procedure is repeated several times, varying the direction of the jaws, until satisfactory fimbrial deagglutination is obtained. Copious irrigation and lavage are done.



Figs. 7A to F: (A) Initial appearance of hydrosalpinx; (B) Appearance of normal fimbria after cruciate incision; (C) Passing the suture through 12 O'clock position; (D) Passing the suture through fimbria; (E) Final appearance after tubal reconstruction; (F) Chromopertubation at the end of procedure.



Figs. 8A to E: (A) Tube showing fimbrial agglutination; (B) Introducing a curved atraumatic grasper in the ampullary segment of tube in closed position; (C) Opening the jaws of the atraumatic grasper inside the ampullary end; (D) Taking out the grasper in an open jaw position; (E) Free spill of dye noted at end.

Adhesion Prevention

The chance of moderate and severe adhesion reformation after laparoscopic salpingo-ovariolysis was 40.2%. It has been claimed that second-look laparoscopy with adhesiolysis following pelvic reproductive surgery may increase the intrauterine pregnancy rate and decrease the ectopic pregnancy rate; however, a systematic review of RCTs has failed to show a significant benefit.[18] Various physical barriers like intercede, intergel, fluid barrier-like Adept, have been used and reported by various authors. Studies have also been done to evaluate efficacy of Adept and Ringer's lactate, and found fluid barrier to be more effective due to ease of universal distribution in pelvis and hydroflotation, which keeps various raw surfaces away by fluid interface.

ENDOMETRIOSIS

Endometriosis is a disease characterized by the presence of endometrial tissue outside the uterus. It is a chronic inflammatory condition resulting is formation of adhesions and fibrosis within the pelvis.

It is common among reproductive age women and causes chronic pelvic pain and infertility. According to the American Society for Reproductive Medicine, endometriosis may be found in up to 50% of infertile women. Endometriosis occurs in 6–22% of women of reproductive age undergoing tubal ligation,[19] 15–80% of women with chronic pelvic pain, and 21–65% of women evaluated because of infertility. Fecundity in normal couples is about 15–20% and decreases with age. It is about 2–10% in age-matched women with untreated endometriosis and infertility. Pelvic examination may necessarily be normal. Sometimes enlargement of ovaries, mass in the ovary, thickened rectovaginal septum, and a retroverted fixed uterus may be present. Other finding may be indurations in the pouch of Douglas and nodules over uterosacral ligament. Vulval, vaginal, cervical, umbilical, and scar endometriosis are rare findings. Recent data suggests that endometriosis may also be associated with autoimmune disorders like multiple sclerosis, rheumatoid arthritis, hypothyroidism, hyperthyroidism, or systemic lupus erythematosus. Ovarian endometrioma are formed by the invagination of the ovarian cortex, as proposed by Hughesdon. They are usually associated with pelvic pain, infertility, or pelvic mass. Diagnosis can be made with reasonable accuracy by transvaginal sonography. Recently, transrectal sonography with a high frequency transducer has been used with 97% sensitivity for identification of vaginal and rectal wall infiltration. Ovarian endometriomas appear as round, hypoechoic, low level echo cyst with or without internal septa, or thin internal trabeculations with no or poor vascularization of the capsule and septa and bilateral endometrioma usually associated with adenomyoma. It has been reported that almost all patients with ovarian endometriomas have some amount of pelvic or intestinal endometriosis. By and large, laparoscopy has become the gold standard for diagnosis and treatment of endometriosis.

Management of Endometriomas

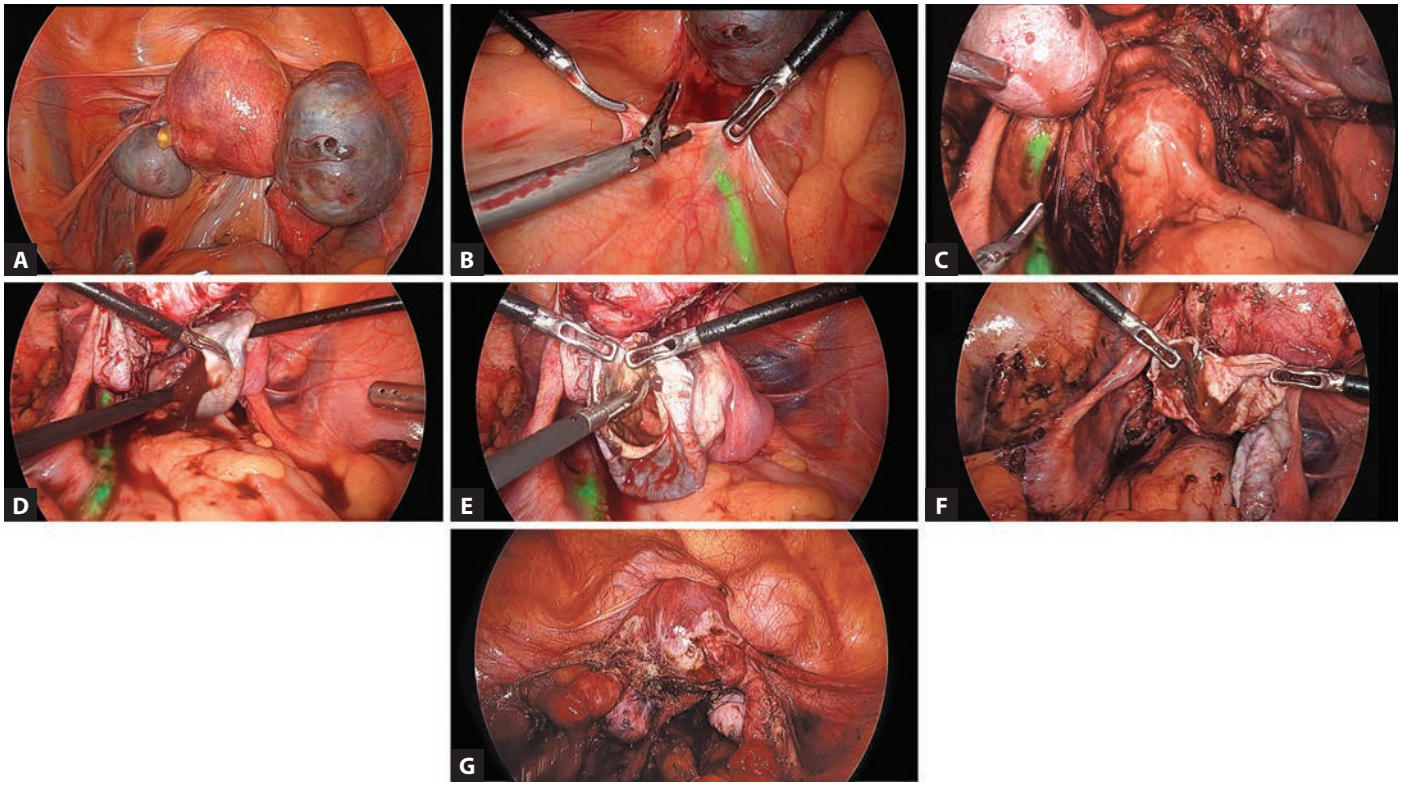
As in all laparoscopic procedures, first pneumoperitoneum is created using veress needle and then ports are made. Then size of the cyst, adhesions, if present, tubo-ovarian relationship, condition of contralateral tube and ovary, presence of peritoneal endometriosis, and implants and obliteration of pouch of Douglas are noted. Adhesiolysis is done by sharp dissection and ovary is freed from bowel and other surfaces like uterosacral ligament and rectosigmoid. In case of large cyst trocar and cannula are directly introduced in the intact cyst and all chocolate material is sucked out, which prevents peritoneal spillage of large quantities of chocolate material. Most of the cysts drain during antegrade adhesiolysis from the point of adherence, which is the weakest point and here ovarian cortex invagination has occurred in the process of forming an endometrioma. Thorough irrigation of the inside of the cyst is done and the cyst lining is inspected closely. To delineate the cleavage plane between the cyst lining and the outer ovarian cortex, the edge of the cyst is held with two graspers and a fresh cut is given with sharp cutting scissors. The cyst wall is held with a toothed grasper and ovarian cortex with an atraumatic grasper and by using the principle of traction-countertraction the cyst wall is stripped off from the ovarian cortex. Ease of enucleation and lack of bleeding confirm a good cleavage plane. Another way of finding a good plane of cleavage is use of diluted vasopressin (20 units diluted in 400 mL of normal saline), which is injected from inside the cyst wall into the space between the cyst wall and the cortex with an aspiration needle to achieve hydrodissection. When the injection is made into an appropriate layer, ballooning is visualized because of the hydrodissection effect. This also avoids damage to ovarian follicles and minimizes recurrence of endometriomas. Hemostasis is achieved using bipolar cautery, keeping it at minimum setting. Enucleated cyst lining is removed through a 10-mm port making cuts with sharp scissors at various segments of the cyst wall, so that it collapses while removing. Multiple cyst linings can also be removed using a 12-mm sleeve of morcellator. Once hemostasis is achieved, about 2 L of liquid adhesion barrier like 4% icodextrin solution or Ringer lactate is left inside the peritoneal cavity **(Figs. 9A to G)**.

Temporary Ovarian Suspension

Ovarian suspension surgery appears to be effective in decreasing adhesions after laparoscopy for endometriosis. This technique can ease the severity of pelvic pain, dysmenorrhea and dyspareunia to some extent. Ovarian suspension is done to anterior abdominal wall using non absorbable ethilon 1-0 on a straight needle or to round ligament with short-term resorbable suture for the prevention of periovarian adhesion formation. In case of big-sized ovary double ovarian suspension is done. The suture removal is done from anterior abdominal wall after 1 month.

Management of Future Fertility

Patients are immediately allowed active management of infertility in the postoperative phase. Only patients who seem to have an aggressive disease or very active endometriosis are given a shot of GnRh analog. Active management of infertility in the form of controlled ovarian hyperstimulation (COH) and intrauterine insemination (IUI) helps. Conception should be tried early because of progressive nature of the disease.



Figs. 9A to G: (A) Appearance of large endometrioma densely adherent to the back surface of uterus, obliterated pouch of Douglas; (B) Retroperitoneal dissection for ureterolysis under ICG illumination; (C) Complete rectovaginal space clearance; (D) Drainage of thick chocolate material during adhesiolysis from the endometrioma; (E) Ovarian cortex held by atraumatic grasper and cyst lining held by tooth grasper; (F) Cyst lining enucleated; (G) Normal looking bilateral ovaries after ovarian reconstruction.

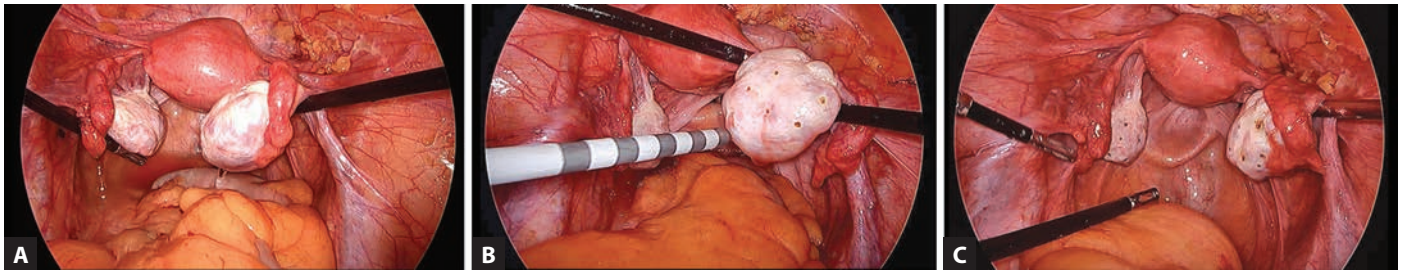
LAPAROSCOPIC OVARIAN DRILLING

Polycystic ovarian syndrome (PCOS) is a fairly common condition in women of reproductive age. The incidence varies from 3 to 15% of women of reproductive age,[20] depending on the population studied and the diagnostic criteria applied.[21] The cause of PCOS is unknown. However, PCOS is thought to be a genetic disorder (autosomal dominant) meaning that each child has a 50% chance of inheriting the disorder from a parent who carries the gene. The gene can be inherited from either mother or father. The exact gene causing PCOS has not yet been identified. The condition was first described in 1935 by American gynecologists Irving F. Stein and Michael L. Leventhal, from whom its original name of *Stein-Leventhal syndrome* is taken.

The insulin resistance with compensatory hyperinsulinemia is a prominent feature of the syndrome and it seems to have a pathophysiologic role in the hyperandrogenism. It is a common hormonal disorder that is poorly understood and is characterized by lack of regular ovulation, irregular menstrual cycles, infertility, abnormal facial hair growth, obesity, and polycystic ovaries. Patients with PCOD are always at a higher risk of metabolic complications such as Type 2 diabetes mellitus, dyslipidemia, and cardiovascular disease.[22] The first line of management is given in the form of lifestyle modification, increase in physical activity, and loss of at least 10% of body weight. This may be combined with ovulation induction drugs like clomiphene citrate or aromatase inhibitors like letrozole. Insulin sensitizers like metformin may also be included in the first-line regimen. National Institute for Health and Clinical Excellence recommended in 2013, that women with PCOS and a body mass index more than 25 to be given metformin when other therapies have failed to produce results. Metformin treatment reduces hyperinsulinemia, LH levels and free testosterone concentrations in obese women with PCOS. Metformin improves menstrual regularity and increases the frequency of ovulation. Ovarian drilling is indicated in clomiphene resistant cases. Another approach in these cases may be gonadotropins. However, we prefer drilling over gonadotropins. This is because drilling appears to be equally effective with lesser chances of multiple pregnancies.

Mechanism of Action

The exact mechanism of induction of ovulation by ovarian drilling is not understood. Different theories were proposed by researchers. Stein and Leventhal postulated that bilateral ovarian wedge resection decreases the mechanical crowding of the cortex by cysts, which enables the progress of the normal Graafian follicles to the surface of ovary.



Figs. 10A to C: (A) Bilateral polycystic ovaries; (B) Holding the ovarian ligament with atraumatic grasping forceps and approaching the ovary with monopolar cautery needle at right angle to the ovarian surface and drilling done; (C) Bilateral polycystic ovaries after ovarian drilling.

Gjonnaess (1984) proposed that ovulation was initiated by either stromal destruction or extensive capsular destruction with discharge of the contents of multiple follicle cysts.[23] Daniell and Miller (1989) suggested that physical opening of subcapsular cysts led to the removal of androgen-containing follicular fluid from the ovarian environment, thus lowering the androgen content of the ovaries.

Changed Hormonal Milieu Following Ovarian Drilling

- The total and free testosterone is decreased by 40–50% of the preoperative levels
- LH levels also decrease following the procedure
- Change in FSH levels is less marked. Generally, they show a cyclical rise in keeping with the restoration of ovulation
- Normal inhibin pulsatility is restored.

The normalization of hormonal relationships leads to recruitment of a new cohort of follicles and resumption of ovarian function. These endocrine changes occur rapidly and are sustained for years.

Procedure of Ovarian Drilling

After inserting the scope, a general inspection of pelvis is carried out to look for any pathology. Fundus of the uterus is inspected as a wide fundus denotes a septal defect and is frequently associated with PCOS. Endometriosis and PID are infrequently associated with PCOS. RUMI uterine manipulator is inserted and uterus is anteverted and taken to contralateral side to stretch the ovarian ligament. A firm platform to ovary for drilling is provided by 5 mm suction irrigation cannula inserted through ipsilateral port between the fimbrial end of the tube and the ovary and wedging its lower end against the cervico uterine junction in pouch of Douglas. Ovaries must be kept static and monopolar needle is inserted from the contralateral lower port and ovary is approached at right angle to cauterize all visible bluish subcapsular follicles using 40 watts of pure cutting current. The number of holes depends on the size of the ovaries and the preoperative sonography. In moderately enlarged ovaries, about 10–12 holes are sufficient but more may be required in voluminous ovaries. Cooling of the ovaries is done using thorough irrigation. All attempts should be made to minimize bleeding from the punctures. An underwater examination is done to look for any bleeding point and if found, is cauterized. The depth of penetration of monopolar needle to just cauterize the capsule and puncture the follicle requires a depth of 2–3 mm and the monopolar cautery time of just 2 seconds. The instruments are changed to contralateral side once one ovary is done because it is better to approach the follicles at right angle, which is best achieved from the contralateral side. About 1000 mL of ringer lactate is left in the abdomen as adhesion barrier. Ovarian drilling is routinely followed by hysteroscopy and if a uterine septum (commonly associated with PCOS) is found, then hysteroscopic resection is done (**Figs. 10A to C**).

Precautions

- Ovary should be stabilized while drilling, because if ovary falls during drilling the charged monopolar needle can hit any vital structure and cause unintended damage.
- Avoid overenergetic drilling in terms of number of holes and electrosurgery as it may lead to premature ovarian failure.
- Cooling of the ovaries using irrigation after drilling should be done.

Future Fertility Management

Active management is done and patients are allowed to conceive immediately after the surgery. The couple is put on minimal required stimulation with clomiphene or letrozole as the ovaries are now receptive to lower dose. Pregnancy rates almost touching 80% as Gjonnaess et al., are achieved. Risk of hyperstimulation after drilling is avoided using ovulogens in moderation.

LAPAROSCOPY COMPLICATIONS

The final step in the infertility workup is diagnostic hysteroscopy laparoscopy, which involves evaluation of all the factors causing infertility. It rarely accounts for any complication and the risk is less than 1%. The most common complication, which can arise during this procedure, is while placing the laparoscope through the umbilicus. It may lead to injuries of the bowel, bladder, ureter, and injuries to the pelvic vessels. According to the American Society of

Reproductive Medicine, laparoscopic complications are observed only in 1–2%.

Few laparoscopic complications are:

- Damage to abdominal structures like bowel and bladder
- Hemorrhage due to abdominal and pelvic vessels injury
- Infection
- Anesthetic complications
- Cystitis after surgery
- Skin reactions at the site of incision
- Postoperative adhesions
- Abdominal wall hematomas
- Hypersensitivity reaction
- Nerve palsy
- Urinary retention
- Embolism
- Thermal injury.

Laparoscopic surgery—not a good choice in conditions such as:

- Patients with reduced ejection fraction and congestive heart failure
- Respiratory distress, COPD
- Presence of a distended bowel.

Laparoscopic surgery requires surgeon expertise in order to afford the best possible outcome for the patient. A good clinical acumen with an aptitude to manage all complications is essential for every surgeon.

HYSTEROSCOPY

The prevalence of uterine abnormalities in patients with infertility is as high as 50%. Therefore, evaluation of a couple with infertility should include assessment of the endometrial cavity. The first instrument known to illuminate the cavities of the human body was invented by Phillip Bozzini, some 200 years back, but his ingenious invention went unnoticeable. After Bozzini's invention Lichtleiter in 1807, Pantaleoni in 1869 successfully performed transcervical intrauterine evaluation and treatment with hysteroscopy. He used a 12 mm cystoscope, candlelight, and a concave mirror to treat polyps with silver nitrate in a 60-year-old woman. Later Nitze and Leiter added the optical lens to the endoscope in 1879, Heineberg used a water irrigation system in 1908, and Rubin used carbon dioxide (CO_2) in 1925.

HYSTEROSCOPIC MYOMECTOMY

Submucous fibroids are the most common types of leiomyomas. They account for 5–10% of all myomas. These submucous fibroids, along with endometrial polyps, are very commonly diagnosed during diagnostic hysteroscopy. Though transvaginal ultrasound and MRI remain the most sensitive techniques to detect the exact number, position, and size of different myomas. Diagnostic hysteroscopy remains the gold standard investigation for diagnosing a submucosal fibroid. It also helps in evaluation of the possibility of resection of the submucous myoma hysteroscopically **(Fig. 11)**.

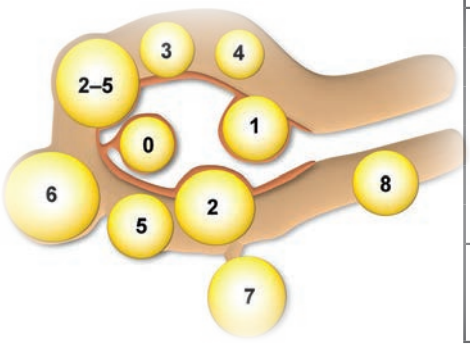
Wamstekar's Classification[24]

- *Type 0:* Pedunculated; 100% within the cavity (fibroid polyp).
- *Type I:* Greater than 50% within the cavity (<50% is intramyometrial).
- *Type II:* Less than 50% within the cavity (>50% is intramyometrial).

Lasmar's Classification[25]

It includes:

- The penetration of the nodule into the myometrium.
- The extension of the base of the nodule with respect to the wall of the uterus:
  - *Score 0:* When the fibroid covers 1/3 or less of the wall
  - *Score 1:* When the base of the nodule occupies between 1/3 and 2/3 of the wall
  - *Score 2:* When it affects more than 2/3 of the wall.



SM – Submucous	0	Pedunculated intracavitary
	1	<50% intramural
	2	≥50 intramural
O – Other	3	Contacts endometrium; 100% intramural
	4	Intramural
	5	Subserous ≥50% intramural
	6	Subserous <50% intramural
	7	Subserous pedunculated
	8	Other (specify e.g. cervical, parasitic)
Hybrid leiomyomas	2-5	Submucosal and subserosal, each with less than half the diameter in the endometrial and peritoneal cavities, respectively.

Fig. 11: FIGO classification of myomas.

Type 8 is fibroid that do not arise from myometrium but include cervical lesions, round or broad ligaments without direct attachment to the uterus, and other "parasitic" lesions.https://obgyn.onlinelibrary.wiley.com/doi/pdf/10.1002/ijgo.12666

- *Size:*
  - *Score 0:* When the nodule measures ≤2 cm
  - *Score 1:* When it is between 2 and 5 cm
  - *Score 2:* When it measures >5 cm
- *Topography:*
  - *Score 0:* When fibroid is in the lower third
  - *Score 1:* When in the middle third
  - *Score 2:* When fibroid is in the upper third
    - An extra point is attributed to lateral wall myomas
    - In case of multiple myomas, the myoma with the maximum points shall be taken into consideration. The maximum total score being 9 points.

Indications

- Symptoms, which are considered to be related to the presence of submucous fibroids.
- Subfertility due to submucous fibroids, when they interfere with the uniformity of the uterine cavity and implantation.
- Submucous fibroids less than 5 cm in diameter at the time of surgery.

Contraindications

- Resection of multiple submucous fibroids is time taking thereby increasing the risk of fluid overload and Asherman's syndrome.
- Large deep Type II fibroid

Others

- Pelvic Inflammation
- Carcinoma cervix and endometrial cancer
- Medical conditions like ischemic heart disease, coagulopathies, etc.

Different Methods to Remove Submucous Fibroids (Figs. 12 and 13)

Laser

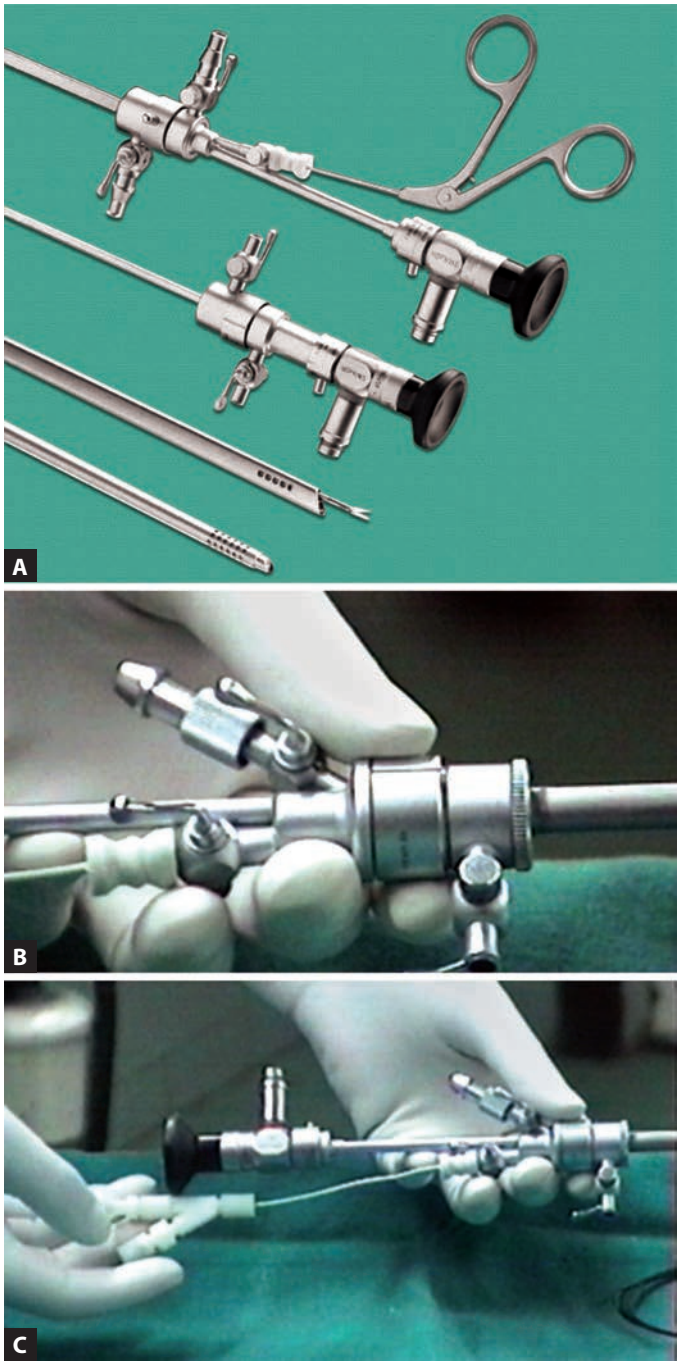
Nd:YAG laser, which is an expensive device was popular in 1980s and 1990s. It can be used as a cutting tool for pedunculated Type 0 myomas or can be used for myolysis by burning numerous holes in the myoma, causing devascularization and shrinkage.

The only advantage is that it can be used in an isotonic fluid. Now a days, accurate fluid monitoring devices are available, the Nd: YAG laser is rarely used for this indication.

Fig. 12: Resectoscope with working element.

Vaporizing Electrode

It includes the bipolar and the monopolar electrodes using very high radiofrequency to vaporize fibroids. Advantage



Figs. 13A to C: (A) Bettocchi hysteroscope, Karl Storz Tuttlingen, Germany; (B) Instrument channel of a number 7F operating hysteroscope through which cannulation system is introduced; (C) Instrument trolley showing the operative.

is that the fibroids are eradicated very quickly without any bothersome fibroid chips to remove.

Bipolar system can be used with isotonic fluid whereas monopolar requires nonelectrolyte containing distention media.

Disadvantages:

- Retrieval of tissue for histopathological examination cannot be carried out
- Due to the high power used, numerous gas bubbles are produced leading to air embolism.

Monopolar Loop Electrode

The instrument most commonly used to remove submucosal myomas is the monopolar loop electrode with a continuous-flow resectoscope. Fluid monitoring should be accurate.

The three most commonly used fluids for uterine distention are:

1. 1.5% glycine (hypotonic)
2. 3% sorbitol (hypotonic)
3. 5% mannitol (isotonic). All three lack electrolytes.

Serum sodium levels are kept in check as the levels of sodium approximately decrease 10 milliequivalents for every liter absorbed. Hence, it is important to monitor the fluid deficit rather than the total volume used.

Few serious but *avoidable* consequences of significant hyponatremia are:

- Pulmonary edema
- Transient blindness
- Cerebral edema.

The resectoscope remains the most efficient and widely used instrument for excising submucous fibroids.

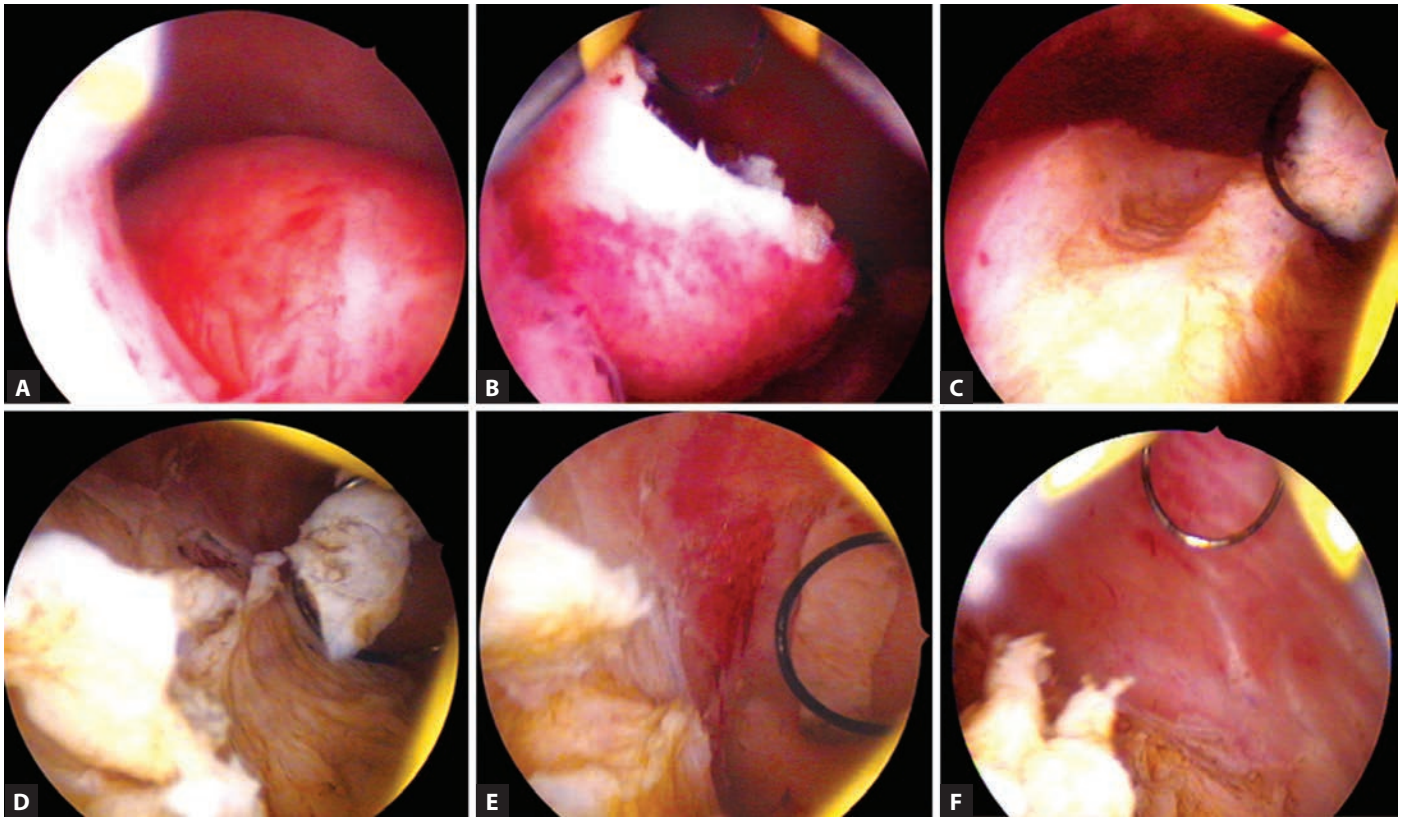
Bipolar Versapoint

More recent alternative to resectoscope.

Technique of Hysteroscopic Resection (Figs. 14A to F)

Before commencing hysteroscopic myomectomy, adequate cervical dilatation needs to be achieved. Most gynecologists use a 26 or 27 Fr gauge resectoscope, with an outer diameter of 8.7–9 mm, so the cervix has to be dilated to Hegar 9 or 10. Over dilatation may cause inadequate uterine distention and difficulty in fluid monitoring, hence avoided.

A simple diagnostic hysteroscopy can be performed using normal saline, to inspect the cavity size, shape, and exact location of the myoma. Subsequently, the fluid can be changed to glycine before insertion of resectoscope. The excision of the fibroid is started medially and progressed toward the base. The loop is pushed beyond the fibroid under direct vision and is moved back and forth to continue



Figs. 14A to F: (A) Submucous myoma; (B) Resection of submucous myoma using forward angle loop; (C) Resection in progress; (D) Removing chip of myoma; (E) Almost completed resection done; (F) Normal uterine cavity noted at end.

the resection. The uterus is closely observed simultaneously from outside by a laparoscope. Only very large size fibroids may require the removal of the instrument from the uterine cavity. The resected chips are collected near the fundus and are removed using an ovum forceps or flushing curette at the end of the procedure. The resected specimen is sent for HPE. Type 0 and Type I fibroids can be resected using this technique. For Type II fibroids can be resected using a simple maneuver where after the resection of the superficial portion, the uterus is deflated and is rubbed bimanually to induce uterine contractions thereby making the deeper part of myoma protrude into the uterine cavity. The surgery shall be continued by redistension of the uterus thereafter. Resection should be avoided, if the residual fibroid remnant does not migrate toward the cavity as it is suggestive of a true transmural fibroid. Resection if continued can lead to dreaded complication like perforation. Glycine overload should be monitored.

Hysteroscopic Morcellation

The U.S. Food and Drug Administration in 2014 discouraged the use of power morcellators for the risk of spreading an unsuspected cancer. However, this Safety Communication does not affect Hysteroscopic Tissue Retrieval system (HTRs). HTRs consist of two metal, hollow, rigid, and disposable tubes with a wide range of diameters adaptable to the use of 5–9 mm hysteroscope. Different HTRs are commercially available: Truclear 8.0 (Medtronic, Minneapolis, Minnesota), Truclear 5C (Medtronic, Minneapolis, Minnesota), and MyoSure (Hologic, Marlborough, Massachusetts). As recently summarized by Noventa et al., Truclear 8.0 has a diameter of 8 mm and is introduced into the uterine cavity with a 9 mm rigid sheath. Truclear 5C hysteroscopy system incorporates a 2.9 mm rotatory-style blade through a 5 mm, 0-degree hysteroscope. MyoSure is introduced into the uterus through a 6 or a 7 mm, 0-degree, continuous-flow hysteroscope. All these devices work with saline solution as distension and irrigation media, instead of the electrolyte-free solutions used for monopolar high-frequency resectoscope.

Advantages of Morcellation

Morcellator uses a blade and a suction tube simultaneously to cut and remove tissue, which improves visibility and reduces the risk of perforations and gas embolus that are more likely with multiple insertions. There is no risk of thermal injury as no energy is used in uterine cavity. There is shorter operating time and the instrument is easy to use.

Disadvantages of Morcellation

Morcellator cannot cauterize blood vessels and have limited utility in cases of Type II myomas. Instrument is costly.

Complications and their Prevention

- *Cervical lacerations:* It can occur from the tenaculum site. They are easily controlled by pressure applied with a sponge forceps. Rarely, a suture is needed. Cervical tears can also result from difficult cervical dilatation, especially in postmenopausal/ nulliparous women or patients who previously received GnRH agonists.
- *Uterine perforation:* Incidence is 0.4–1.6%. If perforation is suspected, laparoscopy should be performed to evaluate the integrity of the abdominal viscera. An intrauterine balloon is not recommended, as it might enlarge the tear or divert bleeding into the peritoneal cavity.
- *Fluid overload and electrolyte imbalance:* Severe complications of operative hysteroscopy are pulmonary and cerebral edema, coagulopathy, and hyponatremia. Fluid management is essential. Careful monitoring of the patient and administration of intravenous furosemide might be needed. One should abandon the procedure, if the fluid deficit is greater than 1000 mL.
- *Incomplete removal*: The use of a preoperative GnRH agonists leads to a decrease in fibroid size and fluid loss, which facilitates complete removal of large fibroids. However, pretreatment with a GnRH agonist may render small myomas less visible and increases the probability of recurrence.
- *Bleeding:* Myometrial contraction is usually sufficient to control bleeding. However, in some patients, intravenous administration of uterotonic drugs or insertion of a Foley catheter balloon into the uterine cavity might be needed.
- *Postoperative uterine infection and intrauterine adhesions:* We use prophylactic antibiotics for hysteroscopic myomectomy.

HYSTEROSCOPIC TUBAL CANNULATION FOR PROXIMAL TUBAL BLOCK

Some 5–20% of hysterosalpingograms reveal PTO. There are two types of PTO. True occlusion can be due to salpingitis, endometriosis, or congenital malformations. Another type is apparent proximal occlusion due to tubal spasm at the time of HSG. Owing to the high incidence of false positives, a hysterosalpingographic finding of PTO must be followed by selective tubal catheterization. The cumulative pregnancy rate after tubal catheterization is 28% at 12-month follow-up. Approximately, 20% of tubes cannot be catheterized; such patients are best treated by in vitro fertilization.

Anatomy of Proximal Tubal Region

The fallopian tubes are 7–14 cm long and the intramural segment ranges 1.5–2.5 cm with an average diameter of 100 micron. Since the diameter of the proximal segment ranges from 0.8 to 1.2 mm, it allows easy passage of a cannula with a diameter of 1–1.2 mm without causing any epithelial injury. The intramural portion of the tube is divided into two

segments (1) a proximal segment ≈1 cm in length, which follows a straight path and (2) a distal segment ≈1.5 cm in length, which is sinuous.

Using the hysteroscopic approach each ostium is visualized at the apex of the uterotubal junction. Therefore, a way of reaching respective tubal ostia is by passing flexible, smooth walled, and J-shaped cannula through the internal os along the uterotubal gutter of that side.

Gardner in 1856 first described the transvaginal approach of passing a wire probe through the intramural segment of the fallopian tube. The intramural bulge at about 1 cm beyond the ostia is a common location for less flexible cannulas and endoscopes to get stuck. Hence, it is important to have over the wire coaxial cannulation systems, which are preferable as they keep the lumen coaxially align with the lumen of the fallopian tube and aid the advancement of wire cannulas.

Cannulation Techniques

The most commonly used are

- Fluoroscopically guided selective salpingography and tubal catheterization.
- Hysteroscopic tubal cannulation. The fluoroscopic procedure is beyond the scope of this chapter.

Hysteroscopic Cannulation Methods

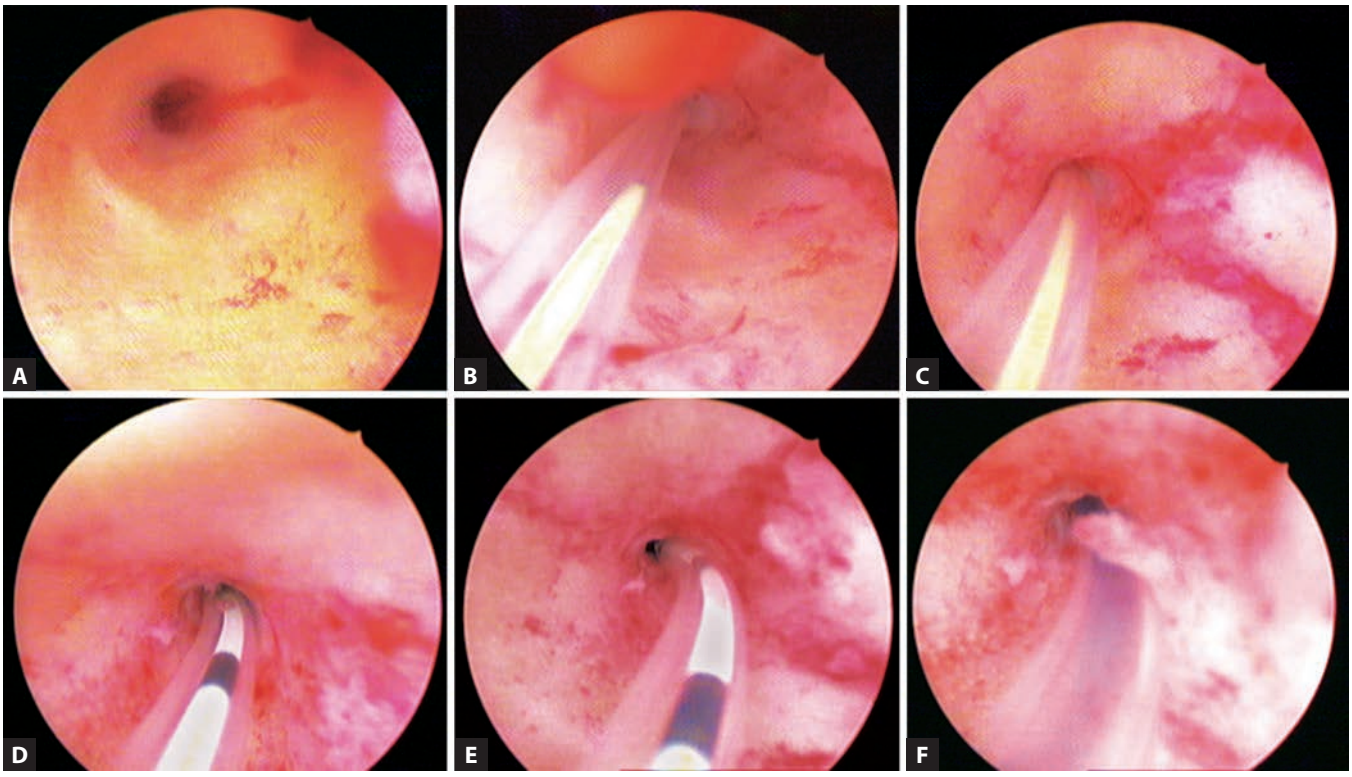
- Flexible guidewire through a catheter.
- Fluoroscopic-guided cannulation.
- Transcervical balloon cannulation with linear catheters

Flexible Guidewire through a Catheter

Procedure: We conduct the procedure in the follicular phase of the cycle. To exclude concomitant distal tubal disease, a laparoscopy is first performed. A second surgeon performs the hysteroscopy—ideally using a second light source and monitor. Cannulation is done with an operating hysteroscope. Guidewire is loaded into the inner cannula and this is loaded into the outer catheter. This whole system is loaded into outer channel of hysteroscope in such a way that its curve is at right angle to the optics of a 30-degree hysteroscope. The cannula is moved in the tube and this can be checked through the laparoscope. The laparoscopist can facilitate cannulation by manipulating the tube to decrease the angle between the cornua and the isthmus. If there is any resistance to the movement of the cannula, it is withdrawn and re-entry is made at a slightly different angle. Forceful negotiation is avoided as it may lead to tubal perforation. One needs to cannulate only 2–3 cm of the proximal tube and then the cannula is withdrawn under vision. Same procedure is repeated on the other side **(Figs. 15A to F)**.

Complications:

- Tubal perforation: Most common. Occurs in up to 6% of cases. Minor complication that does not need any treatment and it heals on its own.



Figs. 15A to F: (A) Tubal ostia; (B) Novy's cannulation system outer catheter and J-shaped inner platinum guidewire; (C) Guidewire is advanced to negotiate the proximal tubal segment; (D) Inner cannula with centimeter markings is advanced over the platinum guidewire; (E) Inner cannula is further passed to negotiate proximal tubal segment up to 3 cm beyond the uterotubal junction; (F) Selective salpingografhy is carried out through outer cannula and flow of dye is monitored laparoscopically.

- Vasovagal reaction can occur in 0.5% of cases.
- We administer prophylactic antibiotics and rarely encounter infection. Infection can occur in the presence of undiagnosed hydrosalpinges.
- Ectopic pregnancy has been reported in 3.6–5.9% of cases following hysteroscopic tubal cannulation.

Contraindications: Women with distal tubal disease or previous tubal sterilization are not the candidates for tubal catheterization. A previous tubal catheterization is not a contraindication, as repeat procedure has led to pregnancies. Tubal catheterization is not indicated for women who are undergoing IVF treatment.

HYSTEROSCOPY FOR METROPLASTY

Congenital uterine malformations also called the Müllerian anomalies. They refer to the structural defects that affect the shape and size of the uterine cavity thereby having a poor reproductive outcome. They might be silent and do not cause any symptoms but, in few patients, they might be a significant cause of infertility or recurrent abortions. The uterine cavity is divided into two halves by a fibrous band, which is referred to as the uterine septum. Septate uterus occurs due to failure of resorption of the septum. This septum is formed when the two Müllerian ducts fuse together during the intrauterine life. A complete septum may involve the upper two-thirds of the vagina, cervix, and uterine cavity, whereas a partial septum only involves the uterine cavity. The highest rate of recurrent pregnancy loss and poor obstetric outcomes, such as preterm labor, intrauterine fetal growth restriction, fetal malpresentation, and retained products of conception is associated with a septate uterus.[26] Septate uterus has a higher incidence than bicornuate uterus as per the data available. Hysteroscopic metroplasty has significantly improved the reproductive outcome in patients with septate uterus.

Hysteroscopy does not cause excision or trauma to the uterine musculature, thereby allowing a shorter recovery time. Conception can be planned within 2 months after the procedure, and the patient can safely deliver vaginally. After hysteroscopic metroplasty, the rates of term delivery significantly improved and accounted for up to 80%, with a miscarriage rate of approximately 15%.

Preoperative Imaging

To assess the shape of the uterine cavity, the most common imaging modality is HSG. However, HSG cannot assess the contour of the uterine fundus or differentiate between different types of uterine anomalies. Office hysteroscopy is another imaging modality, but like HSG, it cannot assess the uterine contour accurately. Combined diagnostic hysterolaparoscopy is the gold standard technique for diagnosing congenital Müllerian anomalies. Transvaginal ultrasound is a good screening tool. Its sensitivity and specificity can be increased with saline-infused sonohysterography or 3D technology. Evaluation of thickness of bulge of uterine side wall or the height and depth of uterine septum should be done by sonography. Diagnosis of bicornuate uterus can be made, if the ultrasound is suggestive of a groove in the corner facing the posterior surface of the bladder between two half-uteri. The best nonsurgical technique for diagnosing and differentiating different types of uterine anomalies is MRI. This is particularly useful to differentiate septate, bicornuate, or didelphys uterus.

Timing of Surgery

- Early in the follicular phase or
- After preparation of the endometrium with progesterone or GnRH administration for a month.

Procedure

It can be performed using monopolar or bipolar system:

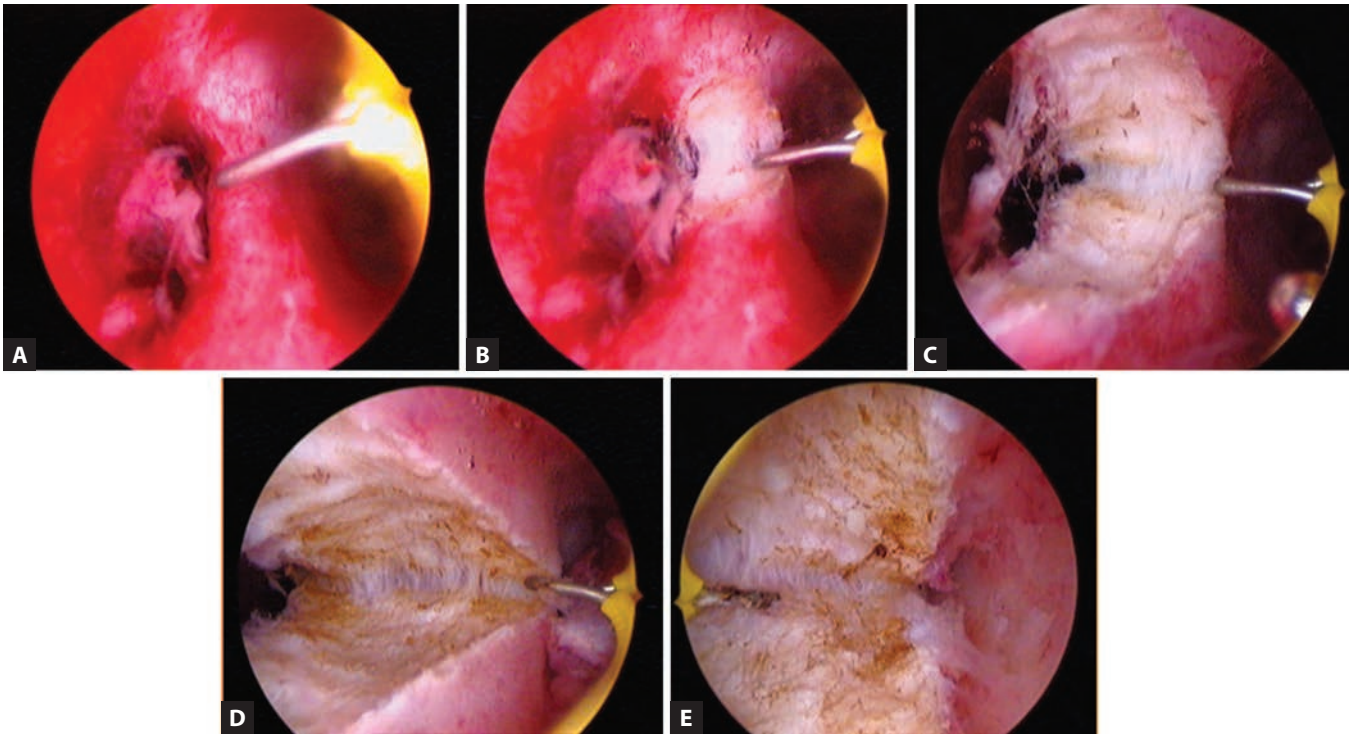
- *Monopolar:* Suction irrigation pump must be preset at flow rate of 250 mL/s, suction pressure should not be more than 0.2 bar and 45 watts of power. It is important to maintain an intrauterine pressure of less than 100 mm Hg during the procedure. The procedure should approximately take 45 minutes. Serious metabolic complications may occur, if there is difference between the suction and irrigation flow rates. These complications can be avoided by precise monitoring of the distension media.
- *Bipolar:* It is a newly developed system. The recommended suction irrigation settings are a flow rate of 150 mL/s, a preset pressure of 80 mm Hg, and a power of 100 watts or less.

Advantages of Using Bipolar

- No limitation to duration of the procedure.
- Reduced metabolic complications.
- Constant visibility of the bipolar system reduces the risk of perforation.

Steps of Procedure

Before starting the procedure, it is important to differentiate between uterus bicornis and uterine septum through laparoscopy. Bicornuate uterus is associated with high risk of perforation. Routine bimanual examination should be performed to evaluate the position and size of uterus before dilatation of the cervix. Hegar's dilators are used for progressive cervical dilatation, which should be performed with care. The hysteroscope with resectoscope is then introduced under visual guidance. Thorough visualization and exploration of the uterine cavity is done. The base of the septum is localized after visualization of the ostia on both sides. The division of the septum is then performed in a progressive manner using repetitive contact between the



Figs. 16A to E: (A) Thick wide deep septum; (B) Septum resection being done using resectoscope; (C) Septum resection done using Collin's knife; (D) Septum resection done; (E) Septum resection done till ostia come in to view.

electrode and the septum **(Figs. 16A to E)**. The septum is divided transversely starting at its apex, halfway between its anterior and posterior surfaces, causing it to retract and become a part of the corresponding surface of the uterus. Distention of the uterus is progressively achieved as the septum is divided (the cavity opens like a book) and the cavity gradually acquires a normal shape. At the end of the procedure, it is preferable to leave a fundic spur of less than 1 cm in place to avoid weakening the fundic myometrium.

Golden Points to be Remembered

- The septal tissue is fibrous. It does not bleed. The septum ends where healthy myometrium is revealed by the occurrence of minimal bleeding and the procedure should be stopped where the two tubal ostia can be visualized in the same hysteroscopic field
- Septum should be divided but not removed in order to avoid destroying the endometrium.
- When septum extends down to the cervix, it is first divided with cold scissors or with a cutting probe. Resection begins at the level of the cervix and extends from external os toward uterus. Plane of tubal ostia should be preserved.
- When uterine septum is wide, division must be stopped as soon as any bleeding occurs. It is then performed in two phases with the second phase scheduled not before 2 months.

Follow-up after Metroplasty

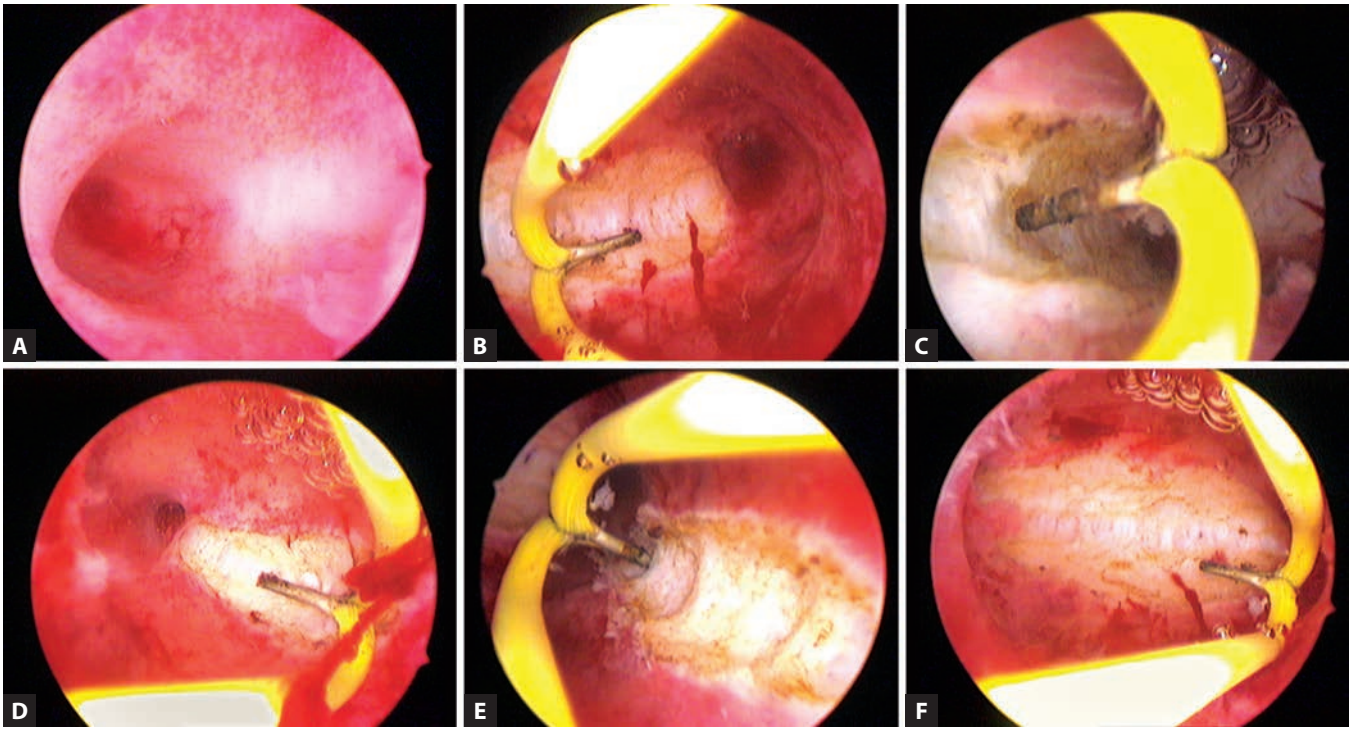
There is no requirement for insertion of any intrauterine device postprocedure. Estrogen therapy is prescribed for 2 months. A diagnostic hysteroscopy can be done after a period of 2 months following estrogen therapy. If the remaining fundic spur is greater than 1 cm or new, fine adhesions have formed, it can be removed in the same sitting.

Metroplasty for Hypoplastic Uterus

Hypoplastic uterus with cylindrical uterine cavity and a bulging of the uterine side walls alone or in combination with adverse pregnancy outcomes in terms of primary infertility, recurrent pregnancy loss, or preterm delivery is an indication for metroplasty.

Procedure

General anesthesia is needed for induction of patient undergoing metroplasty. The cervix is grasped with vulsellum and progressive cervical dilatation is done using Hegar's dilators. Glycine is the media that is used for distension of the uterine cavity. The hook is introduced into the uterine cavity and the incision is performed under visual guidance. It extends from the fundus to the isthmus. The incision should be perpendicular to the lateral wall of the uterus and decreasing the depth of the incision as the section advances. Two incisions in the same groove are performed until a normal triangular and symmetric uterine



Figs. 17A to F: (A) Narrow tubular cavity; (B) Lateral metroplasty using Collin's knife started just below tubal ostia; (C) Successive cuts made by Collin's knife; (D) Lateral metroplasty on left side; (E) Lateral metroplasty incision made up to isthmus; (F) Fundal metroplasty incision between the two tubal ostia.

cavity is obtained **(Figs. 17A to F)**. The same incisions are repeated on the other lateral wall. Depth of incision should not exceed 5–7 mm.

Sequential use of estrogen/progesterone is prescribed for a period of 2 months and a repeat diagnostic hysteroscopy is performed thereafter.

Complications of Hysteroscopic Metroplasty

- *Mechanical complications:* Uterine perforation, which can lead to even visceral burns, if not timely detected.
- *Bleeding:* It occurs rarely. However, if the myometrium is disrupted, large venous sinuses can be encountered. To minimize intravasation, the intrauterine pressure should be reduced. Bleeding from small vessels can be controlled by laser or electrocautery. One can also perform bimanual compression of the uterus. An effective method is insertion of a Foleys catheter into the uterine cavity, with the balloon being filled with 15–30 cm^3 of normal saline. The catheter is left in situ for a few hours to overnight.
- *Postoperative infections:*
  - Endometritis occurs in few cases, hence the justification of giving postoperative antibiotics.
  - Intrauterine adhesion rarely occurs.
- *Metabolic complications:* The intravascular passage of a significant quantity of irrigation fluid can lead to hemodilution. Therefore, inflow and outflow of media used should be meticulously monitored.

INTRAUTERINE ADHESIONS (ASHERMAN'S SYNDROME)

Asherman described two different types of traumatic synechiae:

1. Stenosis or obliteration of the cervical canal in the vicinity of the internal os.
2. Partial or complete obliteration of the uterine cavity by conglutination of the opposing walls. Dilatation and curettage immediately after a delivery or a miscarriage are the main causes of intrauterine adhesions (75%). Infection might contribute to the development of intrauterine synechiae in 26% of cases. Other causes are cesarean or uterine surgery in nonpregnant uterus. The overall pregnancy rate after hysteroscopic adhesiolysis is 43%, with a live birth rate of 32%. The most severe form of intrauterine synechiae is related to endometrial tuberculosis, where the entire endometrial cavity may be completely lost, including the cornual regions. Its prognosis is poor.

Diagnosis

- Amenorrhea in the presence of ovulation suggests target organ defect such as intrauterine synechiae.
- Sonohysterography and HSG may show complete or partial obliteration of the uterine cavity. HSG is generally more sensitive and specific, especially if the adhesions are thin or not calcified.
- Diagnostic hysteroscopy allows accurate evaluation of the uterine cavity.

- Classification of intrauterine adhesions is critical, as it affects treatment outcome. The scoring system in the American Fertility Society classification incorporates
- The extent of the uterine cavity involvement (score 1: less than one-third; 2: one-third or two-thirds; 4: over two-thirds),
- The type of adhesions (score 1: filmy; 2: filmy and dense; 4: dense)
- Menstruation (score 0: normal; 2: hypomenorrhea; 4: amenorrhea). Scores of 1–4 indicate mild cases, scores of 5–8 indicate moderate cases, and scores of 9–12 indicate severe cases with poor outcome.

Treatment

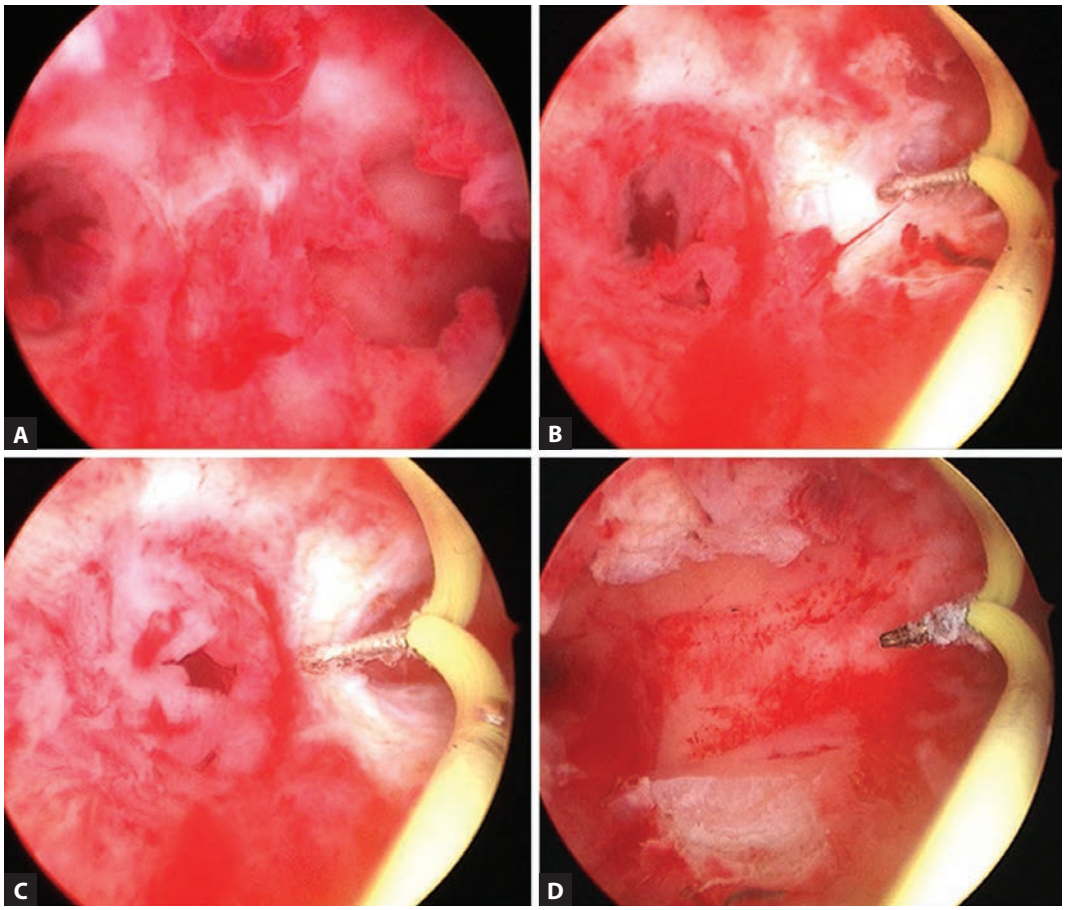
Hysteroscopy remains the main treatment choice for Asherman's syndrome. Adhesiolysis is done using mechanical scissors hysteroscopically. Other modalities like bipolar needles, laser, or vaporizing electrodes may also be used. Postoperatively such patients are treated with estrogen therapy and prophylactic antibiotics should be given. The use of stents during the procedure also aid in complete removal of these adhesions **(Figs. 18A to D)**.

Complications and Their Prevention

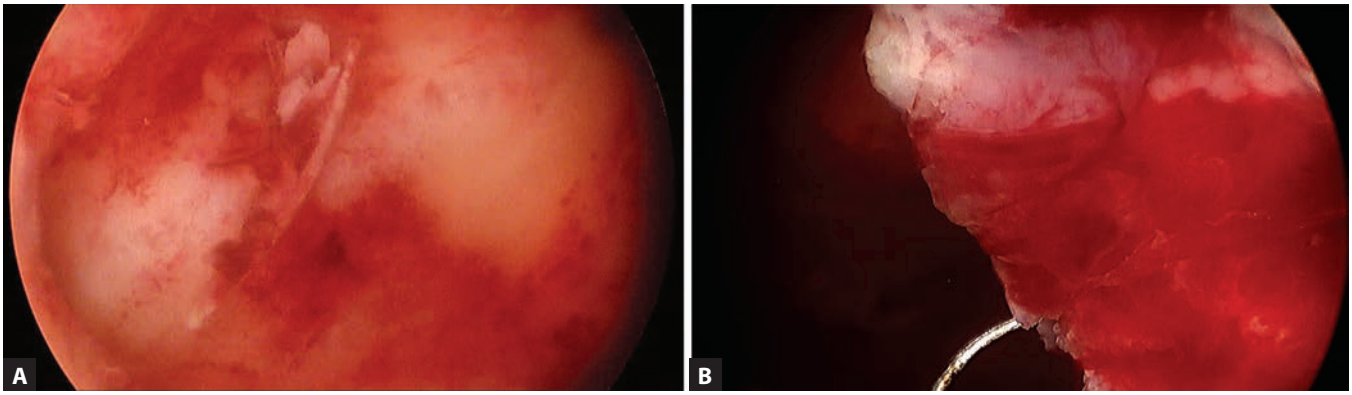
- Besides complications related to hysteroscopy in general, lysis of intrauterine adhesions carries a specific risk of uterine perforation. Attention should be paid to lateral adhesions, where uterine perforation is likely to occur, if aggressive adhesiolysis is attempted. Performing the procedure under ultrasound guidance or laparoscopic control is beneficial.
- Recurrence of intrauterine adhesions and restoration of menstruation are case-dependent. The success rate can be increased with the use of intrauterine devices and estrogen postoperatively.
- Pregnancy after lysis of intrauterine adhesions is associated with an increased risk of miscarriage and hemorrhage because of abnormal placentation. The patient should also be warned of the possibility of placenta accreta.

HYSTEROSCOPY FOR RETAINED FETAL BONES

Majority of patients with retained intrauterine bones have an antecedent history of induced abortion and curettage. First trimester abortions, where fetal bone ossification



Figs. 18A to D: (A) Thick adhesions occluding uterine cavity; (B) Lysis of adhesion; (C) Hysteroscopic division of adhesion using Collin's knife; (D) Normal uterine cavity at end.



Figs. 19A and B: (A) Retained fetal bone visible in hysteroscopy; (B) Hysteroscopic removal of fetal bone.

has not completely occurred, lead to intrauterine bone formation by dystrophic calcification of retained products. Mid trimester abortion frequently require instrumentation and cause retention of fetal skull bones.[26] Incidence is more in anomalous uterus.[27] Bone formation may also be due to chronic endometritis and resulting osseous metaplasia of the endometrium. It can be distinguished from osseous metaplasia by the presence of tissue reaction. Metaplastic ossification following chronic inflammation affects it diffusely.

Diagnosis

- Ultrasonography—calcified specs in the endometrium
- Hysterosalpingography—may reveal filling defects of the uterine cavity
- Hysteroscopy—coral-like osseous fragments embedded within or projecting through the endometrium and confirms the diagnosis

These retained bones can be successfully retrieved with hysteroscopy or with a resectoscope **(Figs. 19A and B)**. Removal of bony fragments is associated with therapeutic success and correction of infertility. A spontaneous pregnancy rate of around 80% has been reported in one of the largest reviews of retained fetal bones and with most of the pregnancies occurring within 6 months of retrieval of fetal bones.

KEY POINTS

- Diagnostic hysterolaparoscopy is most effective and safe method of evaluation of female infertility, mainly in detecting endometriosis, intraperitoneal adhesions, and uterine malformations.
- These are all correctable abnormalities that can be missed by routine pelvic examination and usual imaging procedures.
- It is a very useful method that diagnoses and treats multiple tubal, ovarian, peritoneal, and uterine abnormalities in a single setting, especially in couples with normal hormonal profiles and male factor.
- Thus, hysterolaparoscopy may be considered as gold standard and definitive investigative daycare procedure for evaluation of female infertility.

Reconstructive Surgeries Enhancing Fertility

Yehia Shawki, Osama Shawki, Amr Wahba, Zakiya Ahmed

INTRODUCTION

Conception is a complex and delicate process, the successful fulfillment of which requires normal anatomy and function of the female reproductive tract. Any factor, which might distort the normal anatomy of the female pelvis, or the uterine cavity could lead to the impairment of the fertility potential. Thanks to the advances that took place over the past decades in surgical techniques with the emergence and development of minimally invasive surgeries; namely laparoscopy and hysteroscopy, it has become now possible to reconstruct distorted pelvic anatomy and uterine cavity, and thus, restore fertility. Undoubtedly, comprehensive assessment of subfertile couples with detailed infertility workup is mandatory before proceeding with any reconstructive surgery to exclude other factors of infertility which might change the management plan. This chapter will focus on the factors that contribute in the distortion of pelvic and uterine anatomy and will highlight the surgical procedures used to correct this distortion aiming to increase fertility.

RECONSTRUCTION OF DISTORTED PELVIC ANATOMY

Pelvic Adhesions

Adhesions are bands of fibrous tissue that form as a result of the healing process which remain after the original inflammation or trauma has healed. Pelvic adhesions are one of the leading causes of female infertility. Almost 15–20% of female infertility is accounted for by adhesions.[1] The more extensive the adhesions are, the less likely it is for pregnancy to happen.[2] Peritoneal adhesions[3] can be the consequence of tissue trauma that may result from sharp, mechanical, or thermal injury; infection may result from a variety of causes including most commonly pelvic inflammatory disease (PID) especially if ignored or recurrent, endometriosis **(Fig. 1)**, history of an abdominal or pelvic surgery, complicated appendicitis, and inflammatory bowel disease.[4]

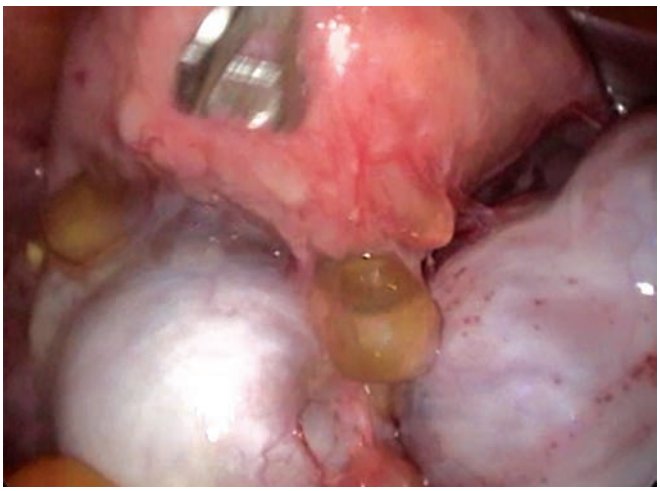

Fig. 1: Severe endometriosis with adhesions distorting the normal pelvic anatomy.

Less commonly, it can be caused by radiotherapy, bacterial peritonitis and foreign body reaction.

Such trauma triggers a cascade of events that begins with the disruption of stromal mast cells, which releases vasoactive substances such as histamine and kinins that increase vascular permeability. Oxidative stress is the result of tissue hypoxia. Free oxygen and nitrogen radicals enhance the inflammatory response that results in tissue injury. As a result, both large and small peritoneal defects heal relatively quickly. Fibrinous exudates form within 3 hours after injury. Most fibrinous exudates are transient and are broken down by fibrinolysis within 72 hours. Trauma-induced local suppression of peritoneal fibrinolysis leads to early fibrinous adhesions. The invasion of fibroblasts and blood vessels soon follows, resulting in permanent adhesions which can be vascular.

The most important potential consequences of adhesion formation are infertility, bowel obstruction, abdominal/pelvic pain, and injury to internal organs. Adhesions may affect fertility adversely by distorting adnexal anatomy and interfering with gamete and embryo transport.

Among infertile women with otherwise unexplained infertility diagnosed with adnexal adhesions at laparoscopy, pregnancy rates after subsequent adhesiolysis by laparotomy were 32% at 12 months and 45% at 24 months compared with 11% at 12 months and 16% at 24 months in women left untreated.

Intra-abdominal surgery is among the most important contributing factors for the development of peritoneal adhesions. The incidence of adhesions is higher after laparotomy rather than laparoscopy,[5] with increasing number of laparotomies[6] and midline incisions rather than suprapubic incisions.[5,6] Abdominal hysterectomy and myomectomy (especially after a posterior uterine wall incision) have high associations with pelvic adhesions.[7,8] The risk of formation of adhesions due to surgery may be predisposed to by several factors including excessive suturing, traction on the peritoneum, omentum, retained blood in the peritoneal cavity, lengthy operations, excessive tissue trauma, infection, ischemia, and latex powder.[9]

Adhesions distort the normal anatomy of the pelvis and can cause infertility by several ways. Peritubal adhesions may occlude the tube and may impair tubal motility which in turn leads to defective ovum pickup and embryo arrival into the uterus, thus, either resulting in infertility or ectopic implantation of the embryo into the tube. Periovarian adhesions prevent proper follicular growth and ovulation.[10]

Several scoring systems have been proposed for the assessment of pelvic adhesions, all of which seek to define a method to calculate the prognosis of adhesiolysis and whether or not the patient should seek in vitro fertilization (IVF). In 1982, Hulka suggested a scoring system based on two criteria; first is whether adhesions are filmy (A) or dense (B) and the second is the coverage of ovarian tissue. The study classified it into stage I, little or all of the ovarian surface is visible; stage II, over 50% of the ovary is visible; stage III, <50% of the ovary is visible; and stage IV, no ovarian surface is visible. Each adnexum should be described separately. Accordingly, the best prognosis was found in the stage I and the worst in stage IV.[11] In 1988, the American Fertility Society (AFS) [currently, the American Society for Reproductive Medicine (ASRM)] proposed a more detailed adhesion scoring system that also describes the site and extent of adhesions as shown in **Table 1**. Dense adhesions are given a score four times the filmy adhesions. The extent of organ involvement is classified into 1/3, between 1/3 and 2/3, and more than 2/3 enclosure. The score doubles with each class. Each adnexum should be described separately. Prognosis is based on the adnexum with the lesser pathology.[12]

According to this scoring system, the numbers are summed up and the adhesions are classified into *minimal* (0–5), *mild* (6–10), *moderate* (11–20), and *severe* (21–32). Several studies support the use of this scoring system to determine the prognosis and the plan of management of patients. Minimal and mild adhesions are associated with the highest pregnancy rates.[13-15] It was also found useful in predicting the rates of pregnancy, oocyte recovery, and embryo transfer for patients undergoing IVF where mild adhesions had higher rates compared to patients with severe adhesions.[16]

Measures to Reduce Adhesions

Formation of postoperative adhesions often may be minimized by careful surgical technique with adherence to microsurgical principles, including gentle tissue handling, meticulous hemostasis, excision of necrotic tissue, minimization of ischemia and desiccation, use of fine nonreactive suture materials, and prevention of foreign body reaction and infection. The larger the residual amount of blood and serosanguinous fluid, favors adhesion formation. Postoperative adhesions have been observed in up to 94% of patients after laparotomy. Laparoscopy does not necessarily result in fewer adhesions than laparotomy; the extent of tissue injury, note the surgical approach, is the determining factor. Risk for the development of de novo anterior abdominal wall adhesions is likely lower after laparoscopy than after laparotomy because the risk relates to the length of the abdominal incision(s).

TABLE 1: Adhesion scoring system, the American Fertility Society.[13]

		Extent		
Side and organ	***Adhesion severity***	***<1/3 Enclosure***	***1/3–2/3 Enclosure***	***>2/3 Enclosure***
Right ovary	Filmy Dense	1 4	2 8	4 16
Right tube	Filmy Dense	1 4	2 8	4 16
Left ovary	Filmy Dense	1 4	2 8	4 16
Left tube	Filmy Dense	1 4	2 8	4 16

The incidence of postoperative infection, another risk factor for adhesion formation, is lower after laparoscopy than after laparotomy. Pneumoperitoneum has a tamponade effect that may help to facilitate hemostasis during laparoscopy.

Evidence suggests that the incidence of adhesions at the site of closure after laparotomy is approximately 22% with peritoneal closure and 16% without peritoneal closure.

Adhesiolysis for Reconstruction of Pelvic Anatomy

Adhesiolysis is the surgical procedure in which adhesions are lysed to restore normal anatomy distorted by the adhesions. It is performed laparoscopically, usually through two or three punctures. Adhesion bands are put under tension using a grasper forceps to identify the limits of the adhesion bands. The bands are divided at their distal margins using either scissors, coagulation current, or laser. If adhesions are filmy and avascular, scissors are sufficient. If adhesions are vascular, coagulation or laser must be used to stop bleeding. When adhesions are near the ovaries, it is wise to cut about 1 mm away from the ovaries to avoid injury. Cohesive adhesions usually require plane dissection either using dissecting scissors, blunt dissection, or hydrodissection. Whenever possible, grasp the adhesions or the ovarian ligament instead of the ovary itself to reduce trauma. Adhesiolysis aims to restore tubo-ovarian relationship as much as possible. At the conclusion of surgery, irrigation of the pelvis by Ringer's lactate solution is needed to wash any blood clots or debris.

Does Adhesiolysis Improve the Fertility Outcome?

Evidence proved that adhesiolysis can improve pregnancy outcomes.[17] In one study, the cumulative pregnancy rate at 24 months follow-up was significantly higher in treated women, 45 versus 16% in the untreated group.[18] In another study, when patients who underwent laparoscopic adhesiolysis were followed up for 1 year, pregnancy occurred in 70.8%, 48.3%, and 21.6% patients in mild, moderate, and severe adhesions, respectively.[19] Some proposed the idea of second-look laparoscopy after pelvic reconstructive surgery. However, randomized controlled trials failed to prove its significance.[20]

ENDOMETRIOSIS AND INFERTILITY

The conundrum on how endometriosis affects fertility has long been debated with new studies changing the suggested course of action every few years. A measure of the issue lies with the number of afflicted patients; a diagnosis of endometriosis was considered "new" after verifying women had not been diagnosed in the previous 10 years. Incidence of endometriosis and adenomyosis in women aged 15–50 years is 0.14%. Prevalence estimated from incidence is 2.00%.[21] In the past, it has been suggested that endometriosis was not resulting in the tubal malfunction, nor endometrioma <5 cm was to be tackled prior to IVF. Revisiting the issue has led to the discovery of vital endometrial receptivity factors including HOXA 10 and HOXA 11 which are suppressed in cases of endometriosis and whose recovery, postsurgical intervention provide healthy additions to the fertility rate.[22] New technologies have also been introduced to tackle these pathologies with the growing concern of how coagulative damage to the ovaries may lead to decreased ovarian reserve compounded by the oxidative stress exerted by the disease progression already affecting ovarian reserve. Here is where the gray zone of risk versus reward of endometrioma surgery lies.[23,24]

Recent The European Society of Human Reproduction and Embryology (ESHRE) guideline recommends offering surgery as one of the options to reduce endometriosis associated pain. And when surgery is performed, clinicians may consider excision instead of ablation of endometriosis to reduce endometriosis-associated pain.[25] They have now concluded that laser uterine nerve ablation (LUNA) is not beneficial. When performing surgery in women with ovarian endometrioma, clinicians are advised to perform cystectomy instead of drainage and coagulation as it reduces recurrence of endometrioma and endometriosis-associated pain. They have also said that both cystectomy and CO_2 laser vaporization as both have similar recurrence rate beyond first year after surgery.[25]

Patients with deep endometriosis should be referred to a center of expertise. Clinicians may consider operative laparoscopy for the treatment of endometrioma associated infertility as it may increase chance of natural pregnancy; however, no data from comparative studies exist.

According to the ESHRE 2022 guideline, decision to perform surgery should be guided by the presence of absence of pain symptoms, patient's age and preferences, history of previous surgery, presence of other infertility factors, ovarian reserve, and estimated endometriosis fertility index (EFI).[25]

RECONSTRUCTION OF BLOCKED FALLOPIAN TUBES

Patency of the fallopian tube and normal function of its lining mucosa are mandatory for the transport of ovum, sperm, and embryo. It is in the ampulla of the fallopian tube where fertilization takes place. Blockage of this conduit will impair fertility and may cause ectopic pregnancy. The most common causes for tubal damage or occlusion are tubal infection and tubal sterilization. Tubal infection occurs as a part of PID secondary to sexually transmitted infections. The most common causative organism is usually *Chlamydia trachomatis*.[26]

Evaluation of Tubes

Hysterosalpingography (HSG) provides information on tubal patency, size, shape, and course along with the data on the shape of the uterine cavity **(Fig. 2)**. However, its accuracy in diagnosing pelvic adhesions is limited. Abnormal HSG must be offered laparoscopy. However, it is worth noting that 5% of patients with normal HSG will reveal a pathology after performing a laparoscopy.[27] Falloposcopy is a procedure which allows the transvaginal microendoscopic visualization of the whole interior of the fallopian tubes. It provides information about the tubal mucosa and the presence of any obstruction as well as the opportunity to cannulate the tube to overcome the obstruction. Its high expenses and technical difficulties limit its use in the clinical practice.[28,29]

Tubal Reconstructive Surgeries

Although several surgical procedures have been proposed to correct or enhance tubal patency, the new era of IVF made their use limited. However, properly selected subjects may still benefit from tubal reconstructive surgery, especially with selecting the proper procedure and optimum technique.

In cases of tubal infection, the resultant damage of the epithelial lining negatively affects the results of reconstructive surgery. On the other hand, reversal of sterilization is considered the most common indication for surgical reconstruction since most patients are young and only segmental damage is present. These factors denote high chances of conception afterwards. Sterilization using a Filshie clip is the most easily reversible as a small portion of the tube is damaged and it gives excellent results that could match an IVF trial. Pregnancy rates may reach 86%, while ectopic pregnancies are as low as 7%.[30]

The type of surgery used will depend on the *site* and *extent* of tubal damage. In cases of adhesions involving the tube and ovary, salpingo-ovariolysis can be performed laparoscopically. The reported pregnancy rates are from 51 to 62% for intrauterine pregnancies and 5 to 8% for ectopic pregnancies.[31] If the fimbrial end is agglutinated or shows fimbrial phimosis, fimbrioplasty can be performed with intrauterine pregnancies ranging from 40 to 48% and ectopic pregnancies from 5 to 6%.[26] On the other hand, distention of the tube with hydrosalpinx can be managed surgically by either tubal occlusion (disconnection), tubal removal (salpingectomy) or making a new tubal ostium (salpingostomy). In cases with mild hydrosalpinx, salpingostomy yields 40–60% pregnancy rates which decline to 20% with more severe affection.[31] Dilated tubes >3 cm with thick walls and damaged mucosa, will have a poor benefit from distal tubal surgeries and are best offered IVF treatment.[32] Disconnecting the tube before an IVF cycle is now the most accepted practice as it prevents spillage of toxic fluid into the uterine cavity which might kill the transferred embryos.[33] Occlusion can be done using Filshie clips or by bipolar diathermy and cutting the tube. In both cases, the site of occlusion must be medial to the proximal end of the hydrosalpinx and as close to the uterus as possible to avoid any residual part connecting to the uterus.

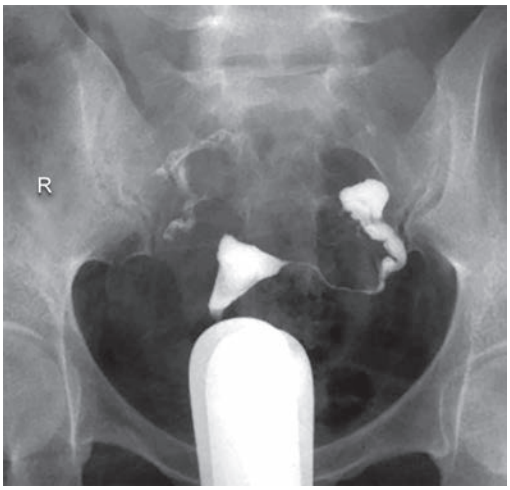

Fig. 2: Hysterosalpingography showing proximal block of right tube and distal block of the left tube.

Cases with proximal tubal block should be offered hysteroscopic tubal cannulation to overcome mild occlusions with mucous plugs.[34] However, true occlusions may be offered tubocornual anastomosis using microsurgical techniques. Intrauterine pregnancy rates may reach 56% and ectopic pregnancies up to 7%.[35] Combined proximal and distal diseases carry a poor prognosis after surgical repair. One study showed no live births after a 2-year follow-up.[30] Thus, such patients should be offered IVF.

Tubal Reanastomosis

When comparing open to laparoscopic approaches for reversal of sterilization, a meta-analysis reveals no significant difference in the rates of intrauterine and ectopic pregnancies. While laparoscopic approach is associated with less postoperative pain and rapid recovery, it took significantly longer operative time.[36] Robotic reanastomosis also had similar pregnancy rates as laparotomies but took longer and costed much higher.[37]

Chromopertubation of the tube may help identify the site of obstruction. The tube is transected using the microscissors just adjacent to the affected site. The incision should not reach the mesosalpinx as not to disrupt the vascular arcade of the adjacent segment. Throughout the procedure, meticulous hemostasis is essential. However, stoppage of unnecessary bleeders will devitalize the healthy tubal mucosa. If unhealthy mucosa is encountered, 1–2 mm thick segments are cut until the healthy mucosa is visible. The two ends are approximated in two layers: (1) musculosa and (2) serosa. The first suture is the most posterior at 6 o'clock. Usually four sutures are enough to hold both ends together. Then, the serosa is sutured in the same manner. The suture

material used is usually 7-0 or 8-0 Vicryl or polydioxanone (PDS).[38,39] While some prefer using splint to facilitate tubal reanastomosis,[40] others recommend not using it as it might damage the tubal epithelium and reduce the success of the procedure. After finishing the procedure on both sides, chromopertubation is performed to ensure a watertight suture line. A more recent technique is called the sutureless laparoscopic reanastomosis where a 3-mm microclip is used to fix the seromuscularis with the addition of a biological glue. The 40-month cumulative clinical pregnancy rate was 74%, whereas the ongoing pregnancy rate was 59% and the ectopic pregnancy rates were 3.9%.[41]

Tubal reconstructive surgeries should follow the microsurgical principles. Microsurgery does not involve only the use of microscope, it is considered a surgical behavior with certain principles and approaches. The following are the important parameters in the microsurgery:[36]

- Delicate tissue handling with minimal injury and thorough hemostasis.
- Avoid foreign body contamination. Surgeons may wash their gloves before handling the cover sheets and may also change their gloves before handling the patient.
- Proper identification of anatomical plans and exact alignment of tissues.
- Proper tissue irrigation and peritoneal lavage using heparinized Ringer's lactate solution.
- The use of microscopic magnification to properly handle the tissues and surgical instruments.

Factors Affecting Surgery Outcome

Many factors were reported to have an impact on the success of tubal reconstruction. These include patient's age, length of fallopian tube, type of sterilization, and site of anastomosis. The older the woman undergoing reconstruction, the less likely she will conceive after having the surgery.[42,43] In one study, pregnancy rates after tubal reanastomosis decreased from 81% in patients below 36 years to 12.5% in patients above 43 years.[43] Pregnancy rates also decreased in cases with short fallopian tubes, especially below 4 cm in length.[40,42] Clip sterilization gave the best results after reversal followed by the ring sterilization, then coagulation, and Pomeroy sterilization.[43] The site of anastomosis influences the success of the surgery, and the best results in descending order were seen in the ampullo-ampullar, isthmo-isthmic, isthmo-cornual, isthmic-ampullary then ampullo-cornual anastomoses. In addition, ectopic pregnancy rates rise in the same order.[43] It appears that less the discrepancy between the diameters of both ends, the better the results.

Management of Hydrosalpinx

In the beginning of IVF era, tubal factor infertility was the sole indication for treatment. It is said that tubal factor infertility often yields worse results than other causes of infertility. Pregnancy rates were significantly lower (15%) in patients with visible hydrosalpinges compared with patients in whom the hydrosalpinges were not visible (31%). (CITE)

Treatment includes salpingectomy, tubal ligation, and transvaginal aspiration. Salpingectomy is the only method of prophylactic surgery in patients with hydrosalpinx that has been properly evaluated in a large randomized trial (CITE). Clinical pregnancy rates were 46 versus 22% in salpingectomized patients versus patients without any surgical intervention.

Other surgeries include laparoscopy with proximal ligation and salpingostomy. The procedure is currently recommended when pelvic adhesions are too extensive to perform a salpingectomy.

Salpingostomy is the method of choice if the tube is suitable for reconstructive surgery. However selection of patient is crucial. The selection of patients suitable for surgical repair has to be based on the evaluation of the tubal mucosa through an endoscopic technique, and tubes with more than half of the mucosa in a good condition may have a fair chance of spontaneous conception.

Transvaginal aspiration of hydrosalpinx is a simple method but leads to rapid recurrence of fluid (34%). To overcome the problem of the high recurrence rate after transvaginal aspiration of hydrosalpinx fluid, ethanol sclerotherapy has been introduced.

RECONSTRUCTION OF DISTORTED UTERINE CAVITY

Uterine cavity is the site where the embryo will implant and grow. Any distortion of this cavity will impair fertility and interfere with the completion of pregnancy. Uterine cavity can be distorted by many intracavitary lesions including endometrial polyps, submucous myomas, intrauterine synechia (Asherman syndrome) and uterine anomalies. Hysteroscopy provides a reliable modality not only for the diagnosis of these lesions but also for the reconstruction of the uterine cavity and treating such lesions.

UTERINE SEPTUM

A uterine septum is the most common uterine anomaly accounting for >50% of all uterine anomalies.[44] Its exact incidence in the general population cannot be determined accurately as many cases are asymptomatic. It results from failure of resorption of the part between the two Müllerian ducts during embryological development **(Fig. 3)**.

Several mechanisms have been postulated to explain the possible adverse impact of the uterine septum on reproduction. Based on the observation made by histopathology and color Doppler imaging that a uterine septum is made up of myometrial tissue and connective tissue, it was proposed that a septum creates irregular contractile patterns that expels an implanted embryo or

Fig. 3: Hysteroscopic view of a septate uterus.

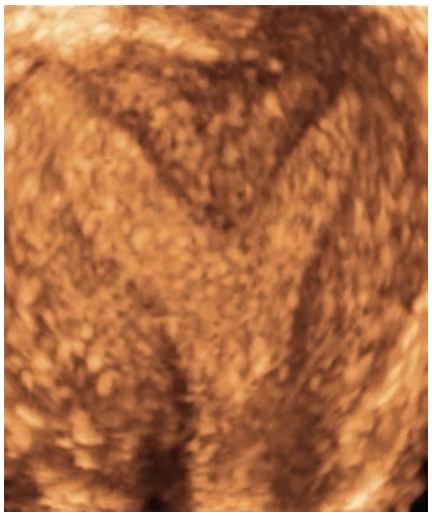

Fig. 4: 3D ultrasonography showing septate uterus.

prevents its implantation.[45] Another study showed that the endometrium overlying the septum is poor in hormonal receptivity which might waver its ability to accept embryos.[46] Being poor in blood supply may explain the cause of repeated spontaneous abortions.[47]

Diagnosis

Accurate diagnosis of a septate uterus is mandatory before considering treating it. The main challenge in diagnosing a septate uterus is differentiating it from bicornuate uterus which has a totally different plan of management. HSG is an easy and simple method for suspecting uterine anomaly. However, its accuracy reaches 55% only in differentiating between septate and bicornuate uterus as the fundus cannot be seen.[48] If a uterus is not well erected during an HSG, a small septum might be missed. More recently, 3D ultrasound was found to be extremely accurate in differentiating between septate and bicornuate uterus[49] and more accurate and cost-effective than HSG[50] **(Fig. 4)**. Before the availability of 3D ultrasound, laparoscopy used to be the gold standard for differentiating between a septate uterus and a bicornuate uterus.

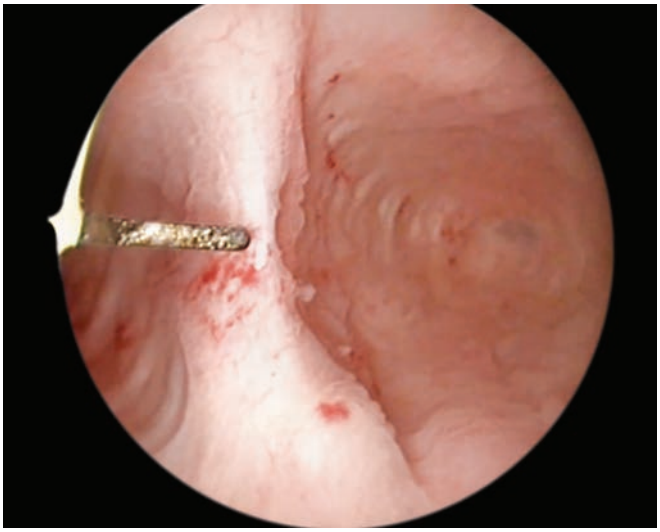

Fig. 5: Hysteroscopic septum resection by Collins knife electrode.

Septum Resection

Historically, Tompkins or Jones procedure was done which involved a laparotomy and excision of the septum, thus necessitating a cesarean section at delivery. Nowadays, hysteroscopy replaces such outdated operations. A hysteroscopic procedure merely incises the septum instead of resecting it. The septal tissues will then retract and the endometrium will heal over it within two cycles. A septum may be incised by scissors, laser, or electrosurgery. No evidence proves the superiority of one method over the other. However, a monopolar electrode requires an electrolyte-free medium which has its own drawbacks as hyponatremia and volume overload, while bipolar electrodes require an electrolyte-containing media which only causes volume overload in lengthy operations **(Fig. 5)**.

Postoperative Treatment

In the past, intrauterine devices were placed and estrogen therapy was given for several months after metroplasty to prevent formation of adhesions. Several studies proved that they have no role in preventing adhesions and do not improve pregnancy outcomes later on.[51,52] Follow-up is by ultrasound or hysteroscopy 1–2 months after metroplasty. The chance that a patient might need a second procedure to incise residual septum is 6%.[53]

Outcome

It has been proved that metroplasty improves the pregnancy rates, live birth rates (LBRs), and reduces abortion rates. In a recent retrospective cohort study over 1,501 women, pregnancy rates were 60% and a LBR was 45%.[49] Metroplasty

improves pregnancy outcomes in patients with recurrent spontaneous abortions[53,54] and in unexplained infertility.[55,56] Incising a uterine septum improves the results of IVF or intracytoplasmic sperm injection (ICSI) cycles and makes them almost the same as an anomaly-free uterus.[57]

INTRAUTERINE ADHESIONS

Intrauterine adhesions (IUAs) or synechia are the bands of fibrous tissue that form within the uterine cavity resulting in distortion of the cavity with subsequent impairment of reproduction and menstrual patterns **(Fig. 6)**. >90% of IUA occurs following over curettage.[58,59] Usually, it occurs following postpartum or postabortive excessive bleeding. Curettage erodes the basal endometrial layer leaving it exposed which in turn heals by fibrous tissue formation. Other causes include abdominal metroplasties and myomectomies, but here misplaced sutures are more responsible for the adhesions rather than the procedure itself. Rarely, endometrial tuberculosis destroys the uterine lining which heals thereafter by secondary intention forming IUA. Another growing cause in the developing world is abuse of C-sections and misplaced sutures and infections resulting in IUA. The occurrence of amenorrhea following curettage for incomplete or missed abortion and postpartum hemorrhage has been described as Asherman syndrome.[59]

Diagnosis

Intrauterine adhesions should be suspected whenever a patient presents with amenorrhea, hypomenorrhea or infertility following a history of endometrial trauma after delivery or abortion. IUA may present with pregnancy morbidities, e.g., abortion, ectopic pregnancy, preterm labor, or even placenta accreta. HSG may show a small, fragmented, and distorted uterine cavity as a result of IUAs. Using ultrasonography, echogenic foci detected within endometrial lining may point to the presence of IUAs.[60]

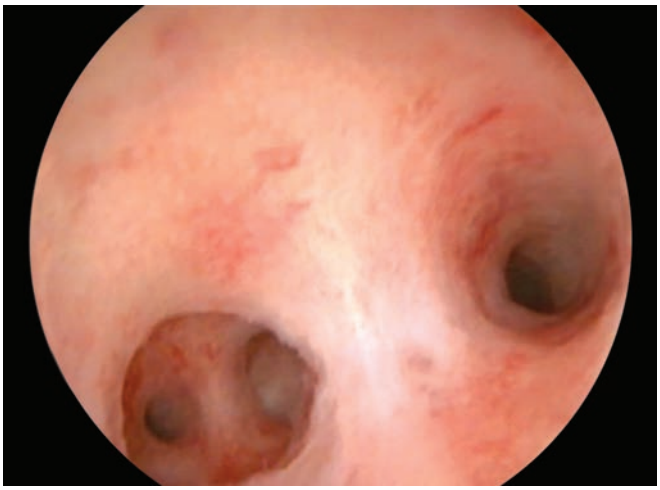

Fig. 6: Hysteroscopic view of intrauterine adhesions.

No worldwide consensus is made on the classification of IUAs. The ASRM[12] proposed a classification depending on the findings of HSG and hysteroscopy. Another classification divides IUA into central (Degree I), marginal (Degree II) and absent uterine cavity by HSG (Degree III).[61] IUAs can be classified as well into mild, moderate, and severe adhesions.[58]

- *Mild:* Filmy adhesions, partially or completely occluding the cavity
- *Moderate:* Fibromuscular adhesions (connective tissue covered by endometrial tissue), partially or completely occluding the cavity
- *Severe:* Connective tissue only (not covered by endometrial tissue), partially or completely occluding the cavity.

Hysteroscopic Adhesiolysis for Restoration of the Uterine Cavity

Historically, curettes, probes, dilator, and open hysterotomy were used to cut the adhesions but these methods had high morbidities and poor results. Currently, operative hysteroscopy is considered the gold standard approach. Filmy adhesions can be cut by the mere push of the hysteroscope. Division of more dense adhesions can be achieved with the use of semi-rigid scissors introduced through the operative sheath of hysteroscope with no risk of bleeding since most adhesions are avascular. Alternatively, resectoscope can be used to divide IUAs with loop, knife, or needle electrodes, though the effectiveness of the current on what remains of the endometrium is debatable and more studies are needed to prove if electrosurgery has a role in advanced Asherman syndrome. Fiberoptic lasers such as neodymium doped yttrium-aluminum-garnet (Nd:YAG), KTP/532, or argon can be used to divide IUAs. It can be used to selectively divide lateral and fundal adhesions due to its flexibility.[62] Laser can be used in electrolyte-containing media. Although, hemostasis is excellent with the use of electrocautery or laser, their use may cause damage to adjacent healthy endometrium. Also, they may lead to over division with increased risk of uterine perforation. Thus, some recommend the performance of concomitant laparoscope to guide the hysteroscopic division of IUAs. Following hysteroscopic adhesiolysis, the uterine wall should be kept separate from each other using either a pediatric 8F Foley catheter[9] or intrauterine devices.[63,64] Postoperative estrogen or estrogen and progesterone are given to promote growth of the endometrium.[9,63,64]

Outcome

Restoration of menses and reproductive outcome correlates well with the severity of IUA. Normal menstruation is restored in about 90% of cases.[58,65,66] Highest pregnancy rates are achieved after mild adhesions and lower in moderate and severe adhesions.[58,67,68]

SUBMUCOUS MYOMAS

The incidence of myomata in infertile women without any obvious cause of infertility is estimated to be between 1 and 2.4%[63] **(Fig. 7)**. Different theories have been suggested to explain how myomata can impair the fertility potential. The anatomical location of a myoma plays an important role with submucous myomata most commonly implicated followed by intramural and subserous myomas. Myomas may cause abnormal uterine contractility which may interfere with sperm migration and ovum transport.[69] Also, it has been postulated that myomata may be associated with implantation failure or gestation discontinuation due to focal endometrial vascular disturbance, endometrial inflammation, secretion of vasoactive substances, or an enhanced endometrial androgen environment.[70]

Fig. 7: Submucous myoma.

Preoperative Evaluation

The comprehensive preoperative evaluation of submucous myoma would entail the use of ultrasonography, sonohysterography, and hysteroscopy to determine the *number, size, location, degree of intramural extension of the submucous myomas* as well as *the distance between the myoma and the serosa*. Wamsteker et al.[70] classified submucous myomata according to the degree of intramural growth into three categories; (1) grade 0 (myoma with no intramural extension), (2) grade 1 (myoma with intramural part <50%), and (3) grade 2 (myoma with intramural part ≥50%). This classification was adopted by the European Society for Gynecological Endoscopy (ESGE) and is widely used by hysteroscopists **(Table 2)**.

TABLE 2: European Society for Gynecological Endoscopy classification of submucous myomas.

Grade	*Degree of intramyometrial growth*
0	No intramural extension (myoma is completely within the uterine cavity)
1	Intramural part <50%
2	Intramural part ≥50%

Hysteroscopic Myomectomy

Traditionally, symptomatic submucous myomata in infertile women were treated surgically by abdominal myomectomy. This approach requires an opening of the uterine cavity which may compromise any future parturition as it requires cesarean delivery; moreover, it may lead to the development of pelvic postoperative adhesions which may further reduce rather than enhance fertility.[71,72] Operative hysteroscopy has recently provided a better alternative for resection of submucous myomata transcervically, thus, avoiding the drawbacks of laparotomy and uterine incision. Many techniques have been described, however, the standard technique entails slicing of the submucous myoma from its top toward its base using the cutting loop of the resectoscope.

Using this technique, an intracavitary myoma is repeatedly and progressively shaved till its bases[73] **(Fig. 8)**. The resulting fragments can be pushed away from the myoma till they interfere with proper visualization, and then the fragments can be removed by withdrawing the resectoscope with its loop electrode grasping the loose fragment.

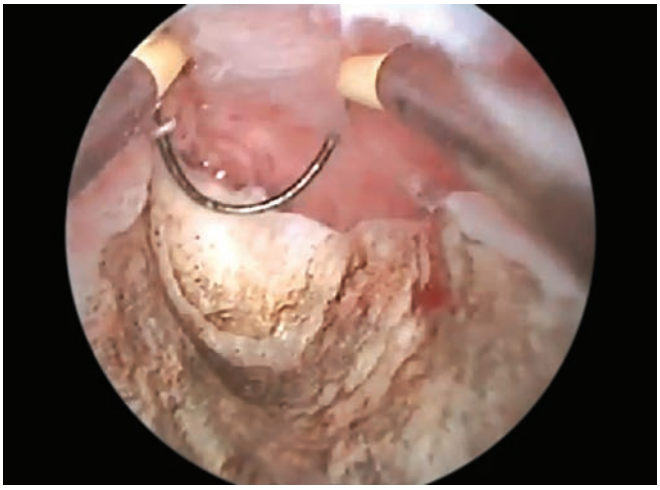

Fig. 8: Hysteroscopic myomectomy.

Outcome

Surgical management with hysteroscopic myomectomy has been reported to yield pregnancy rates of 16.7–76.9% (mean of 45%) in infertile women.[74] For patients with recurrent miscarriage and intracavitary fibroids, surgery increases rates of viable pregnancy outcomes.[75]

ENDOMETRIAL POLYPS

Endometrial polyps are localized hyperplastic overgrowths of glands and stroma that project form the surface of the endometrium. They vary in size from few millimeters to few centimeters and when large enough they can protrude

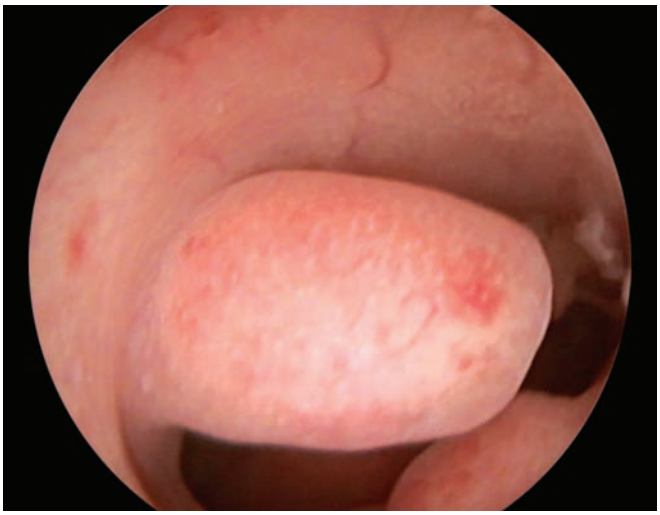

Fig. 9: Sessile endometrial polyp.

through the cervix. They may be single or multiple (polypoid endometrium), sessile or pedunculated, and may rarely include foci of neoplastic growth[2] **(Fig. 9)**. Endometrial polyps have been accused of causing infertility. Although the precise mechanism by which they do is unclear, it has been shown in a larger series that hysteroscopic polypectomy improves fertility and increases pregnancy rates, irrespective of the size, or the number of the polyps.[8] Hysteroscopy can precisely identify number, location, size of endometrial polyps, and presence of any suspicious features. It can also resect these lesions for pathological examination replacing the formal dilatation and curettage (D and C), as D and C has been reported that about 10% of polyps remain in situ after curettage.[16,17,76-82] Hysteroscopic resection currently represents the gold standard in the treatment of endometrial polyps[19] since it allows there complete removal under visual control preventing persistence or recurrence of these lesions. Resection of endometrial polyps under direct hysteroscopic visualization can be achieved with the use of different methods either using mechanical instruments or electrosurgery or more recently, intrauterine morcellator.

KEY POINTS

- Pelvic adhesions are commonly caused by PID and best treated by laparoscopy.
- AFS adhesion scoring system is a reliable method for choosing the management and predicting the outcome.
- Reversal of sterilization may give results similar to IVF while women with severe tubal damage are best offered IVF.
- While laparoscope is the golden standard for diagnosing a uterine septum, 3D ultrasound is as almost as accurate.
- Adhesiolysis is best done by scissors, and outcome depends on severity.
- Submucous myomas are divided into grades 0, 1, and 2, and are removed by resectoscope.
- Although the mechanism of infertility in endometrial polyps is not exactly known, their removal is important using hysteroscope instead of D and C.

MULTIPLE CHOICE QUESTIONS

1. Most common cause of pelvic adhesions is:
   a. Laparotomies
   b. Endometriosis
   c. Chlamydia infection
   d. Irradiation
2. Severe tubal disease is best managed by:
   a. IVF
   b. Adhesiolysis
   c. Tubal reanastomosis surgeries
   d. Tubal cannulation
3. Which of the following is not true concerning the adhesion scoring system of the American Fertility Society?
   a. Depends on the site and thickness of the adhesions
   b. Outcome depends on the pathology of the less affected side
   c. Not very accurate in predicting pregnancy rates
   d. The denser the adhesions, the higher the score
4. Which of the following is true about adhesiolysis?
   a. Open and laparoscopic approaches give almost the same results
   b. Has the same outcome regardless of the severity of the adhesions
   c. Second look laparoscopy after adhesiolysis improves pregnancy outcomes
   d. Mainly aims at restoring the anatomic relation between the tube and ovary
5. Concerning tubal blockage, the following are true except:
   a. A normal HSG cancels the benefit of a diagnostic laparoscope
   b. Highest rates of success of reconstructive surgery follow reversal of sterilization
   c. A remaining fallopian tube <4 cm usually carries a poor prognosis
   d. Laparoscopic reconstruction carries the same results as open reconstruction but takes more time to finish and learn
6. A uterine septum may cause abortion or infertility by all the following methods except:
   a. Low receptivity of the endometrium
   b. High vascularity on the septum
   c. Irregular contraction of the myometrial fibers of the septum
   d. Unknown mechanism
7. Which of the following is true about a uterine septum?
   a. 2D ultrasound can diagnose almost as accurate as 3D ultrasound
   b. Removed by excised instead of incised septum
   c. Hysteroscopic approach necessitates a cesarean delivery afterward
   d. Increases pregnancy rates as high as 60%

8. All of the following about intrauterine synechia is true except:
   a. Excessive curettage is the most common cause
   b. Best diagnosed by hysteroscopy
   c. Adhesiolysis best done by laser
   d. 9 out of 10 patients will regain menstruation after adhesiolysis
9. Concerning hysteroscopic myomectomy, which of the following is not true?
   a. Removed by shaving the myoma using a resectoscope
   b. Grade 2 myoma is the easiest in removal
   c. Care should be taken during long procedures to avoid volume overload
   d. Improves pregnancy rates as well as reduces rates of miscarriage
10. Concerning endometrial polyp, the following are false except:
   a. D and C is a method of management but 10% of the polyps may be missed
   b. Must be removed with scissors
   c. Considered a definite cause of infertility
   d. Only multiple polyps should be removed

ANSWERS

1. c	2. a	3. c	4. d
5. a	6. b	7. d	8. c
9. b	10. a

Intrauterine Insemination

CHAPTER

44 Intrauterine Insemination

Natchandra Chimote, Bindu Chimote

INTRODUCTION

About 15% couples, all over the world, have certain fertility problems that can be treated only with medical interventions. One of them is first-line treatment such as intrauterine insemination (IUI) with or without ovarian stimulation (OS) as recommended by World Health Organization (WHO).[1,2] The very first documentation of IUI was done in 1962 by Cohen MR.[3] Since then, IUI has evolved a lot through innovations such as sperm preparation, monitoring of follicular development using transvaginal sonography to determine preovulatory timing, and induction of ovulation with human chorionic gonadotropin (hCG). IUI also has been combined with OS using clomiphene citrate (CC)/letrozole or gonadotropins or combination of both. Though it has not been classified as an assisted reproductive technique (ART),[4,5] it is widely used, often as an empirical treatment, for a broad range of profertility indications.

The European IVF Monitoring Program in 2004 reported live birth rate (LBR) of 12.3% per cycle with 87% births of singletons 13% multiple births.[6] There is little evidence of the effectiveness of widely used IUI in male infertility,[7] and in stimulated IUI in the treatment of unexplained infertility.[8] The effectiveness of IUI across the range of methods and indications has to be evidence based. This includes the extent of IUI utilization, the indications for IUI, the optimal procedures for sperm preparation, insemination methods and timing, and the need, if any, to prevent premature luteinizing hormone (LH) surges and luteal deficiency in stimulated IUI cycles. Also, because IUI is often a stopgap treatment while waiting for, or instead of in vitro fertilization (IVF), a consideration of the evidence on IUI and IVF in treatment protocols is relevant to clinical practice.

INDICATIONS FOR IUI TREATMENT

Rationale

The rationale behind IUI is to increase this gamete density at the site of fertilization even when sperm or cervical mucus abnormalities are present. The increasing use of IUI in idiopathic and male infertility is mainly the result of the refinement of techniques for the preparation of washed motile spermatozoa, as used in IVF procedures.

In order to improve the quality and outcome of IUI procedures, there is a need for simple, inexpensive, reliable and safe sperm preparation techniques that isolate and select sperm cells with intact functional and genetic properties, including normal morphology, minimal DNA damage, and intact cell membranes with functional binding properties.[9] Seminal fluid acts as a transport medium for sperm, prostaglandins, ions, and antioxidants. Cells other than spermatozoa are also present in the ejaculate, including epithelial cells from the urinary tract, prostate cells, spermatogenic cells, and leukocytes. Reactive oxygen species, either produced by the different germ cells or by leukocytes, can be detrimental for the fertilizing potential of the spermatozoa.[10,11] The seminal plasma also contains decapitation factor(s) that need(s) to be removed for complete capacitation of the spermatozoa.[12] This process of capacitation is essential for both fertilization in vivo or in vitro, and hence spermatozoa to be used in IUI must be separated from the seminal plasma and its decapacitating factors such as spermine phosphate and prostaglandins. Preparation of human semen samples should also result in the removal of nonviable spermatozoa, leukocytes and/or bacteria, and other sources of contamination. Donor sperm is mainly cryopreserved and kept in quarantine for at least 6 months to prevent the transfer of infectious diseases. Thawed sperm is mostly used for IUI as compared to intracervical insemination, as supported by older evidence.[13]

CONTRAINDICATIONS

Intrauterine insemination is contraindicated in women with cervical atresia, cervicitis, endometritis or bilateral tubal obstruction, and in most cases of amenorrhea or severe oligospermia.

IUI IN A HISTORICAL PERSPECTIVE

Over the last centuries, the popularity of IUI has varied tremendously.[14] After the first description of spermatozoa by Antoni van Leeuwenhoek and his assistant Johannes Ham in 1678, it took >100 years before the first IUI was reported by John Hunter (1770) when he described the first case of human intravaginal insemination because of severe hypospadias. In the mid-1800s, J Marion Sims reported on 55 intravaginal inseminations. Only one pregnancy occurred, which is probably explained by the fact that Sims believed that ovulation occurred during menstruation. The first report on human IUI was documented by Guttmacher in 1943 and Kohlberg 1953.[15-17] This represents the start of a new era in assisted reproduction.

Dr Jerome K Sherman[18] introduced a simple method of preserving human sperm using glycerol and reported the first successful human pregnancy with frozen sperm in 1953. Due to the hostile climate for donor insemination (DI) at the time, nearly a decade passed before the first successful birth from frozen sperm was announcement in public in 1964.[19]

The renewed interest in sperm washing procedures owing to the introduction of IVF could be regarded as one of the most important milestones in the history of IUI.[20] Sunde et al.[21] reported the data of a European collaborative report on IUI describing 127 births in 20 clinics as a result of IUI with pretreated sperm. In 1989, the results of the first prospective controlled trials were published describing the value of IUI in case of cervical hostility and male factor infertility.[22,23] The evidence-based value of IUI as a treatment for cervical hostility, male factor, and unexplained infertility was first described in 2004.[24] Recent reports of Bensdorp et al.[25] and Tjon-Kon-Fat et al.[26] have shown that according to the results of a prospective multicenter trial, IUI–OS is recommended as the most cost-effective strategy for mild male factor or unexplained infertility with a poor prognosis of becoming pregnant with normal coitus. Insemination of semen in humans was originally developed to help heterosexual couples to become pregnant in case of severe male factor infertility of a physical or psychological nature; however, insemination with homologous semen nowadays is most commonly used for unexplained and mild male factor infertility. In the previous century, DI was mainly used for male infertility caused by azoospermia or very low-sperm count and for inherited genetic diseases linked to the Y chromosome. At present, DI is commonly used for individual women who desire a pregnancy.

Since IUI is a simple and noninvasive technique, it can be performed without expensive infrastructure resulting in IUI becoming the only treatment for male and unexplained infertility in resource-poor countries where IVF is either not available or not accessible for the majority of the population, owing to high costs.[27] In addition, it can be provided as a safe and simple treatment with minimal risks when appropriately monitored. These factors are responsible for high couple compliance in IUI programs when compared to IVF.[28]

It may be essential to mention that this chapter is based on comprehensive search using question-specific relevant search terms as per ESHRE draft recommendation (2018). For each PICO (population, intervention, comparison, and outcomes) drafted by WHO, specific search terms were used to find the available evidence in Medline (1950 to May, 2015) and the Cochrane Library (until May, 2015). The quality of the evidence was assessed using the GRADE system. The evidence and draft recommendation for each PICO question are summarized as follows. Women and men may have fertility problems that can only be resolved through medically assisted interventions. The WHO invited experts to help to develop and provide draft recommendations based upon the available evidence for six prioritized areas, including the fertility treatment IUI with or without OS. Prioritization of questions was accomplished and stakeholders considered global relevance that included the importance of cost-effectiveness, safety, and affordability. Thus, this chapter provides an overview of the process applied and the draft evidence-based recommendations generated.

What are the indications for IUI versus intercourse or expectant management in infertile couples and when should treatment be initiated?

- In couples with unexplained infertility with a prognosis of becoming pregnant without assistance within the next 12 months (estimate >30%), IUI could be postponed for at least 6 months.
- In couples with unexplained infertility and men with a total motile sperm count (TMSC) >10 million and a prognosis of spontaneous pregnancy <30% within a year, it is recommended that IUI plus OS is the treatment of first choice.
- In couples with solely a poor sperm quality (severe oligozoospermia, i.e., sperm count <5 million or asthenozoospermia, i.e., Grade III and Grade IV motility <36%, or teratozoospermia, i.e., normal sperm morphology <4% as per strict criteria) in the male partner, it is not recommended either for or against use of IUI.

When is OS required in an IUI cycle?

In couples with unexplained infertility and men with a TMSC above 10 million, IUI should be combined with OS to improve LBRs would be a moderate statement.

What is the influence of sperm quality on IUI outcome? Can we define threshold levels for successful IUI?

It is not possible to define clear lower cut-off levels of pre- or postwash sperm parameters below which IUI should be withheld. A very few evidence about lower cut-off values of sperm parameters is available.

When is the best timing of insemination in an IUI cycle? What is the optimal method of timing in natural or stimulated IUI cycles?

Timing of trigger or insemination, whether in natural or stimulated cycles, cannot be exactly determined, as there is no concrete evidence for or against any particular method.

If an hCG injection is used, single IUI can be performed any time between 24 and 40 hours after hCG injection without compromising pregnancy rates.

Intrauterine insemination in a natural (not ovarian stimulated) cycle should be performed 1 day after LH rise.

What is the value of "fallopian sperm perfusion" (FSP) compared to IUI?

It is highly recommended that the intervention FSP, when compared to IUI, should not be the treatment of choice.

What is optimal number of inseminations per cycle?

In both unexplained and male infertility, there is insufficient evidence that the intervention, a double IUI, within the same cycle will lead to better pregnancy rates than a single IUI within a cycle.

Women undergoing IUI should be offered a single insemination per cycle.

Is there a benefit of bed rest after IUI?

Women undergoing IUI should have 10–15 minutes of bed rest after an insemination.

What is the ultimate number of consecutive IUI cycles per couple/woman in which pregnancy rates still increase significantly?

In couples with an indication for IUI, at least three consecutive IUI cycles should be performed. There is insufficient evidence to recommend a maximum number of IUI treatment cycles. However, most of the clinics withdraw IUI procedures after six procedures of IUI.

Which semen preparation technique used yields the best results (in terms of pregnancy rates) for IUI?

According to the available evidence, it is not possible to recommend any semen preparation technique over another (swim-up, gradient, wash and centrifugation).

What is the cost-effectiveness of IUI versus IVF/intracytoplasmic sperm injection (ICSI)?

In couples with unexplained infertility and men with a TMSC of >10 million and a prognosis of a pregnancy without assistance <30% within a year, at least three cycles of IUI–OS are the most effective option.

How can you prevent infections in an IUI laboratory?

Good practice point: Couples and individuals undergoing IUI and males providing semen samples for IUI should be screened for infectious agents based on local, regional, and national standards and regulations.

How can you prevent multiple pregnancies and ovarian hyperstimulation syndrome in an IUI program?

In order to prevent high rates of multiple gestation pregnancies in IUI–OS, IUI should be withheld when more than two dominant follicles of >15 mm or more than five follicles of >10 mm at the time of hCG injection or LH surge are present. When gonadotropins are used in IUI, regimens with 75 IU or lower should be used because higher doses have similar pregnancy rates but increase multiple pregnancy rates (MPRs).

Clomiphene citrate or tamoxifen is acceptable alternative to low-dose gonadotropins for low multiple pregnancy and birth rates and with lesser costs, although at a lower LBR than with gonadotropins.

Addition of gonadotropin-releasing hormone (GnRH) agonist to gonadotropins in IUI–OS is not recommended because there is no increase in pregnancy rate despite increased MPRs and increased costs.

Good practice point: As an alternative to cycle cancelation, aspiration of excess follicles at the time of hCG injection or LH surge might be additional options for reducing the risk of multiple pregnancy in IUI–OS.

Is there a different perinatal outcome for IUI pregnancies and how does this perinatal outcome differ from normal coitus and IVF/ICSI pregnancies?

Individuals with infertility undergoing treatment with IUI–OS should be informed about a possible increased risk for preterm birth and low-birth weight in singletons and twin pregnancies when compared to pregnancies in fertile couples not requiring assistance (IVF/ICSI outcome comparisons are assessed in the IVF/ICSI prioritized guideline).

Indications for IUI

After 36 years of publication of the first randomized controlled trial (RCT) by Kerin et al. in 1984, the indications for IUI remain a subject of debate. Widely used indications for IUI are:

- Unexplained infertility (including mild endometriosis)
- Male factor infertility
- Female cervical factor

Patients prefer IUI, with or without OS, over expectant management when their chance of spontaneous conception is <50 or 40%, respectively, and they prefer IUI over IVF up to six treatment cycles.[29,30]

Unexplained infertility from RBMO, 2012.

Possible reasons for unexplained infertility: The current knowledge of the reproductive system assessment is far from complete. There are many steps which are not routinely evaluated or unavailable, including cervical mucus, capacitation, or the ability of spermatozoa to negotiate the uterotubal junction. There is also a need for a test for the

acrosome reaction and the ability to bind to and penetrate the zona pellucida. There is no infallible test which can provide fertilization profiles of spermatozoa. Similar limitations are also present in female fertility assessment. Defective oocytes, especially in aging patients, are an important cause of infertility which is difficult to assess. Tubal patency does not assess the characteristics of bidirectional tubal motility which is important for embryo transport. Tests for the evaluation of the chance for successful implantation are not available. Random delays in conception do not appear to account in a major way for unexplained infertility, whereas a nonrandom age effect is important. Therefore, the ideal definition for unexplained infertility should be a couple with a real but unobservable defect leading to infertility which may be prolonged and permanent.

Unexplained infertility and IUI: The diagnosis of unexplained infertility encompasses an important subset of couples seeking treatment for infertility. After evaluation of ovulatory function (baseline transvaginal ultrasonography/baseline hormone evaluation including serum AMH), tubal patency (HSG/sonosalpingography/diagnostic laparoscopy/hysteroscopy), and semen analysis (WHO, 2010; strict criteria which may include sperm function tests/DNA fragmentation index), no etiology is identified in 10–30% of couples seeking treatment for infertility.[31,32] Any treatment for unknown infertility is empiric by default, and the broad range of treatment, including expectant management, superovulation, and IVF, reflects the uncertainty with this diagnosis. However, there are limited data to support the efficacy of many of these treatments in the management of unexplained infertility, and no uniform protocol exists in clinical practice. One must take into account that, unexplained infertility is best characterized as 'subfertility'.[33] This nomenclature is significant, in that, some couples will conceive naturally without any fertility interventions. In one randomized trial of 253 patients with unexplained infertility, a 27% ongoing pregnancy rate was observed in the expectant management group.[8] Others observed a 13% spontaneous pregnancy rate in a group of patients awaiting IVF, although this cohort consisted of patients with unexplained subfertility of 2 years' duration or more and may represent a poorer prognostic subgroup.[34] Another cohort experienced only a 5.9% cumulative pregnancy rate over 12 months in an untreated group of patients awaiting IVF.[35] Despite this variability, it is evident that a proportion of couples will achieve pregnancy with no intervention.

Superovulation, which induces the development of more than one follicle per cycle, combined with either timed intercourse or IUI, is commonly used to treat unexplained infertility. The use of oral or injectable agents may increase the number of dominant follicles available for fertilization and correct subclinical ovulatory dysfunction.[36] Many argue that the addition of IUI ensures that sufficient numbers of sperm overcome any cervical barrier.[37] Disadvantages of treatment with gonadotropins and IUI include significant cost, ovarian hyperstimulation syndrome (OHSS), and higher rates of multiple pregnancies.[38] IVF has also been used to treat unexplained infertility. According to 2013 Society for Assisted Reproductive Technology data, LBRs per cycle of IVF ranged from 25 to 43% in patients with unexplained infertility aged <40 years.[39]

CC with timed intercourse versus expectant management: Bhattacharya et al.[37] in a high-graded quality trial of 580 patients (507 with unexplained infertility) found no benefit of therapy, with a 16% LBR with expectant management versus 13% after CC therapy. This trial randomized patients to one of three arms for a treatment period of 6 months:

1. Expectant management, consisting of no visits or interventions
2. CC at a starting dose of 50 mg on cycle days 2–6 with timed intercourse on cycle days 12–18 (initial cycle monitored with ultrasound and midluteal serum P, with subsequent cycles monitored only with midluteal progesterone)
3. IUI in the spontaneous cycle, with monitoring by urine LH kit starting on cycle day 12, with a single IUI performed at 20–30 hours after surge.

Patients in the study had a mean duration of infertility of 30 months and a mean age of 32 years. The median number of treatment cycles was five in the CC/timed intercourse group and four in the natural-cycle IUI group.

CC with IUI versus expectant management: Deaton et al.[40] examined CC with IUI in comparison with expectant management, and it found no significant difference. Of the 51 patients included in the data analysis of this trial, 24 patients had unexplained infertility, and 27 patients had endometriosis. This study had a crossover design whereby patients were randomized to either four treatment cycles or four control cycles and would then crossover to the other arm if pregnancy did not occur in the first four cycles. Mean age was 33 years, with a mean duration of infertility of 3.5 years. In the treatment cycles, patients received CC (50 mg) on cycle days 5–9 (or days 4–8 if the patient's average cycle length was <27 days), with hCG (10,000 IU) given when the lead follicle was 18 mm on ultrasound. IUI was performed 36 hours after hCG administration. In the control cycles, patients were instructed to have intercourse during the periovulatory period. The ongoing pregnancy rate in the treatment cycles (defined in this study as >20 weeks' gestation) was 10 of 46 (21%) and OPR in the control cycles was 5 of 40 (12%). Because of the crossover design of the study, some patients were counted twice in this analysis.

Gonadotropins with IUI versus expectant management: Steures et al.,[8] involving 253 patients, compared gonadotropins and IUI with expectant management, and it found no significant difference in ongoing pregnancy rate over the 6-month study period. In the treatment arm, patients received follicle-stimulating hormone (FSH) or human

menopausal gonadotropin (hMG) (average 75 IU, range 37–150 IU) starting on cycle day 3 until the lead follicle measured 16 mm, when hCG was administered at a dose of either 5,000 or 10,000 IU, with IUI performed 36–40 hours later. If there were three or more follicles of >16 mm or five follicles of >12 mm, hCG was withheld. Patients' mean age was 33 years, with a mean duration of 2 years of infertility and baseline mean FSH of 7.0 and 6.7 IU/L in the gonadotropin and expectant management groups, respectively. Of the 127 patients assigned to the treatment arm, there were 29 ongoing pregnancies (23%) and 26 live births. In the expectant management arm, there were 34 ongoing pregnancies (27%) among 126 patients and 30 live births. There was no significant difference in OPR in the treatment arm compared with expectant management.

CC with IUI versus letrozole with IUI: Two trials examined CC with IUI versus letrozole with IUI. In a trial of 214 patients, Fouda et al.[41] demonstrated an improved ongoing pregnancy rate with letrozole plus IUI (33%) compared with CC plus IUI (19%), which was statistically significant. Mean age of patients was 26 years, with a mean duration of infertility of 3.7 years in the letrozole group and 3.4 in the CC group (no statistical difference); mean baseline FSH was 5.7 and 5.5 IU/L, respectively. Patients underwent up to three cycles of treatment. The letrozole arm consisted of an extended letrozole regimen of 2.5 mg daily on cycle days 1–9, and in the CC group, patients received CC (100 mg) on cycle days 3–7. Ultrasound monitoring was performed, and IUI was done 36–40 hours after administration of hCG (10,000 IU).

In the Diamond trial,[42] 900 patients were randomized to one of three treatment arms: (1) letrozole (5 mg) on cycle days 3–7; (2) CC (100 mg) on cycle days 3–7, and (3) FSH (150 IU) starting on cycle day 3 through the day of hCG administration. Mean age of patients in this trial was 32 years, and mean duration of infertility was 35 months. The mean anti-Müllerian hormone level was the same (2.6 ng/mL) and baseline FSH was similar at 7.0, 7.2, and 6.9 mIU/mL, respectively.[43] The oral intervention arms included a combined 599 patients and demonstrated a higher LBR in the clomiphene group (23.3%) compared with the letrozole group (18.7%), although the result was not statistically significant. Rates for ongoing clinical pregnancy and multiple gestations were also not significantly different between these two interventions, although this study was powered for a comparison of the letrozole group with the combined gonadotropin and clomiphene groups, not for individual comparisons.[43,44]

Gonadotropins with IUI versus CC with IUI: Three trials compared gonadotropins with clomiphene. The Berker et al. trial[45] with 93 patients reported ongoing pregnancy rate in 11.6% patients in the clomiphene arm versus 18% patients in the gonadotropin arm, which was not a statistically significant difference.

In the Dankert et al. trial,[46] a total of 138 patients (68 with unexplained infertility) were randomized to CC/IUI or FSH/IUI for up to four cycles. Mean age of the study population was 31 years, with a mean duration of infertility of 33 months. This trial, such as the Berker et al. study, showed no difference in these treatments, with a LBR of 31.4% in the CC group and 30.3% in the FSH group. Of note, neither of these studies achieved statistical power. The Diamond et al. trial[44] also directly compared these two interventions, however, showed a statistically significant difference in LBR, with 32.2% in the gonadotropin group compared with 23.3% in the clomiphene group. The rate of multiple gestations was also higher in the gonadotropin group, with 10 triplets and 24 twins, versus 0 and 8, respectively, in the CC group. One patient in the gonadotropin group developed OHSS, compared with none in the CC group.

Gonadotropins with IUI versus letrozole with IUI: Three trials assessed the efficacy of gonadotropins with IUI versus letrozole with IUI. Baysoy et al.[47] in a study involving 80 patients, reported that the efficacy of IUI using letrozole (5 mg daily from day 3 to day 7) was comparable with that using gonadotropins (75–150 IU per day). The primary outcome was clinical pregnancy rate, which was 18.4% for letrozole and 15.7% for gonadotropins. One triplet gestation occurred in the letrozole group, and a twin gestation in the gonadotropin group. One case of moderate OHSS occurred in the gonadotropin group. Gregoriou et al.[48] study (with 50 patients) similarly found no significant difference in the efficacy of letrozole (5 mg/day 3–7) after three cycles of CC/IUI failure versus gonadotropins (r-FSH 150 IU daily), with respect either to clinical pregnancy rate per cycle (the primary outcome) or LBR per couple. LBR in the gonadotropin group was 28%, compared with 20% in the letrozole group, which did not reach statistical significance, and there were no multiple gestations in either group. In contrast to the Baysoy and Gregoriou studies, the Diamond trial[44] showed a significantly higher LBR in the gonadotropin group (32.2%) compared with the letrozole group (18.7%). The letrozole group had nine twin pregnancies and no higher-order multiples, compared with 24 and 10, respectively, in the gonadotropin group.

These were the available evidence from clinical trials for the relative efficacy of various treatments for unexplained infertility with respect to the outcomes of clinical or ongoing pregnancy rate or LBR per couple.

Although there is considerable clinical heterogeneity among the studies mentioned above; the following significant findings are demonstrated:

- Clomiphene citrate with timed intercourse was more effective than expectant management in an older study,[33] although a larger, relatively more recent trial found no benefit.[37]

- When expectant management was compared either with CC with IUI[13] or with gonadotropins with IUI,[40] it was as effective as either intervention.
- Applicability of the Steures gonadotropin IUI trial[8] to clinical practice is limited, given its clear potential for underestimation of pregnancy due to a high cycle cancellation rate (14.9%), in addition to underestimation of multiple gestation rates due to the incidence of monofollicular recruitment (58%).
- When CC and letrozole (both with IUI) were compared, letrozole with IUI was superior in one study;[41] the larger, more recent Diamond trial[44] showed a higher ongoing pregnancy rate and LBR with CC, although the difference was not statistically significant. Two studies that examined letrozole with IUI versus gonadotropins with IUI showed these interventions to be equally effective,[47,48] as did two other studies that examined clomiphene with IUI versus gonadotropins.[45,46] However, Diamond trial demonstrated that gonadotropins were significantly more effective than either letrozole or clomiphene, despite a higher cycle cancellation rate of 6.9% versus 3.7% and 3.3%, respectively.
- Natural-cycle IUI was comparable to expectant management in Bhattacharya et al. study.[37] However, in the Goverde trial,[49] the per cycle pregnancy rate was higher for IVF than for IUI using gonadotropins.
- Additionally, an accelerated approach involving CC plus IUI followed by IVF seems to shorten the median time to pregnancy when compared with a conventional stepwise method of CC plus IUI, gonadotropins plus IUI, then IVF.[50]
- Any discussion of unexplained infertility must bear in mind that many of the reports contain treatment-independent pregnancies, highlighting the fact that "subfertility" is a better descriptor for this patient population.

Many of these individual studies had small sample sizes and lacked the statistical power to detect significant differences between interventions.

Conclusion: On the basis of the currently available literature—

- Expectant management may be comparable to treatment with CC and timed intercourse or IUI in patients with unexplained infertility.
- For patients who undergo superovulation with oral agents, clomiphene may be more effective than letrozole.
- Treatment with gonadotropins seems to be more effective than either oral agent, although its attendant risk of multiple gestations is an obvious disadvantage that should limit utilization.
- Despite its cost and widespread utilization, IVF was no more effective than gonadotropins with IUI but may accelerate the time to clinical pregnancy.
- Well-designed prospective trials with adequate sample size are needed to directly compare superovulation with oral agents and gonadotropins, as well as the role of IUI and IVF, with careful assessment of the risk and benefit profiles. Until such data are available, clinicians should individualize the management of unexplained infertility for each patient with appropriate counseling regarding the empiric nature of their treatment.

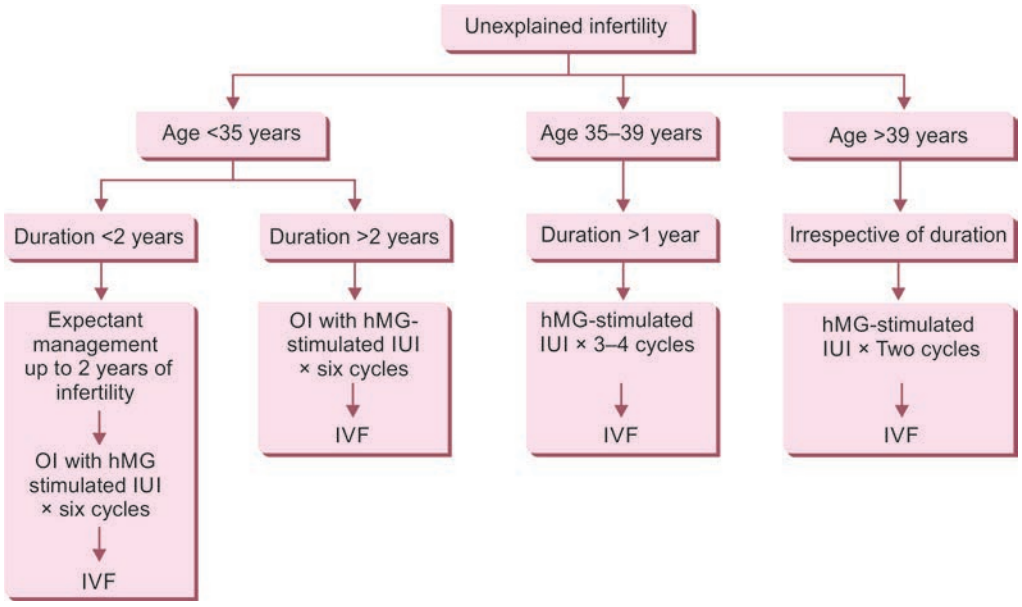
Male infertility and IUI: Intrauterine insemination for male infertility is still under debate. One of the major problems in male subfertility is the lack of validated definitions and strict cut-off values of sperm parameters to make a clear distinction between mild, moderate, and severe male infertility. A Cochrane systematic review by Bensdorp et al.[7] analyzed IUI (with or without OS) in patients with male infertility with various definitions of male infertility. The authors of this review concluded that there was insufficient evidence to recommend for or against IUI (with or without OS) in male infertility, mainly because large high-quality randomized trials are lacking. A recently published large RCT showed us that IUI–OS is noninferior to IVF in couples with unexplained and mild male infertility, defined as a TMSC of 3–10 million. However, the number of included couples in this study with mild male infertility was relatively low (only 10% of total inclusions).[25] Therefore, it is not possible to recommend for or against IUI in couples with solely poor sperm quality.

Over the past decades, the reported percentage of morphologically normal spermatozoa has decreased with the introduction of stricter criteria and the tendency toward lower reference values.[51] This is a disturbing factor in the use of sperm morphology as a prognostic factor for the probability of achieving a pregnancy. However, later, it was concluded that sperm morphology has no prognostic value in individual IVF and ICSI patients.[52]

However, it can be hypothesized that the role of sperm factors in IUI is different from their role in IVF and ICSI. Literature reviews reveal an ongoing debate on the value of sperm parameters as predictors of IUI outcome.[53-55] More specifically, conflicting results have been reported for the influence of sperm morphology assessment using strict criteria on pregnancy outcomes with IUI.[56-65] But these studies are characterized by a lack of standardization.

Besides sperm morphology, there is disagreement about the predictive value of the total progressively motile sperm count (TPMSC) to predict IUI outcomes.[55] In their review, Ombelet et al.[53] stated that the TPMSC has a substantial discriminative value. Others, however, have concluded that the TPMSC has poor sensitivity for selecting the couples most likely to conceive with IUI, but high specificity for identifying the couples unlikely to conceive with IUI.[55,66,67] The required number of inseminated progressively motile spermatozoa (NIPMS) is under discussion as well, although

Flowchart 1: Suggested unexplained infertility management protocol.



(hMG: human menopausal gonadotropin; IUI: intrauterine insemination; IVF: in vitro fertilization; OI: ovulation induction)
Courtesy: https://obgyn.onlinelibrary.wiley.com/doi/abs/10.1111/tog.12253

in general, a minimum of 5 million spermatozoa are stated as accurate.[51] This study reveals that couples with a lower percentage of morphologically normal spermatozoa (i.e., ≤4%) and a moderate NIPMS (i.e., 5–10 million) had the highest probability of becoming pregnant in the first finished IUI episode. In couples with a NIPMS of ≤1 million, this probability was lower. The TPMSC had no predictive value in this perspective.

In general, the predictive power of the semen parameters was limited, and it seems that especially female factors were critical for predicting the probability of becoming pregnant in individual couples.

Consequently, it is likely that the presence of female factors affects the relation between semen parameters and pregnancy outcome. When female factors are excluded, however, the probability of becoming pregnant based on semen parameters does not change in the opposite direction. Instead, the probability to become pregnant even increased in couples with ≤4% morphologically normal spermatozoa [OR: 1.58; 95% confidence interval (CI): 1.13–2.22]. These apparently contradictory results raise the question of whether sperm morphology is an adequate predictor for the outcome of IUI. This view is supported by many others.[61,65,68]

Note that it is also possible that the current WHO classification system may be inadequate (i.e., too strict criteria) but sperm morphology itself still could be an important parameter. It might be useful to consider the development of a new classification system. Another striking result is that the TPMSC showed no prognostic value to predict the probability of becoming pregnant in couples with IUI treatment. Other studies have shown that TPMSC is of great value when choosing between IUI and IVF or ICSI,[49,66,69,70] and TPMSC has been described as a relatively good indicator for male factor infertility in general.[70]

In contrast to TPMSC, NIPMS was relevant in predicting the ongoing pregnancy rate after IUI. This is in agreement with the literature.[51,53,55,59] Finally, the ongoing pregnancy rate in couples undergoing IUI was negatively influenced by a higher (>4%) percentage of morphologically normal spermatozoa, NIPMS of ≤1 million, higher female age, higher male age, and higher number of cycles within the episode. For most prediction models in reproductive medicine, the discriminatory performance is low to moderate.

Many factors of influence are taken into account. Along with the methodologically stable period with respect to semen analysis and adequate statistics, the influences of ejaculatory abstinence, type of ovulation induction, and the time interval between the fertility workup and IUI on the probability of becoming pregnant were checked. No effects were found. Still, it would be valuable to set up a prospective, multicenter study with clear inclusion of couples, sound statistics, and standardized and controlled protocols for semen analysis, semen preparation, fertility workup, and the IUI procedure in general. This will provide an opportunity to develop a better prognostic model. Accurate study design also would be helpful for reconsidering the accuracy of the percentage of morphologically normal spermatozoa as factor for sperm quality assessment.

The evidence based draft recommends that expectant management be attempted for at least 6 months in heterosexual couples with unexplained infertility and a prognosis of becoming pregnant without assistance within the next

12 months >30% prognosis. When this is <30%, IUI with OS is recommended in couples with unexplained infertility and men with a TMSC > 10 million as the first treatment option. The quality of the evidence found was graded as moderate to high.

In summary, with the lack of high-quality randomized trials investigating the effectiveness of IUI in male infertility, the question whether IUI should be applied in male infertility remains. Furthermore, a clear and generally accepted definition of mild, moderate, or severe male infertility terms often used in IUI studies is missing.

Cervical factor infertility and IUI: A Cochrane systematic review by Helmerhorst et al.[71] concluded that IUI with or without OS is not an effective treatment of cervical factor infertility. Although more recent studies were published on this subject, most clinicians no longer support performing postcoital testing as part of a fertility checkup. Therefore, cervical factor is less often diagnosed; however, it is recognized that good practice indicates that for heterosexual couples where the male partner refuses semen analysis (e.g., for personal or cultural reasons), the postcoital test can be used to suggest that further evaluation of male factor infertility is indicated (evidence-based consensus to support this draft recommendation is reviewed by the WHO evidence synthesis team which addressed female infertility diagnosis and management).

When is OS required in an IUI cycle?

- In couples with unexplained infertility with a prognosis of becoming pregnant without assistance within the next 12 months (estimate >30%), IUI could be postponed for at least 6 months. In couples with unexplained infertility and men with a TMSC above 10 million, IUI should be combined with OS to improve LBRs.
- In couples with unexplained infertility and men with a TMSC > 10 million and a prognosis of spontaneous pregnancy <30% within a year, it is recommended that IUI plus OS are the treatments of first choice.

The rationale of OS is to achieve multifollicular growth. van Rumste et al.[72] showed that multifollicular growth resulted in significantly higher pregnancy rates compared to monofollicular growth (15 versus 8.4%). Compared to one dominant follicle, pregnancy rates increased by a further 5, 8, and 8% when two, three, or four dominant follicles were present, respectively.[72] Cohlen et al.[73] conducted an RCT comparing IUI with or without OS in male infertility. In couples with a TMSC <10 million, OS did not improve pregnancy outcome, while it did in couples with a TMSC >10 million.

For unexplained infertility, the Cochrane systematic review of Veltman-Verhulst et al.[74] showed that IUI without OS does not positively influence pregnancy outcomes. Adding OS to IUI significantly increases LBRs in couples with unexplained infertility (OR: 2.07, 95% CI: 1.22–3.50, n = 396). However, when there is still a reasonable chance of becoming pregnant through normal intercourse with prognosis >30%,[75,76] expectant management for at least 6 months should be the first option because in these good prognosis couples, IUI in cycles with OS does not improve LBRs significantly [relative risk (RR): 0.85, 95% CI: 0.63–1.1, n = 253].[74] Furthermore, OS is well-known risks factor for (high order) multiple pregnancy as described above.

It is, therefore, recommended that expectant management can be attempted for at least 6 months in heterosexual couples with unexplained infertility and a prognosis of becoming pregnant without assistance within the next 12 months and prognosis >30%. When this prognosis is <30%, IUI with OS is recommended in couples with unexplained infertility and men with a TMSC > 10 million as the first treatment option.

Now that, it has become clear that IUI–OS is a first-line treatment option for mild male and unexplained infertility, the question arises whether IUI, with or without OS, is beneficial for moderate male infertility as well. Furthermore, as mentioned above, a clear definition of mild or moderate male infertility is mandatory.

What is the influence of sperm quality on IUI outcome? Can we define threshold levels for successful IUI?

It is not possible to define clear lower cut-off levels of pre- or postwash sperm parameters below which IUI should be withheld.

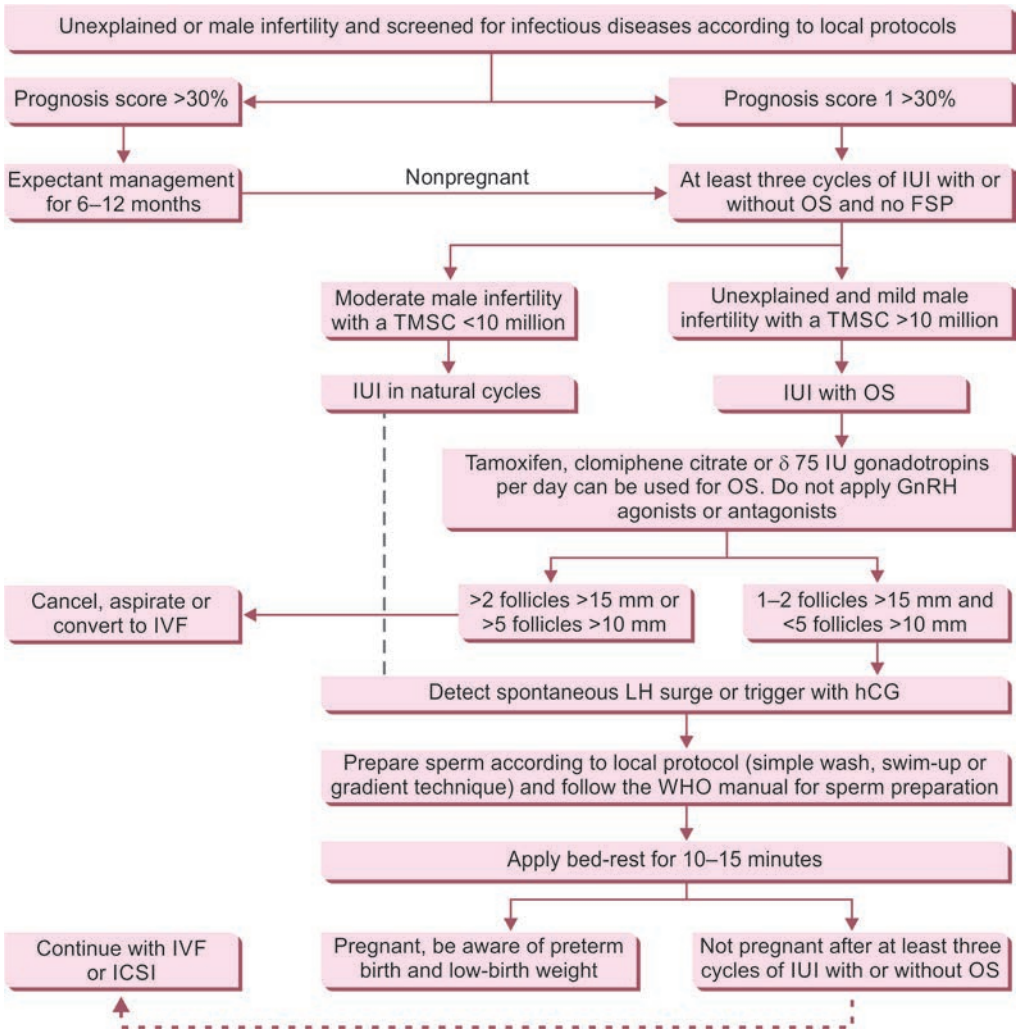
A recent systematic review and meta-analysis clearly presents the lack of robust evidence for clear lower cut-off levels of sperm parameters in IUI treatment. Based on very low quality evidence, it is recommended that IUI should be withheld below a TMSC count of 1 million and morphology <4%.[53] Van Weert et al.[55] found the postwash TMSC to be predictive for nonpregnancy but the lower cut-off levels varied tremendously between 0.8 and 5 million. So it cannot define clear lower cut-off levels of pre or postwash sperm parameters below which IUI should be withheld.

Because the lower cut-off level of semen parameters below which IUI is no longer cost-efficient has not been clearly identified, a randomized trial comparing IUI with either conventional IVF or IVF/ICSI to define these lower cut-off levels is required before any conclusion can be drawn.

When is the best timing of insemination in an IUI cycle? What is the optimal method of timing in natural or stimulated IUI cycles?

- Providers can determine the method of triggering in IUI stimulated with gonadotropins as there is no evidence to recommend for or against a method.
- Providers can determine the method of timing IUI in natural cycles (no OS) as there is no evidence to recommend for or against a method.

Flowchart 2: IUI with or without ovarian stimulation.



(GnRH: gonadotropin-releasing hormone; FSP: fallopian sperm perfusion; IUI: intrauterine insemination; ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization; LH: luteinizing hormone; TMSC: total motile sperm count)

- If an hCG injection is used, single IUI can be performed any time between 24 and 40 hours after hCG injection without compromising pregnancy rates.
- IUI in a natural (not ovarian stimulated) cycle should be performed 1 day after LH rise.

Age, indications of IUI, sperm preparation, and insemination methods are several important factors affecting the outcome of controlled ovarian hyperstimulation–IUI.[77-80] However, the timing of administration of IUI seems to be the most critical factor among them. It should be noted that medical regimens vary between centers and also between clinicians. Hence, the correct timing of insemination to improve pregnancy has been the subject of recent debate.

Huang et al.[81] compared 210 IUIs performed at 24 hours and 36 hours with different diagnostic and etiological categories including endometriosis, ovulation dysfunction, and unexplained infertility. The patients were divided into three subgroups who received FSH, hMG, and CC/hMG. Spermiogram parameters were all normal. Additionally, no significant difference in pregnancy outcomes was found between the two groups. Wang et al.[82] demonstrated the effects of different timings (24 hours and 36 hours) of IUI after hCG injection in the subgroups of patients who received CC, CC plus gonadotropin, and gonadotropin alone. The pregnancy rates were found to be similar between two groups. Similarly, Osuna et al.[83] performed a systematic review of the literature and they concluded that no significant differences were observed when two inseminations per cycle were performed, compared with one insemination. They also found great heterogeneity concerning ovarian management and insemination timing. The same group detected an improved pregnancy rate with two inseminations compared with one insemination when CC with or without gonadotropins and 5,000 IU of hCG were used. In another study, Ragni et al.[84] detected significant increases in pregnancy rates when the IUI procedure was performed during the preovulatory and periovulatory periods, but not the postovulatory period. According to another study, Kucuk[85] suggested that IUI

should be withheld until follicular rupture is detected. He also claimed that monitoring of follicular rupture prior to IUI provides a pregnancy rate similar to natural fecundity.

In a Cochrane meta-analysis evaluating the effectiveness of different synchronization methods in natural and stimulated cycles for IUI in subfertile couples, the authors concluded that insufficient evidence exists to determine whether there is any difference in safety and effectiveness between different methods of synchronization of ovulation and insemination among subfertile patients.[86]

In our study, we compared the clinical pregnancy rates of patients with polycystic ovarian syndrome (PCOS) and unexplained infertility according to the timing of single IUI procedures. To homogenize the study groups, we excluded other possible causes of infertility. Clinical pregnancy rates per cycle were 22.9% in the PCOS group and 26.9% in the unexplained group. However, IUI procedures performed 24 hours following hCG trigger day were found to be related to better cycle outcomes among patients with unexplained infertility, unlike PCOS patients. This result can be related to the sperm capacitating process within the woman's genital tract. Intercourse performed before ovulation has been related to an increase in the fertilization potential and pregnancy establishment.

Primarily, the leading defect in pregnancy establishment for patients with unexplained infertility is fertilization defects.[77] This statement explains the importance of IUI procedure timing and the technique used for this group of patients who regularly menstruate and ovulate preceding the ovulation induction treatment cycle. Spermatozoa and oocytes have only a limited survival time (around 72 hours and 24 hours, respectively); therefore, correct timing of insemination is essential. Delaying the IUI procedure in couples with unexplained infertility theoretically decreases the fertilization potential of the inseminated sperm due to the short viability time of the oocyte. Also, in a prospective randomized controlled study, Blockeel et al.[87] demonstrated that significantly higher clinical pregnancy rates per IUI cycle were observed in patients undergoing IUI 1 day after the LH rise, when compared with patients undergoing IUI 2 days after the LH rise in natural cycles. This proves the clinical importance of IUI timing on pregnancy rates among subfertile patients.[87] The main problem for PCOS patients is anovulation. Accordingly, for PCOS patients, IUI timing is not as important as for patients with unexplained infertility. A significant relationship between the hCG trigger day of cycle and clinical pregnancy establishment was observed. This result can be a reflection of higher quality of oocytes in the later hCG/day trigger cycles than in earlier hCG day trigger cycles. Perhaps, clinicians trigger the preovulatory follicles earlier than physiologically needed, which decreases the fertility potential of an originally competent oocyte. In a study,[88] it was also found a significant relationship between hCG day endometrial thickness and clinical pregnancy establishment, which is consistent with the previous literature.

In conclusion, IUI performed at either 24 hours or 36 hours after ovulation triggered by hCG injection does not change the clinical pregnancy rates for PCOS patients. Contrarily, patients with unexplained infertility seem to benefit from earlier IUI procedures, which increase their fertility potential during ovulation induction with gonadotropins. However, avoiding artificial hCG triggering before IUI procedures earlier than physiologically needed results in improved pregnancy rates. Utilization of clinical interventions such as IUI during the treatment of infertile women necessitates rational applications, which increases the clinical usefulness of the procedure. Ultimately, large multicenter trials with increased patient numbers are necessary to elucidate the optimal timing of insemination among different infertile patient groups.

What is the value of fallopian sperm perfusion compared to IUI?

It is recommended that the intervention fallopian sperm perfusion (FSP), when compared to IUI, should not be the treatment of choice.

With regard to FSP, a technique that ensures the presence of higher sperm densities in the fallopian tubes at the time of ovulation, the recommendation of this PICO is clear. Based on a recent Cochrane systematic review,[89] without any more recent papers identified, the review was not able to show a beneficial effect of FSP on LBRs per couple compared to IUI (OR: 0.94, 95% CI: 0.59–1.49), therefore, IUI is the treatment of choice and the quality of this evidence was graded as high.

What is the optimal number of inseminations per cycle?

- In both unexplained and male infertility, there is insufficient evidence that the intervention, a double IUI, within the same cycle will lead to better pregnancy rates than a single IUI within a cycle.
- Women undergoing IUI should be offered a single insemination per cycle.

An assumption can be made that increasing the number of inseminations per cycle from one to two (or more) might increase the probability of a pregnancy in IUI treatment since more spermatozoa may be present at the moment of ovulation. One Cochrane systematic review and two additional relevant systematic reviews were identified after a systematic search. One additional RCT not included in one of these systematic reviews was also identified. The Cochrane systematic review[90] found a significant difference in favor of double insemination (OR: 1.8, CI 95%: 1.4–2.4) in heterosexual couples with unexplained or male infertility. This observed effect is largely due to the contribution of one study with a weight of 66.5%; however, this study yielded an unclear risk of bias because allocation concealment was not

mentioned. Another systematic review[91] compared single versus double insemination in male infertility. This review showed a significant benefit of double IUI in male infertility but, again, this effect was largely due to the same dominant study.

A third systematic review[92] analyzed double versus single insemination in unexplained infertility. This meta-analysis showed that double IUI does not result in significantly higher pregnancy rates compared with single IUI in women with unexplained infertility. This was confirmed by a more recent RCT by Rahman et al.[93] The overall quality of evidence from systematic reviews was graded as moderate, mainly because of the dominating effect of one study, which did not clearly described allocation concealment.

Based upon our review, it can be concluded that there is insufficient evidence for a beneficial effect of double insemination in couples with unexplained infertility. Yet, in the case of male infertility, there might be a positive effect. However, this was only proven by one study with an unclear risk of bias. We, therefore, provide a draft recommendation that women undergoing IUI should be offered a single insemination per cycle.

The number of inseminations per cycle is not well defined. Future large prospective cohort studies or randomized trials for each indication separately might help clinicians to advise couples or individuals about the number of inseminations per cycle.

Is there a benefit of bed rest after IUI?

Women undergoing IUI should have 10–15 minutes of bed rest after an insemination. Studies on the intrauterine behavior of spermatozoa have shown that spermatozoa already reach the fallopian tubes within 5–10 minutes after insemination.[94] After vaginal intercourse, a large percentage of the semen is lost by "flowback" and no >1% of the spermatozoa are retained in the female reproductive tract. Thus, an assumed hypothesis is that immobilization in supine position after IUI could prevent direct loss of a large percentage of the spermatozoa and this action will improve fertility outcomes.

A systematic search resulted in the identification of two relevant articles[95] randomized 95 heterosexual couples to either direct mobilization after IUI or immobilization in supine position for 10 minutes. Groups were rather unbalanced with 40 couples in the mobilization group and 55 couples in the immobilization group. After three cycles, pregnancy rates per couple were significantly higher in the immobilization group. No information on LBRs was reported.[95] Custers et al.[96] performed a well-designed RCT in 391 heterosexual couples. They randomized between immobilization in a supine position for 15 minutes (n = 199) or immediate mobilization (n = 192) after IUI. LBRs after three cycles were significantly higher in the immobilization group: 27 versus 17%, respectively (RR = 1.6, 95% CI: 1.1–2.4).

Recently, results of a large RCT comparing immobilization for 15 minutes versus direct mobilization were published. In total, 498 patients with either unexplained or mild male infertility were included. No significant difference in cumulative ongoing pregnancy rate was found (RR = 0.81, 95% CI: 0.63–1.02).[97] Pooling the data of the last two studies mentioned here showed a nonsignificant difference between mobilization and immobilization (OR = 1.00, 95% CI: 0.74–1.33). However, a substantial statistical heterogeneity (I2 = 88%) was found. Conclusions should, therefore, be drawn with caution.

The data of van Rijswijk et al.[97] demonstrated that immobilization for 10–15 minutes after IUI has been determined to be an evidence-based draft recommendation.

What is the ultimate number of consecutive IUI cycles per couple/woman in which pregnancy rates still increase significantly?

- In couples with an indication for IUI, at least three consecutive IUI cycles should be performed.
- There is insufficient evidence to recommend a maximum number of IUI treatment cycles.

Three to six cycles of IUI have become common practice worldwide and the INeS trial from Bensdorp et al.[25] showed us that six cycles of IUI–OS are still cost-effective compared to direct IVF in patients with unexplained and mild male infertility.[25] But is there evidence to perform more cycles? Custers et al.[96] performed a retrospective cohort study among 3,714 women that had undergone 15,303 treatment cycles. Analysis was limited up to the ninth treatment cycle (15,245 cycles). There were 935 ongoing pregnancies, resulting in a mean ongoing pregnancy rate of 5.6% per cycle. The ongoing pregnancy rates were relatively high in the first two cycles, with 7.4 and 7.0%, respectively, compared with ~5% in higher order cycles. The cumulative clinical pregnancy rate after three cycles was 18%, which increases to 30 and 41% after six and nine cycles, respectively.[96] Aboulghar et al.[98] conducted an observational prospective study in 594 women with unexplained infertility. All participants had one to three cycles of treatment and 91 participants underwent four to six cycles of IUI–OS after failing to achieve pregnancy in the first three cycles. The clinical pregnancy rate per cycle was significantly higher in the first three cycles compared to the second three cycles ($p < 0.001$).[98] The overall quality of the evidence was graded as low to moderate mainly because of the retrospective and observational design of the studies. Based on this moderate quality evidence, a draft recommendation was developed to perform at least three cycles of IUI. There is insufficient evidence to recommend a maximum number of IUI treatment cycles.

The number of IUI cycles that couples or single woman should be offered is not well defined. Future large prospective cohort studies or randomized trials for

each indication might help clinicians to advise couples or individuals when to switch to IVF.

Which semen preparation technique used yields the best results (in terms of pregnancy rates) for IUI?

- According to the available evidence, it is not possible to recommend any semen preparation technique over another (swim-up, gradient, wash, and centrifugation).

Currently, there are three semen preparation techniques that are routinely used worldwide: a simple dilution and washing technique, a swim-up technique, and use of density gradient centrifugation.

Whether one of these techniques is preferable was the subject of a Cochrane systematic review.[99] The Cochrane systematic review analyzed five RCTs comparing two or three techniques with each other. Concerns regarding heterogeneity might be suspected since they vary widely over the five studies or were not described clearly. The review found no significant difference in pregnancy rates among semen preparation techniques: swim-up versus gradient technique (OR = 1.57, 95% CI: 0.74–3.32), swim-up versus wash and centrifugation (OR = 0.41, 95% CI: 0.41–1.10), or gradient technique versus wash and centrifugation (OR = 1.76, 95% CI: 0.71–5.44).

Karamahmutoglu et al.[100] randomized 223 couples with unexplained and mild male infertility to either the swim-up technique or the gradient technique. They found a significantly higher ongoing pregnancy rate per patient after the gradient technique compared to swim-up: 23.4 versus 10.7%, respectively ($p < 0.05$). A subgroup analysis revealed that this difference was significant only in couples with unexplained infertility.[100] The overall quality was graded as low across all studies because of the suspected clinical heterogeneity, unclear descriptions of randomization and allocation in almost all included studies, and a low number of couples in the relevant comparisons. Therefore, according to review of evidence supporting IUI recommendations, it was not possible to recommend any semen preparation technique over another (swim-up, gradient, wash, and centrifugation).

It remains unclear that which semen preparation technique is superior (expressed as LBR per couple) in case of either unexplained or male infertility; therefore, a multicenter randomized trial comparing various techniques is recommended.

What is the cost-effectiveness of IUI versus IVF/ICSI?

- In couples with unexplained infertility and men with a TMSC of >10 million and a prognosis of a pregnancy without assistance <30% within a year, at least three cycles of IUI–OS are the most effective option.

The goal of research on cost-effectiveness is to maximize health outcomes with a minimum use of resources. As costs linked to fertility care in many countries are not covered by government or insurance companies, the relative cost-effectiveness of fertility treatments is a very important consideration.[101] Healthcare systems can become burdened by high costs associated with premature infants who are born from multiple gestations as a result from unregulated fertility treatments.[102] Therefore, cost-effectiveness studies in fertility are important not only to the individual and family but also to healthcare systems and society.

Large randomized trials evaluating the relative cost-effectiveness of different infertility treatments are scarce. Moreover, the outcome most often reported is the cost per delivery of at least one child and this outcome parameter does not include the substantial costs of caring for premature infants owing to the high rates of multiple gestations. On the other hand, there is the potential to consider twins as perhaps eliminating the need for future fertility treatments for some couples or individuals. However, this comes with a clear understanding of the maternal and perinatal morbidity and mortality outcomes of twin pregnancies in a local context. All of these factors have to be considered when studying the cost-effectiveness of IUI and IUI–OS.

Many retrospective cohort cost-effectiveness studies have compared IUI, IUI–OS, and conventional IVF in couples and individuals with differing causes of infertility. Most large cohort or randomized studies from individual centers have found IUI alone or IUI–OS to be the most cost-effective first-line therapy for heterosexual couples with infertility linked to cervical factor, endometriosis, unexplained infertility, and relatively mild male factor infertility,[103-105] but the retrospective designs make it difficult to draw firm conclusions.

For male factor infertility, several studies have been identified that support the concept of threshold values for sperm parameters below which IUI becomes significantly less effective.[53,69] Moolenaar et al.[69] studied the cost-effectiveness of interventions for male infertility according to the TMSC. A computer-simulated cohort of infertile women with a partner with a prewash TMSC of 0–10 million was investigated. They compared IUI with and without OS, conventional IVF, and IVF/ICSI. LBR was the main outcome parameter. Study results showed that above a prewash TMSC of 3 million, IUI is less costly than conventional IVF, and below a prewash TMSC of 3 million, IVF/ICSI is less costly. However, these findings need to be confirmed in a large randomized trial.

Contradictory results are published concerning the cost-effectiveness of IUI in heterosexual couples with unexplained infertility.[36,49,104-106] A multicenter RCT from Scotland (graded as high-quality evidence) compared the outcomes of 6 months of natural cycle IUI, CC stimulation followed by normal intercourse, and expectant management in couples with 2 years of unexplained infertility.[37] LBRs were not significantly different with 32/193 (17%) for expectant management,

26/192 (14%) for CC intercourse, and 43/191 (23%) for natural cycle–IUI. The authors recommended that IUI–OS should be the subject of future trials for unexplained infertility.

Most of the large retrospective cohort studies on cost-effectiveness tend to become "dated" as both costs and outcomes change over time. It is well known that IVF clinical pregnancy rates have increased steadily over time and high-order multiple births have declined, as there has been increased emphasis on the value of transferring less embryos. These changes have made conventional IVF a more attractive option from a cost-effective point of view when compared to IUI or IUI–OS. van Rumste et al.[72] stated in an economic analysis comparing IVF with elective transfer of a single embryo (eSET) with IUI–OS that when IVF–eSET would result in an ongoing pregnancy rate of >38%, IVF would be the preferred treatment.[72]

Only a few prospective randomized trials have compared natural cycle IUI, IUI–OS, and conventional IVF. In couples with male factor and unexplained infertility, Goverde et al.[49] compared three treatment arms—IUI alone, hMG–IUI, and conventional IVF, each performed for up to six cycles. The costs in this study were calculated through 12 weeks of pregnancy and neglecting the high costs associated with multiple gestations. According to this study, IUI was as effective as IVF, and IUI–OS did not yield higher pregnancy rates when compared with natural cycle IUI. They conclude that IUI was the most cost-effective first-line therapy for the infertile heterosexual couples. Furthermore, IUI was better tolerated by couples while IVF was associated with a higher dropout rate.[49] A big criticism against this study was an extremely low IVF pregnancy rate of 12.2% per cycle, a value that is clearly outdated. Even after careful monitoring and using low doses of FSH (75 IU/day), the MPR was 27% in the IUI–OS arm demonstrating the risky nature of this treatment.

In the prospective randomized Fast Track and Standard Treatment (FASTT) trial, graded as high quality, Reindollar et al.[50] addressed the important issue of time to pregnancy, both to alleviate the suffering and disappointment of infertile couples and to avoid the negative effects of aging on their reproductive potential. Only women between the ages of 21 and 39 years with unexplained infertility and a normal ovarian reserve were included in the study. Cost-effectiveness was calculated by summing all insurance charges divided by the number of women having at least one live birth. Out-of-pocket expenses (indirect costs) to the patient and the cost of multiple gestations as well as their associated increased hospital perinatal costs were included in the analysis. They concluded that CC–IUI seems to be the best first-line therapy for couples with unexplained infertility and, if not pregnant after three cycles, moving directly to conventional IVF was the most cost-effective approach.[50]

As mentioned before, in a recent multicenter randomized noninferiority trial in the Netherlands, the effectiveness of IVF with SET or IVF in a MNC was compared with the effectiveness of IUI–OS, with an outcome indicator of a healthy live birth.[25] The data of this trial showed that IUI–OS was noninferior as the two alternative strategies of IVF had a reasonably low multiple birth rate and was a more cost-effective strategy for heterosexual couples with mild male factor or unexplained infertility with a poor prognosis of becoming pregnant with expectant management. In another cost-effectiveness study on the same cohort of participants and investigating direct healthcare costs, it was concluded that both IVF strategies were significantly more expensive when compared with IUI–OS, without being significantly more effective.[26] Therefore, based on high-quality evidence, IUI–OS is recommended as the initial treatment for mild male factor and unexplained infertility with a poor prognosis of becoming pregnant through normal coitus. As mentioned before, there are no strict criteria for how to define mild male factor. Bensdorp et al.[25] used a TMSC of between 3 and 10 million although Cohlen et al.[73] showed that OS was only effective in couples with a TMSC above 10 million, which they defined as mild male infertility.

A significant increase in pregnancy rates has been observed with IVF and IVF/ICSI during the last decade; however, similar increases have not been reported with IUI treatments. If the singleton delivery rate per cycle can be improved, IVF or IVF/ICSI may become the favored first-line treatment for most causes of infertility.[72] On the other hand, it might be that a better selection of patients for IUI treatment and further improvement of the methodology of IUI may increase the success rates of IUI as well, and, hopefully not at the expense of increased multiple pregnancies. At present, the balance of all randomized trials still favors starting with a more conservative treatment regimen of IUI–OS before moving to IVF for the treatment of heterosexual couples with unexplained and mild male infertility.

Clear definitions of mild or moderate male infertility should be established before randomized trials can be started to define lower threshold levels of sperm parameters below which IUI with or without OS is no longer cost-effective and IVF or IVF/ICSI should be the first-line treatment option.

How can you prevent infections in an IUI laboratory?

- *Good practice point:* Couples and individuals undergoing IUI and males providing semen samples for IUI should be screened for infectious agents based on local, regional, and national standards and regulations.

In this era of semen preparation, infection is a lesser problem especially when managed in higher income settings. In some lower- and middle-income countries and settings, prevention of infections remains a critical issue. It is generally recommended that couples and individuals undergoing IUI and/or males providing semen samples for IUI should be screened for infectious agents based on local, regional, and national standards and regulations.

Furthermore, facilities for performing semen preparation for IUI should meet the criteria of the WHO laboratory safety manual for reducing the risk of infection.

Studies are lacking concerning the prevention and transmission of viral diseases in IUI treatment and thus these guidelines are, therefore, based upon best practice, guidelines associated with prevention of sexually transmitted infections, and local regulatory guidelines (good practice point).

It is recommended to compare various sperm preparation techniques in multicenter randomized trials both for success rates concerning the elimination of transmission of infectious diseases to both partners and to offspring.[107]

How can you prevent multiple pregnancies and OHSS in an IUI program?

- In order to prevent high rates of multiple gestation pregnancies in IUI–OS, IUI should be withheld when more than two dominant follicles of >15 mm or more than five follicles of >10 mm at the time of hCG injection or LH surge are present.
- When gonadotropins are used in IUI, regimens with 75 IU or lower should be used because higher doses have similar pregnancy rates but increase MPRs.
- Clomiphene citrate or tamoxifen is acceptable alternative to low-dose gonadotropins for low multiple pregnancy and birth rates and with lesser costs, although at a lower LBR than with gonadotropins.
- Addition of GnRH agonist to gonadotropins in IUI–OS is not recommended because there is no increase in pregnancy rate despite increased MPRs and increased costs.
- *Good practice point:* As an alternative to cycle cancellation, aspiration of excess follicles at the time of hCG injection or LH surge might be additional options for reducing the risk of multiple pregnancy in IUI–OS.

The most common side effects of IUI in cycles with OS are multiple pregnancies and OHSS. Multiple pregnancies carry increased risks of pregnancy complications and diminished neonatal outcome, such as preterm delivery, growth retardation, and preeclampsia. High MPRs are mainly caused by multifollicular growth following OS. Measures to prevent multiple pregnancies can be divided into primary and secondary measures. Primary measures include attempting to prevent the growth of more than two to three dominant follicles, as showed by van Rumste et al.[72] in a systematic review and meta-analysis including 14 studies (11,599 IUI cycles) (moderate quality of evidence). Multifollicular growth resulted in significantly higher pregnancy rates compared to monofollicular growth (15 vs. 8.4%). Compared with one dominant follicle, pregnancy rates increased by a further 5, 8, and 8%, respectively, when two, three, or four dominant follicles were present. Subsequently, the risk of multiple pregnancies after two, three, and four dominant follicles increased at 6, 14, and 10%, respectively.[72]

Another primary measure to prevent multiple pregnancies is to apply the appropriate drug and doses, and to individualize the doses when possible. CC (100 mg per day for 5 days) or tamoxifen is acceptable alternative to low-dose gonadotropins for low multiple birth rates and also results in lower costs, although at a lower LBR[108] (moderate quality of evidence). In this systematic review of Cantineau et al.,[108] significantly higher pregnancy rates were found with gonadotropins compared to antiestrogens (OR = 1.8, 95% CI: 1.2–2.7, n = 556, moderate quality of evidence). Two more recent high-quality evidence RCTs confirmed the outcomes of the Cochrane systematic review. In these trails, compared to CC, gonadotropins showed significantly higher LBRs and comparable, relatively low MPRs of between 3.6 and 12.5%.[109,110]

The Cochrane systematic review concluded also that there is no benefit in using letrozole compared to CC (pregnancy rate per couple: OR = 1.2, 95% CI: 0.64–2.1) based upon moderate-quality evidence. High-level evidence shows that when gonadotropins are used in IUI, regimens with 75 IU or lower should be used as higher doses have similar pregnancy rates while increasing MPRs.[108-110] Currently, an ongoing large multicenter trial is attempting to identify factors that might predict ovarian response with low-dose gonadotropin stimulation and thus might help to individualize stimulation doses in the future (PRORAILS study, NCT01662180). Based upon moderate-quality evidence, addition of GnRH agonist or antagonist is not recommended for our draft evidence-based guideline, because there is no increase in pregnancy rate despite increased MPRs and costs.[108] Cycles should be closely monitored by regular vaginal ultrasounds and when more than two to three follicles of >15 mm or when more than five follicles of >10 mm are seen, secondary measures can be advocated (moderate quality of evidence).[72] Of course, cycles can be cancelled and heterosexual couples should be advised to abstain from unprotected intercourse. As an alternative to cycle cancellation, aspiration of excess follicles at the time of hCG injection or LH surge, or conversion to IVF, might be additional options for reducing the risk of multiple pregnancy (good practice point). Finally, multifetal reduction can be proposed when a multiple pregnancy is observed.[111] However, multifetal reduction should be prevented at all costs with the above-mentioned measures for prevention of multiple pregnancies with IUI (good practice point). OHSS is very rare in IUI–OS treatment because the aim of the stimulation protocol should be two to three dominant follicles.[72] Regular ultrasound monitoring should identify any hyper-response early, such that hCG to induce ovulation can be withheld to avoid OHSS. With an adequate program to prevent multiple pregnancies, OHSS should be rarely encountered.

There is still debate regarding the most cost-effective drug for mild stimulation in IUI programs. Many randomized trials comparing gonadotropins with CC or letrozole have been published but the results are contradictory and often these trials are of (very) low quality. A large multicenter trial comparing gonadotropins with CC is ongoing in the Netherlands (SUPER trial NTR4057) and might be able to answer the question as to which strategy is the most cost-effective when addressing side effects and maternal and neonatal morbidity, and mortality associated with multiple pregnancies.

The majority of couples would prefer IUI with or without COH when the probability of a treatment-independent pregnancy in the next 12 months is 50% and 40%, respectively. The risk of a multiple pregnancy does not affect their preference for IUI, whereas IUI is rejected when the risk of OHSS exceeds 10%.[29]

Is there a different perinatal outcome for IUI pregnancies and how does this perinatal outcome differ from normal coitus and IVF/ICSI pregnancies?

- Individuals with infertility undergoing treatment with IUI–OS should be informed about a possible increased risk for preterm birth and low-birth weight in singletons and twin pregnancies when compared to pregnancies in fertile couples not requiring assistance (IVF/ICSI outcome comparisons are assessed in the IVF/ICSI prioritized guideline).

The perinatal outcome of pregnancies caused by ART and IUI is substantially worse when compared to pregnancies after normal coitus.[112] This is mainly attributed to a higher rate of multiple births. Few studies have been published reporting the obstetric and perinatal outcome after IUI in a direct comparison with medically unassisted pregnancies, with contradictory results. According to Nuojua-Huttunen et al.[113] using the data obtained from the Finnish Medical Birth Register, IUI treatment did not increase obstetric or perinatal risks compared with matched pregnancies through normal coitus or IVF pregnancies.[113] Wang et al.[114] examined preterm birth in 1,015 IUI/artificial insemination by donor (AID) singletons compared to 1,019 IVF/ICSI and 1,019 medically unassisted singletons. Singleton IUI/AID births were ~1.5 times more likely to be born preterm than medically unassisted singletons, whereas the IVF/ICSI group was 2.4 times more likely to be born preterm. They found no significant difference in the risk of preterm birth for IUI with partner or donor semen (7.0 vs. 7.5%, respectively).[114]

In a retrospective cohort study, Gaudoin et al.[115] described a poorer perinatal outcome of singletons born to infertile mothers through OS–IUI compared to matched medically unassisted pregnancies within the Scottish national cohort. The difference in perinatal outcome was caused by a higher incidence of prematurity and low-birth weight infants. The poor perinatal outcome of singletons after OS–IUI was associated with low-birth weight, but only when IUI was performed with partner's semen and not with donor semen.[115] In a matched case–control study, De Sutter et al.[116] did not observe a difference in pregnancy outcome in IUI versus IVF gestations.[116]

Two large cohort studies comparing the perinatal outcome after OS and/or IUI with medically unassisted pregnancies or IVF/ICSI pregnancies were performed in Flanders, Belgium.[117] Data were obtained from the Study Centre for Perinatal Epidemiology of Flanders. In the first study, the outcome from 661,065 births could be investigated. All women were matched for maternal age, parity, fetal sex, plurality, place, and year of birth. A significantly higher incidence of extreme prematurity (<32 weeks), very low-birth weight (<1,500 g), stillbirths, and perinatal death for OS–IUI singletons could be observed. Twin pregnancies resulting from OS–IUI showed a higher rate of neonatal mortality, assisted ventilation and respiratory distress syndrome when compared to medically unassisted twin pregnancies.

In the second study,[118] 1,039,415 singletons and 39,041 twins were available for analysis. Following logistic regression analyses, it was shown that IVF/ICSI singletons had a significantly worse outcome when compared to OS–IUI and medically unassisted pregnancies for almost all investigated perinatal parameters. OS singletons were also significantly disadvantaged for birth weight and prematurity when compared to pregnancies obtained through normal coitus. The outcome of twin pregnancies was similar for the three groups unless only unlike-sex twins were studied separately. Among this subgroup, IVF/ICSI carried a higher risk for low-birth weight when compared to medically unassisted pregnancies.

In a retrospective cohort study, Poon and Lian[119] also observed that perinatal outcomes after IUI/CC pregnancies represent an intermediate risk between IVF/ICSI and pregnancies obtained through normal coitus. A national cohort study in Denmark on 6,338 singletons born after IUI showed an increased risk of adverse perinatal outcomes compared with children born after normal coitus. Stimulation with CC was associated with higher risk of small for gestational age compared with natural cycle IUI.[120]

The reason why perinatal health problems occur more frequently after IUI is still unknown, but can be explained by the procedures itself, the endocrine changes caused by OS medication or the underlying reason for infertility.[121] In a structured review, Pinborg et al.[122] concluded that infertility is a major risk factor for adverse perinatal outcome for singletons, and even in the same mother, an ART singleton has a poorer outcome than the non-ART sibling. This could mean that factors related to the hormone stimulation and/or ART methods per se may play a role.

Both OS–IUI and IVF/ICSI are associated with an increased risk for multiple pregnancies.

It has been shown that spontaneous reduction of multiple pregnancies causes a higher risk for adverse obstetric and perinatal outcome compared to pregnancies without spontaneous reduction. >10% of IVF/ICSI singletons are the result of a vanishing twin, and the same can be expected after OS–IUI. Survivors of a vanishing co-twin have a higher risk for prematurity and low-birth weight compared to singletons from single gestations, the higher the gestational age at fetal demise, the higher the risk for the surviving co-twin.[123] This phenomenon can explain, at least partly, the worse perinatal health outcome after OS–IUI compared to singleton and twin pregnancies born without medical assistance.

Pregnancies in patients with diabetes insipidus (DI) carry no increased risk compared to pregnancies obtained through normal coitus.[114,115,124] In a large French population study, it was shown that after DI, the miscarriage and tubal pregnancy rate, the children's weight, and the prematurity rate were not different from that of the general French population.[125] The rate of birth defects was comparable to the figures reported in a general population. The chromosomal abnormality rate was normal and correlated not only to the mother's age but also to the sperm donor's age. In addition, not further elaborated upon here, according to the available literature, the use of frozen spermatozoa does not seem to affect the health of children. On the other hand, a clinical pregnancy resulting from IUI with donor sperm appears to increase the incidence of preeclampsia.[126] In a structured review and meta-analysis, it was shown that pregnancy using donor sperm was associated with an increased risk of preeclampsia (OR = 1.63, 95% CI: 1.36–1.95) compared with using partner's sperm. No difference was observed in any risk for gestational hypertension.[127]

Couples and single women undergoing treatment with IUI require counseling concerning the increased risk of perinatal mortality and morbidity in twins compared to singletons. They should also be informed about an increased risk for perinatal health problems if they become pregnant after IUI with homologous and donor sperm, even for singletons, although this draft recommendation is based upon low-quality evidence. A close follow-up of IUI pregnancies from the early beginning of pregnancy is mandatory to detect spontaneous reduction of multiple pregnancies, which might be very important for that particular pregnancy.

PROGNOSTIC FACTORS INFLUENCING IUI SUCCESS

Female age is the most relevant predictor of the probability of clinical pregnancy in IUI treatment and moderate-quality evidence-based data show that a sharp decline of IUI success rate is observed in women over the age of 40 years, which is presumably related to review of evidence supporting IUI recommendations oocyte quality.[2] In heterosexual couples with unexplained infertility, IUI treatment should be limited to women with female age <40 years, although IUI may be encouraged to continue up to 42 years when donor sperm is used.[74] Whether IVF or ICSI should be recommended as a first-line therapy when the female is in her late 30s or >40 years of age is still debatable and more studies are needed to examine the cost-effectiveness of such an approach.[2]

Male age seems to have no profound effect when the female partner or sperm recipient is <35 years but a synergistic adverse effect seems to exist when the woman is >35 years and the man as well.[128] A possible explanation may be a decline in sperm quality with increased male age, especially for semen volume, sperm motility, and sperm morphology, but not for sperm count.[129] Therefore, men in a heterosexual relationship (or identified as sperm donor) with a female partner >35 years should be informed that increasing paternal age (40 years and above) has a potential negative impact on IUI success rates.[130] Moreover, oxidative stress-induced mitochondrial DNA damage and nuclear DNA damage in aging men may put them at a higher risk for transmitting multiple genetic and chromosomal defects.[131]

Additional parameters can also influence the IUI success rates although well-organized prospective randomized trials are not available. In a structured review, Ombelet et al.[53] investigated which sperm parameter in the native and washed semen sample influences success rates after IUI. Their search indicated a lack of prospective studies, a lack of standardization in semen testing methodology, and a huge heterogeneity of patient groups and IUI treatment strategies. The review identified an urgent need for more and better prospective cohort trials investigating the predictive value of semen parameters on IUI success rates.

The four sperm parameters most frequently examined were—inseminating motile count after washing: cut-off value between 0.8 and 5 million; sperm morphology using strict criteria: cut-off value >4% normal morphology; TMSC in native sperm sample: cut-off value of 5–10 million; and total motility in native sperm sample: threshold value of 30%.

Several studies support the concept of threshold values for sperm parameters below which IUI becomes significantly less effective. Most important are sperm morphology with a threshold value of 4%[53,54] and the TMSC either in the ejaculate (an average of 10 million total motile sperm in at least two samples) or in the postwash inseminating motile count (between 0.8 and 5 million motile sperm).[53,55] When using these threshold values, a poor sensitivity for predicting pregnancy but high specificity for predicting failure to become pregnant with IUI could be observed.

Ultrasound parameters can also be used to provide important information on egg quality and endometrial receptivity that will optimize the chances of success in an IUI program. However, robust evidence is lacking and the role of Doppler assessment in the ovaries and endometrium needs to be studied in future randomized trials.[132,133] Endometrial

thickness is another important factor predicting endometrial receptivity. It has been shown that endometrial thickness in stimulated IUI cycles is lower than in IVF cycles and is lower in cycles stimulated with CC compared with natural nonstimulated cycles.[134] A recent systematic review and meta-analysis on preovulatory endometrial thickness in IUI treatment (n = 3,846) showed that women treated with CC had a significantly thinner endometrial thickness than women treated with gonadotropins [n = 383, mean difference (MD): –0.33, 95% CI: –0.64 to –0.01]. However, pooling of seven relevant studies (n = 1,525) did not reveal an association between endometrial thickness and pregnancy rates (MD: 0.51, 95% CI: –0.05 to 1.07). Also, after a sensitivity analysis, the results remained nonsignificant.

The authors, therefore, concluded that endometrial thickness is not a good prognostic factor for IUI treatment success (low to moderate quality of evidence).[135] Studies on the influence of the body mass index (BMI) and obesity on IVF success rates are contradictory. A population-based cohort study[136] showed that an increased female and male BMI, both independently and combined, negatively influenced LBRs after IVF treatments.[136] In another prospective cohort study, weight status did not influence fecundity among heterosexual couples undergoing IVF treatment.[137] However, the influence of weight on IUI outcome remains unclear. Contradictory results were published in two retrospective analyses investigating the influence of BMI on IUI success: in one study, a BMI of 25 kg/m^2 or more in the woman was associated with higher success rates,[138] while in the second study, a BMI of <25 kg/m^2 was positively correlated with clinical pregnancy rates after IUI.[139] In most studies, it seems that a woman's BMI is not a determining factor for success rate after IUI although obese women require higher doses of medication. Once medication is adjusted to overcome the weight effect, the success rate is comparable for obese and normal weight women.[140-144] In addition, an underweight BMI may also be associated with poor fertility.[144] However, the advice to patients should be focused not only on ensuring optimal treatment outcomes, but also on promoting the best obstetrical outcomes because a high BMI is undoubtedly associated with adverse obstetrical and perinatal outcome.[145]

Studies on the influence of the smoking status on IUI success rates are almost nonexistent. It was shown that female smokers undergoing IUI–OS need significantly more gonadotropins than nonsmokers in order to achieve a comparable clinical pregnancy rate.[146] However, smoking was not significantly associated with a chance of becoming pregnant after secondary analyses of data from a prospective, randomized, multicenter "Assessment of Multiple Intrauterine Gestations from Ovarian Stimulation" (AMIGOS) clinical trial.[147] However, focus would need to be placed on obstetrical and perinatal outcome because of the detrimental effects of smoking.

EFFICACY AND SAFETY OF INTRAUTERINE INSEMINATION AND ASSISTED REPRODUCTIVE TECHNOLOGY IN POPULATIONS SERODISCORDANT FOR HUMAN IMMUNODEFICIENCY VIRUS

The controversy over whether the partners of patients infected with human immunodeficiency virus (HIV) should undergo procreative therapy was sparked in the 1980s when noninfected women were suspected to have contracted HIV through IUI.[148,149] Semprini et al.[150] subsequently demonstrated safe and effective sperm-washing techniques that could minimize the risk for transmission to the negative partner in 1992.[150] Though this has resulted in increased use of sperm processing and insemination for HIV-serodiscordant couples in Europe, it still is not commonly practiced in the United States. Couples who are HIV serodiscordant have both fertility desires and fertility needs. Infertility affects approximately 15% of the general population, and people with HIV have greater reproductive challenges secondary to sequelae from their HIV infection. Studies of the sperm quality of men with HIV who are on antiretroviral treatment have demonstrated significantly lower ejaculate volumes, lower sperm count, and lower progressive motility despite normal morphology.[151-153] This is consistent with HIV-associated hypogonadism, which can occur even without highly active antiretroviral therapy (HAART). Women with HIV have lower fertility rates across the world. The Joint United Nations Programme on HIV/AIDS (UNAIDS) estimated that the global age-specific fertility ratios for women with HIV in the reproductive-age group of 20–44 years are lower than that of women without HIV (ranging from 0.76 to 0.53).[154] These were suspected to be secondary to higher rates of gynecologic infections in women with HIV, with tubal factor infertility from pelvic inflammatory disease being an important obstacle to conception.[155,156] Many of these factors can be overcome via reproductive therapies, including insemination and assisted reproductive technology (ART).

The risk of transmission of HIV is 2.3 per 1,000 acts of receptive vaginal intercourse when a partner has a detectable viral load.[157] However, an undetectable viral load does not clearly translate to safety with unprotected intercourse, as almost 10% of men with undetectable viral load on HAART may still have detectable seminal virus.[158] Any ulcerative lesion in the genital tract and even seemingly benign conditions such as bacterial vaginosis can increase the risk of transmission of HIV several fold.[159,160] With no reported HIV transmission among serodiscordant couples identified in a systematic review,[161] with the upper 95% confidence limit for the risk of transmission from insemination therapy being fivefold less than the rate with coitus, and with the true value likely being even more favorable, this illustrates the

potential value of using ART or IUI to reduce risk in couples committed to using their own gametes.

In terms of the balance of risk and benefits for procreation with IUI relative to ART, it appears that IUI in seropositive men results in approximately half the pregnancy rate per cycle. It does so at about 1/10th to 1/20th the cost and also has a lower risk for multiple gestations and miscarriage as well as a lower surgical risk. There were no detected cases of HIV transmission with either method. Finally, in the context of an increasing number of HIV-serodiscordant couples being counseled by their physicians to conceive through coitus while on antiretroviral therapy, we have to determine whether insemination-based approaches serve as a middle ground while more data are collected on the safety and efficacy of unassisted conception.

Serodiscordant couples with HIV who do not meet the criteria for AIDS have a reasonable chance of pregnancy through fertility therapy. Male and female candidates for insemination seem to have pregnancy rates comparable to the general fertility population. Miscarriage rates seem similar to those for HIV-seronegative subfertile couples for IUI but are higher for ART. Seropositive men with unaffected partners have pregnancy and live birth rates with ART comparable to seronegative couples. However, seropositive females undergoing ART were found to have lower pregnancy rates per cycle. This disparity may have multifactorial origins, and further studies will be needed to address this issue. For studies meeting inclusion criteria, there were no seroconversions of HIV-negative partners by either IUI or ART.

There certainly will be clinicians who believe any risk of HIV transmission is unacceptable, even if none are seen in our large meta-analysis. However, so that decisions are evidence based rather than emotional, the risks should be quantified and placed in the context of similar accepted risks.

Moreover, the procreative desires and needs of serodiscordant couples often mean that they may be exposing themselves to far greater risks when without medical alternatives. As clinicians striving to promote health, we need to reconsider the role of procreative therapy in HIV-serodiscordant couples.

FUTURE DEVELOPMENTS

Increasing success rates following IVF/ICSI with better implantation rates per embryo are reported year-on-year; however, similar increases have not been reported following IUI. This could eventually lead to an unacceptable high difference in cost-effectiveness between IVF/ICSI and IUI, subsequently encouraging those who prefer IVF above IUI in all cases. However, such a statement does not take into account the couple's or the individual woman's preference, and the difference in complications related to the various treatment strategies. Nevertheless, IUI will remain an effective first-line treatment in unexplained infertility and mild male factor infertility, as well as the use of donor sperm in same sex female couples and single women, if we succeed in increasing the delivery rate per cycle without increasing the risk for complications such as a higher MPRs and increased risk for OHSS.

A well-controlled mild OS with gonadotropins aiming for two dominant follicles is the most effective strategy when performing IUI for unexplained infertility, minimal-to-mild endometriosis, and moderate-to-mild male factor infertility. A standardized methodology for IUI taking into account evidence-based data on how to perform IUI as described in this chapter will likely increase IUI singleton pregnancy rates worldwide. Other methods to increase the delivery rate per IUI cycle will be a better selection of patients who have a reasonable prognosis with IUI. The evidence has identified several factors that might influence IUI outcome as presented and will require further confirmation by well-designed and adequately powered randomized trials. Prewashing the catheter with culture medium prior to IUI seems to increase the success rate per cycle and could be recommended in Good Laboratory Practice Guidelines, as is already the case for embryo transfer catheters. It is clear that more studies are needed examining the influence of certain infections, sperm DNA abnormalities, and other (unknown) factors on IUI outcome results. More evidence-based research is also needed to optimize IUI outcome in terms of a better selection of couples or individual women who are the best candidates for IUI.

CONCLUSION

After collecting and appraising the most recent evidence on IUI in infertility care, it is possible to conclude that most of the presented "evidence" does not stand up to modern quality parameters, and is of moderate or (very) low quality. Issues such as randomization method, allocation concealment, blinding, adequate power, and outcome measures are often not adequately dealt with and thus most evidence is often graded from moderate to low. Especially in an "old treatment option", as IUI is often viewed, many RCTs are published in the previous century and firm conclusions are hard to draw.

Nevertheless, recently published higher quality multicenter RCTs fail to devalue IUI in the world of more advanced medically assisted reproductive treatments. Therefore, IUI, often in combination with OS, remains a first-line treatment option for many heterosexual and same-sex infertile couples and single women as this strategy is supported by the results of cost-effectiveness trials. However, applied inappropriately, IUI–OS could be a harmful treatment. In the delivery of fertility care interventions and treatments, the prevention of multiple pregnancies should be as important as optimizing LBRs. In low- and

middle-income countries and settings, the prevention of infections with a high risk of transmission, including review of evidence supporting IUI recommendations 315 endemic viral diseases such as HIV or hepatitis, is equally important.

This chapter presented several factors that might influence IUI outcome, such as women's age, BMI, and ultrasound parameters, and that need further confirmation by randomized trials so that in future, it might become possible to select those patients who would benefit most from IUI with a low risk of adverse events.

CHAPTER 45

Optimizing Success in Intrauterine Insemination

Kamini A Rao, Jampana Pallavi

INTRODUCTION

The principle behind intrauterine insemination (IUI) is based on increasing sperm density at the time and site of fertilization.[1] The very first IUI dates back in 1770s when John Hunter performed IUI for women whose husbands had hypospadias. Since then various revolutions have happened in improving the success of IUI. Despite being easy to perform, inexpensive, and offers particular advantages such as the minimal equipment required, less stringent laboratory conditions, an easy technique to learn, being less invasive with a reduced psychological burden on the couple as compared to in vitro fertilization (IVF), or intracytoplasmic sperm injection (ICSI), the effectiveness of procedure is still controversial. The global success rate of IUI is 15–20%. This overview is to optimize the success of IUI, though the good quality evidence is still lacking.

Intrauterine insemination success depends on various factors **(Fig. 1)**.

PATIENT SELECTION AND WORKUP

One of the important factors for successful IUI is duration of infertility. Maximum success in IUI is noted in 5 years

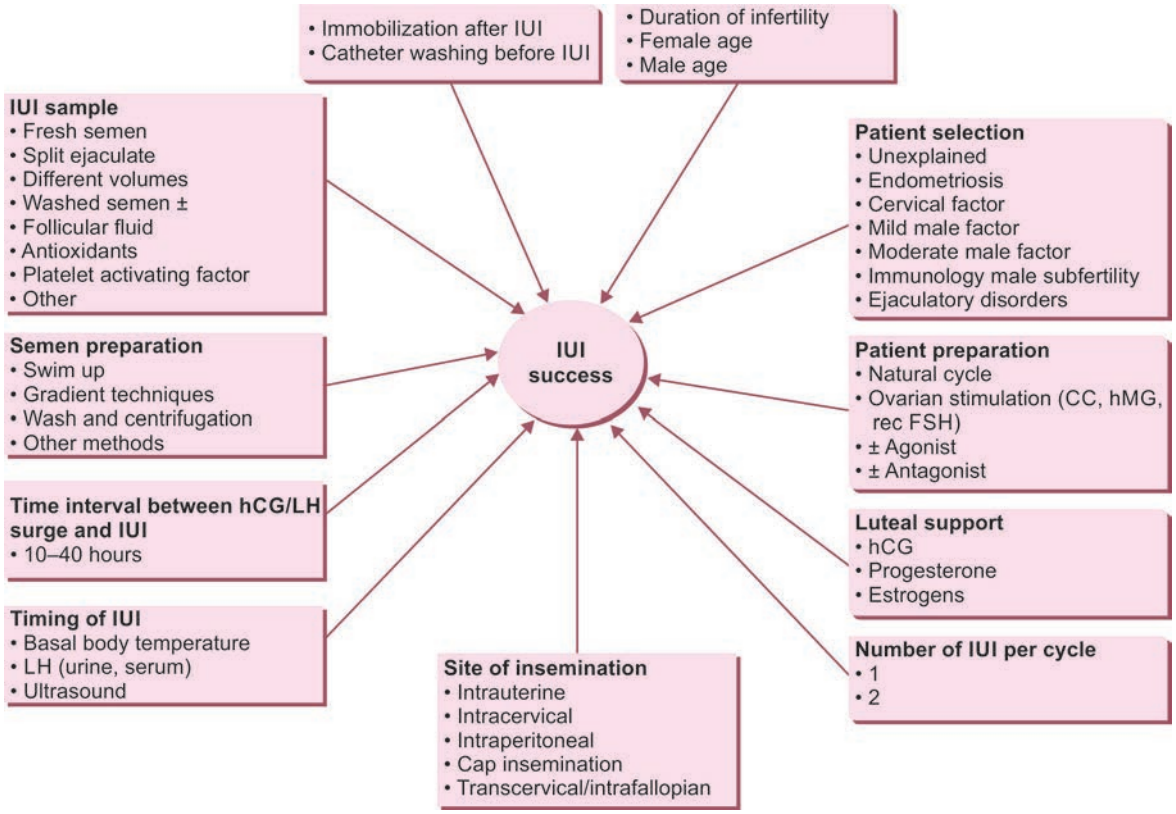

Fig. 1: Factors for intrauterine insemination (IUI) success.
(CC: clomiphene citrate; FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin; hMG: human menopausal gonadotropin; LH: luteinizing hormone)

suggested that IUI is not recommended in long duration infertility.[2,3] Although few studies such as Tay et al. found insufficient evidence of significant association of success of IUI with duration of infertility.[4]

Age of the couple, especially female age, has been found to be an important factor predicting success of IUI in many studies.[5,6] Increasing female partner age has adverse impact on oocyte number, oocyte quality, corpus luteal function, and endometrium and thus decreases the pregnancy rate.[2,7] Jayakrishnan et al. reported negative impact of >40 years of male partner age on IUI success.[8]

Evaluation of tubal factor and ovarian reserve must be done. At least one patent fallopian tube with healthy tubo-ovarian relationship is a good predictor of IUI success. In retrospective cohort study, with 3,217 IUI cycles, body mass index (BMI) between 25 and 29.99 did not have an inverse relationship with clinical pregnancy rate after IUI cycles; however, obesity may have higher chance of biochemical pregnancy.[9]

INDICATIONS OF INTRAUTERINE INSEMINATION

Way back in the 1770s, first IUI was done for hypospadias; the most common indications of IUI are mild male factor infertility, cervical factor, and unexplained infertility. Other indications include mild endometriosis, ovulatory dysfunction, and immunological factors. Cochrane review was inconclusive, there is no evidence of a difference in live birth or multiple pregnancy for couples with unexplained subfertility treated with IUI when compared with timed intercourse, both with and without ovarian hyperstimulation (OH).[10]

Different causes of an unexplained infertility are problems with egg quality, the inability of the sperm to fertilize the egg, undiagnosed tubal dysfunction, implantation failure, or genetic causes. Some studies have found that ovulatory dysfunction and unexplained infertility have better clinical pregnancy rates than other factors.[2,11]

Merviel P et al., results showed that pregnancy rates were greater in ovulatory and cervical factor infertility, but lower in endometriosis over varying numbers of cycles.[12] This implies that stimulation protocols successfully overcome the ovulatory disturbances.

According to many authors, endometriosis has been found beneficial in women younger than 35 years and with mild-to-moderate endometriosis.[13] Severe endometriosis, bilateral complete tubal block, severe male factor infertility, and ovarian insufficiency are absolute indications for IVF.

Though some authors find it unnecessary, in case of male infertility, sexual disorders such as erectile dysfunctions, ejaculatory failure, vaginismus, and hypospadias, IUI can be used as infertility treatment. Often subnormal semen parameters are accompanied by premature ejaculation, where use of IUI is absolutely justified.[14]

Donor insemination remains option in case of nonobstructive azoospermia, genetic hereditary diseases, homosexual couples, or single women willing for childbearing.[14] Selection of patients with ideal indication remains the key to optimize success of IUI.

PATIENT PREPARATION

Intrauterine insemination is done in the natural cycle and/or ovarian stimulation cycle with either oral ovulation agents or gonadotropins. The rationale behind the ovarian stimulation is to rectify the hidden ovulation disorders, to improve availability of oocyte number, to increase the steroid synthesis, and to time the ovulation so as to increase the chance of fertilization. Clomiphene citrate (CC) alone is not found to be efficacious in IUI in unexplained infertility.[15]

Although OH seems to result in higher pregnancy rates, it also increases the incidence of multiple pregnancy and ovarian hyperstimulation syndrome (OHSS). These both increase the risk and complications of both mother and baby's health.[16] Gonadotropins have been found to be the most efficient drugs when IUI is combined with OH.

Low-dose gonadotropins use is advised for ovarian stimulation as there is no difference in pregnancy rates with use of high-dose gonadotropins, instead complications from ovarian stimulation such as multiple pregnancy and OHSS are high with high-dose gonadotrophins.[17] A meta-analysis inclusive of 14 studies with 11,599 IUI cycles reported the association between multifollicular growth and increased pregnancy rates but at the cost of multiple pregnancy and hence no substantial increase in live birth rate. Hence, controlled ovarian stimulation for IUI is to be limited to one or two follicles only.[2,18]

Recently, there has been a shift of focus to letrozole (aromatase inhibitor) for ovulation induction in PCOS patients. According to European Society of Human Reproduction and Embryology (ESHRE), evidenced based guidelines on PCOS, letrozole should be used as a first-line drug for ovulation induction in anovulatory PCOS.

Cochrane review states that letrozole appears to improve live birth and pregnancy rates in subfertile women with anovulatory PCOS; however, the risk of OHSS seemed to be similar in both letrozole and clomiphene groups.[19]

In a pilot study, analysis was done for human chorionic gonadotropin (hCG) before IUI (228 cycles) versus hCG after IUI (104 cycles). The pregnancy rates were 10.9% and 19.6% ($p = 0.040$), respectively. Improved pregnancy rate was reported when hCG was given after IUI.[20] Similar analysis was done by Mustafa et al., he reported no difference in pregnancy rate between hCG injection immediately following IUI and standard hCG injection 24–32 hours before IUI.[21]

Ultrasound monitoring is better when ovarian stimulation is done to help to decide the timing of IUI and to cancel the IUI in cases of OHSS.

MONITORING OF INTRAUTERINE INSEMINATION

Different methods such as basal body temperature recording, luteinizing hormone (LH) kits, serum estradiol levels, and ultrasonography (USG) to time the IUI have been used. Although Ozkan et al. found the best results of IUI with serum estradiol levels >465 pg/mL, Marviel et al. found the best results of IUI with an estradiol concentration >500 pg/mL on the day of hCG administration, estradiol monitoring is costly.[22]

Perifollicular vascularity is an important factor modulating the success of IUI in stimulated treatment cycles. Study conducted on 601 follicles suggests that perifollicular vascularity has an important role to play in the success of IUI cycles, also power Doppler has the ability to improve the management of assisted reproduction treatment cycles.[23]

Growing follicle and corpus luteum require increased blood flow. A developed or mature follicle shows increased vascularity by >75% of its circumference. During this, the ovarian stromal arteries show peak systolic velocity of >10 cm/sec. This is the time where LH surge is started in natural cycles and this is the time to trigger in assisted reproductive cycles.[24]

Three-dimensional power Doppler ultrasound for evaluating endometrial and subendometrial neovascularization in IUI cycles may be useful predictors for pregnancy.[25] Elastography is another promising innovative tool for monitoring the IUI. The elasticity index is recorded for 5 minutes. The elasticity index can be calculated as the mean ratio of elastographic measurements between the subendometrial area (of interest) and the endometrial area (control). Uterine contraction frequency, endometrial thickness and volume, and subendometrial vascularization are other parameters helpful in predicting the success of IUI.[26] Correct timing of the insemination is essential as spermatozoa and oocytes have only limited survival time. Different techniques for timing IUI such as hCG, agonist, and LH surge and different time intervals are reviewed in Cochrane which concluded no evidence of any one technique to improve IUI success.[27]

TIME AND NUMBER OF INTRAUTERINE INSEMINATION

Among the different time intervals, IUI after hCG injection anywhere between 12 hours and 60 hours is recommended for management of infertility. A randomized controlled trial (RCT) was done on 125 cycles to evaluate the best time for IUI after hCG, comparing pregnancy rate of IUI after 24, 36, and 48 hours after hCG. Pregnancy rates were found similar between all groups.[28]

Blockleel et al. conducted an RCT, which showed significant higher pregnancy rates when IUI is performed one day after LH surge in natural cycles, compared to IUI being done after 2 days of the surge.[29]

Another study inclusive of 1,146 stimulated cycles concluded the better cycle pregnancy rate (CPR) with single postovulation IUI when compared with single preovulation IUI for non-male infertility, whereas for male factor infertility, double IUI gives a better CPR when compared with single IUI.[30,31] Other studies and recent meta-analysis too found no difference in single and double IUI though evidence in low quality.[32-35]

Cochrane review studied nine RCTs and concluded that benefit of live births and reduced miscarriage in double IUI over single IUI in subfertile couples is uncertain. The reported clinical pregnancy rate may be improved with double IUI, however results should be interpreted with caution.[36]

SITE OF INSEMINATION

Insemination of sperm can be done either cervical (CI) or intrauterine (IUI) routes. IUI has been found to be potentially more effective than CI as the sperm bypasses the cervical mucus and is deposited closer to the fallopian tubes.[37,38]

SEMEN

Sperm quality is of paramount importance in any assisted reproductive technique.

ABSTINENCE DURATION

The duration of sexual abstinence to provide maximum sperm quality is one of commonly discussed controversial issue. Eliahu et al. did analysis of 9,489 semen samples in relation to abstinence duration. Patients with male factor infertility should have abstinence of not >1 day to give best semen parameters.[39] The highest pregnancy rates per cycle were demonstrated with an ejaculatory abstinence period of ≥2 days before IUI when compared with longer intervals of ejaculatory abstinence.[40]

While in normospermic men, shorter duration of ejaculatory abstinence is not detrimental and it is a method of reducing DNA fragmentation.[41] A short period of abstinence leads to a significant improvement in the semen parameters on second day insemination. Hence, 2 days consecutive intercourses or inseminations maybe helpful for men with abnormal concentration or multiple abnormal semen parameters.[42] Whereas in men with normal basic semen parameters, a single-timed insemination and longer abstinence can be recommended because of reduction in semen quality is expected after 24 hours.[42]

TABLE 1: Correlation of processed TMC (total motile sperm count) and pregnancy rates.[47]

Processed total motile sperm		
Number of sperm recovered (×106)	***Numbers of men with indicated sperm count/ total number of men (%)***	***Pregnancy rate 1st/ pregnancy rate all cycle***
<5	168/1,768 (9.5%)	0 0
5–10	336/1,768	3.1 7.2
>10	1,264/1,768 (71.5%)	15.9* 13.7*

*p <0.001 vs. other groups by chi square analysis.

SEMEN PARAMETERS

Sperm parameters most frequently evaluated to achieve improved pregnancy rates are: (1) Inseminating motile count after washing: cut-off value between 0.8 million and 5 million; (2) sperm morphology using strict criteria: Cut-off value 5% normal morphology; (3) total motile sperm count (TMC) **(Table 1)** in the native sperm sample: Cut-off value of 5–10 million; and (4) total motility in the native sperm sample: Threshold value of 30%.[43] The postwash TMC more than or less than 5 million/mL at time of insemination can be a potential parameter used in counseling patients for either IUI or IVF.[44-46]

Recent retrospective cohort study done in 2019, which studied 655 IUI cycles, showed no live birth rates, whose prewash TMC is <2 million. However, prewash TMC is a poor predictor of pregnancy rate in IUI cycles.[48]

Taylor et al. performed a systematic review and meta-analysis to assess the effect of abnormal sperm morphology on pregnancy success for couples undergoing IUI. The thresholds of sperm morphology between >4% and 4% and 1% and <1% were not significant statistically or clinically to improve IUI success. Thus for couples with abnormal morphology, IUI must be tried before to advising significantly more expensive IVF.[49]

Branigan et al. evaluated the effect of total motile count of density gradient processed semen samples on IUI success. Although he suggested the processed TMC as useful prognostic factor of IUI, he did not find any significant relation between any of the basic semen parameters of concentration, motility, and morphology by World Health Organization (WHO) standards and pregnancy rates.[47]

DNA FRAGMENTATION INDEX

Altered DNA structure of sperm may also cause male infertility. These alterations are reflected by DNA fragmentation index (DFI). A study in 2019 evaluated the impact of DFI on the pregnancy outcomes by clinical pregnancy rates in IUI cycles and found no difference. DFI is not a part of evaluation before IUI cycles.[50,51]

PATERNAL AGE

A study with 901 IUI cycles showed reduced cumulative pregnancy rates in men aged >35 years compared to <30 years when maternal age, duration of infertility, ovulatory status, and teratozoospermia and asthenozoospermia in men are matched.[51]

COLLECTION TO INTRAUTERINE INSEMINATION TIME INTERVAL

The processing of semen specimens must be done just after liquefaction and within 30 minutes of collection, and IUI is to be performed immediately after processing and within 90 minutes of collection.[52] The prolonged incubation impairs the sperm parameters.[53]

SEMEN PREPARATION TECHNIQUE

The rationale of sperm preparation techniques (SPTs) is to isolate and select sperm cells with intact functional and genetic properties, including normal morphology, minimal DNA damage, and intact cell membranes with functional binding properties. To improve the quality and outcome of IUI procedures, simple, inexpensive, reliable, and safe SPTs are required. There is no specific evidence to recommend any specific semen preparation technique.[54] The WHO laboratory manual suggests the choice of the type of SPT is dictated by the nature of the semen sample. Swim-up generally produces a lower recovery of motile spermatozoa (<20%) than does density gradient concentration (>20%) though not supported by few studies.[55]

Cochrane review in 2019 studied six RCTs regarding the semen preparation techniques used in IUI, gradient versus, wash and centrifugation, there is uncertainty in clinical pregnancy rates in one technique over the other.[56]

Advanced techniques such as annexin V magnetic-activated cell sorting (MACS) based on the principle of separation nonapoptotic sperms from apoptic sperms.

Glass wool technique, separation technique based on electrical charge on sperm are still not validated. Integration of these techniques may help in improving the success of IUI.[57]

Frozen Semen Sample

The prefreezing progressive sperm motility is an important predictor for frozen sample IUI success.[58]

Pooled Semen Ejaculates

A recent retrospective study analyzed patients who underwent IUI in a single center between 2012 and 2019. All the participants with TMC <5 million were asked to ejaculate the second sample within an hour or two of the first sample. The pooled sample is used for processing and insemination.[59]

Combination of the first and consecutive ejaculates in oligoasthenoteratozoospermia men have higher

inseminating motile count in the processed samples, which improves IUI success rates as in normozoospermic men. This simple intervention can help to overcome moderate male factor infertility and may be used in resource poor settings before referring for IVF.

TECHNIQUE OF INTRAUTERINE INSEMINATION

Intrauterine insemination success increases with use of abdominal USG with partially filled urinary bladder, no touch to fundus, slow injection of 0.3–0.5 mL of processed semen, and slow withdrawal of catheter.

Type of Catheter

Catheter technology has achieved a lot of importance in assisted reproductive technology (ART) with its proven benefit during embryo transfer technique. Catheters must be firm enough to negotiate the rigid curvature of the cervix, but soft enough to avoid any trauma to the endocervix and/or endometrium as it finds its way into the uterine cavity. Cochrane and other studies have found no evidence of flexible catheter over rigid catheter in IUI in regards to pregnancy rates.[60-62] In retrospective analysis of 1,038 cycles, the type of catheter used was correlated with differing pregnancy rates, 15.3% per cycle for soft catheter versus 7% for a hard catheter (p <0.02).[12]

Volume of Insemination

The postwash inseminated semen volume between 0.3 mL and 0.5 mL has been found to be useful for successful pregnancy in IUI.[63]

Ultrasound-guided Insemination

A prospective RCT did not report benefit of ultrasound guidance in IUI.[64]

Whereas other studies noted improved pregnancy rate, reduced frequency of difficult IUI, and also higher success with use of ultrasound in hands of experienced personnel.[65,66]

Bed Rest

An RCT on 296 women recommended bed rest for 10–20 minutes after that showed positive effect on pregnancy outcome after IUI.[1,67]

Recently van Rijswijk et al. studied 498 patients in a RCT and found no significant difference in cumulative pregnancy rate between both immobilization and mobilization groups.[68,69]

Luteal Phase Support

Based on few studies and one meta-analysis, luteal support with vaginal progesterone appears to increase the pregnancy rate in gonadotropin-stimulated cycles where there is growth of more than one follicle.[70,71] While few studies recommend that a routine supplement of vaginal progesterone does not improve the pregnancy rate in normo-ovulatory women with CC stimulation or monofollicular growth.[72]

Number of Treatment Cycles

The maximum number of IUI required for successful pregnancy has been a controversial issue all the time. In a multicenter retrospective cohort analysis, 15,303 IUI cycles with controlled ovarian stimulation (COS) were analyzed. The cumulative ongoing pregnancy rates reported were 18% in the third cycle, 30% by seventh cycle, and 41% by ninth cycle. This study recommended not to abandon IUI treatment before nine cycles with mild COS, especially in young people (female age <35 years) and still have considerable time to conceive.[73] Maximum conception rate is reported in the first cycle, the decreasing trend toward second and third cycle.[7] Few studies reported no significant increase in pregnancy rates beyond four cycles.[2,8] Studies recommend that IVF-ICSI is a better plan of management after three cycles of IUI with COS for unexplained infertility.[74]

Premature Luteinizing Hormone Surge in Intrauterine Insemination Cycles

Final maturation and follicle rupture are under control of LH surge. Though the cause of premature luteinization is variable, it completely disturbs the treatment outcome. The premature luteinization occurs in almost 25–30% stimulated cycles of IUI, which ultimately leads to treatment failure or cancellation of cycles or interfere with timing of IUI which is of crucial importance.[75]

Gonadotropin-releasing hormone antagonist is a best technique to prevent premature luteinization but not cost-effective and not found to improve the pregnancy rates in IUI.[76]

Laboratory

According to the Assisted Reproductive Technology Bill 2014, Indian Council of Medical Research recommends the registration of IUI laboratories as mandatory. Ideal IUI laboratories should be isolated and should include a distinct area for diagnostic and therapeutic procedure with a sterile environment with the help of laminar airflow. Adequate space according to the number of tests done, air conditioning, air quality, and cleaning to be maintained. There should be separate space for liquid nitrogen cylinder and storage of disposables and media. Record maintenance and standard operating procedure should be meticulous.

According to Assisted Reproductive Technology Act 2022, all IUI centers should be registered under level 1 ART centers and need to be recognized by the authorities.

Personnel should have good laboratory skills and knowledge of the subject. Validation of all new equipment before use is must; it should be reliable in function and periodically monitored for efficiency.[77]

EUROPEAN SOCIETY OF HUMAN REPRODUCTION AND EMBRYOLOGY CAPRI WORKSHOP 2009

Intrauterine insemination is most widely and empirically used as stop gap treatment while waiting for or instead of IVF. ESHRE Capri group has tried to consider the evidences for IUI for best clinical practice.[75]

Recently, Cochrane and Capri studied three studies comparing three cycles of ovarian stimulation with IUI with IVF, no clear benefit was noted in either groups.[78]

KEY POINTS

- The live birth rate is better even without treatment in good prognosis couples.
- Most widely used treatment modality for infertility is IUI, except for bilateral tubal obstruction, severe male infertility, and severe ovulation defects.
- Success rate of IUI does not vary profoundly with different SPTs and IUI methodology.
- IUI with oral ovulation agents or gonadotropins is a relatively cheap, easy, convenient option before IVF, and many couples will conceive without need of IVF.
- A more number of placebo-controlled trials of CC/IUI required determining the optimal length, duration, and protocol of treatment.
- Higher-order multiple births are associated with ovarian stimulation which is effective in patients with >3 years' duration of infertility.
- The larger number of trials is required to confirm the good success rate recently associated with mild stimulated IUI cycles.
- Prevention of premature LH surges and luteal phase support are not mandatory for better success in IUI cycles.
- IVF is the most effective treatment for infertility even though IUI treatment is cheaper and less demanding for the patient.
- Requirement of management trials to evaluate the order of treatment and overall effectiveness of treatment strategies in more clinical and cost settings cannot be ruled out.

Ovarian Stimulation

CHAPTER 46

Drugs for Ovarian Stimulation

Duru Shah, Sabahat Rasool

INTRODUCTION

Drugs for ovarian stimulation are aimed at boosting the follicular growth and inducing ovulation. A number of drugs are available for stimulating the ovaries, the most commonly prescribed ones being clomiphene citrate (CC), tamoxifen, letrozole, and gonadotropins such as follicle-stimulating hormone (FSH) and luteinizing hormone (LH) **(Box 1)**. Human chorionic gonadotropin (hCG) and gonadotropin-releasing hormone (GnRH) analogs are used primarily for ovulation trigger and pituitary downregulation, respectively.

ORAL OVULOGENS

Clomiphene Citrate

Clomiphene citrate was synthesized in 1956 and introduced as a follicle stimulant in 1961 when Greenblatt and his group observed that it exerts a stimulatory effect on ovarian function in anovulatory women.[1] This synthetic nonsteroidal agent is a chlorotrianisene (TACE) analog consisting of three benzene rings. The molecular weight is 598.09 Daltons. CC is a white or pale yellow, odorless powder, unstable in air, and light. It is a racemic mixture of two stereochemical isomers, zuclomiphene (cis), and enclomiphene (trans).

The commercial preparations have these isomers in the ratio of 38% Zu and 62% En clomiphene. The En isomer is more estrogenic and potent, absorbed faster, and eliminated more completely than the Zu isomer. CC is metabolized by hepatic degradation, excreted through feces, with a small amount being cleared by kidneys. The drug can be detected in serum for up to 30 days if administered at a dose of 100 mg daily for 5 days.

BOX 1: Ovarian stimulation drugs.

Estrogen antagonists:
- Clomiphene citrate
- Tamoxifen
- Letrozole

Gonadotropins:
- Urinary-purified/highly purified FSH, LH, and hCG
- Recombinant—FSH, LH, CG, and FSH + LH

(CG: chorionic gonadotropin; FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin; LH: luteinizing hormone)

Action

Clomiphene citrate is a selective estrogen receptor modulator (SERM). It is a competitive estrogen receptor (ER) antagonist, exerting weak estrogenic activity in some tissues and moderate antiestrogenic activity in others. It acts on the ERs in hypothalamus, pituitary, ovary, endometrium, vagina, and cervix. CC blocks the negative feedback of endogenous estrogen primarily by prolonged depletion of hypothalamic and pituitary ERs. This causes a compensatory rise in GnRH release from the hypothalamus with a consequent rise in the release of pituitary gonadotropin.[2] To sum up, the antiestrogenic effect on the central nervous system increases FSH and LH pulse frequency and LH pulse amplitude, thereby moderately stimulating the ovaries with these gonadotropins.[3,4]

Clomiphene citrate is usually administered orally from early follicular phase of a natural or induced menstrual cycle in a dose of 50–150 mg daily for 5 days. This is aimed to coincide with the onset of gonadotropin-sensitive phase of follicle growth.

Indications

- Anovulatory infertility—polycystic ovary syndrome (PCOS)
- Unexplained infertility
- Luteal phase defect (CC induces LH receptors in corpora lutea)
- Coadministration with gonadotropin in in vitro fertilization (IVF) for poor responders.

Contraindications

- The WHO type I and III infertility
- Women with a defective hypothalamic pituitary axis like Sheehan's syndrome or Kallmann syndrome.

Clomiphene citrate is ineffective in hypogonadotropic hypogonadism because these women have a deficient estrogen signal to the hypothalamus.[5]

Efficacy

- *Ovulation rate*: 70–92%
- *Pregnancy rate*: 20–40%.

Treatment with CC is effective, safe, and economical. Low pregnancy rates are explained by the antiestrogenic effect of CC on tubal motility, cervical mucus and endometrium, decreased uterine blood flow, endometrium-embryo asynchrony, and detrimental effect on oocytes themselves.[6] CC gets accumulated within the body, leading to extended depletion of ERs and hostile effects on estrogen sensitive genital tissues.

Around 20–25% women are resistant to CC.[7] *CC resistance* is defined as failure to ovulate with 150 mg CC daily for 5 days for at least three cycles and occurs in 15–40% women with PCOS. Genetic predisposition, insulin resistance, hyperandrogenemia, and obesity all contribute to clomiphene resistance.[8] The treatment options for CC resistant patients include weight loss and lifestyle modifications, insulin sensitizers like metformin, oral contraceptive pill pretreatment, laparoscopic ovarian drilling, and use of gonadotropins.[9,10]

Clomiphene citrate failure is inability to get pregnant despite ovulating during three cycles with CC.

Side Effects

- Mood swings (64–78%)
- Hot flushes (10%)
- Abdominal distension (5%)
- Breast discomfort (2%)
- Nausea and vomiting (2%)
- Visual symptoms and headache (1.5%)
- Multiple pregnancy rate (5%)
- Adverse effects on cervical mucus (15%)
- Ovarian cysts (5%).

Tamoxifen

Tamoxifen is a nonsteroidal SERM widely used as adjunct therapy in breast cancer. It is structurally very similar to CC. Various studies have reported an ovulation rate of 50–90%, with pregnancy rates of 30–50%.[11] The drug is known to show good ovulation rates even in CC resistant cases. Since it acts as an agonist on ERs in vaginal mucosa and endometrium, there is a positive effect on endometrium and cervical mucus.[11,12] Side effects include headache and mild ovarian enlargement.

Aromatase Inhibitors

The conversion of androgen to estrogen occurs under the effect of a cytochrome P_{450}-dependent enzyme, aromatase. Aromatase inhibitors (AIs) are competitive inhibitors of aromatase enzyme **(Table 1)**. They lower the serum levels of estrone, estradiol as well as estrone sulfate, with maximum suppression achieved within 48–78 hours.[13] AIs were introduced for ovulation induction in 2001. AIs are also used for treatment of postmenopausal breast cancer.

TABLE 1: Generations of aromatase inhibitor.

Generation	*Type I (steroid analogs)*	*Type II (nonsteroidal analogs)*
First	–	Aminoglutethimide
Second	Formestane	• Fadrozole • Rogletimide
Third	Exemestane	• Anastrozole • Letrozole • Vorozole

Letrozole is a nonsteroidal competitive inhibitor of aromatase, with a half-life of 48 hours, and is mainly excreted through feces and urine.[14] It is administered orally in a dose of 2.5–5 mg per day for 5 days in early follicular phase.

Indications

- Obese PCOS
- PCOS with CC resistance and/or failure
- Unexplained infertility
- Coadministration with gonadotropin for poor responders.

Action

One of the most common causes of anovulation in PCOS (normogonadotropic anovulation) women is a static level of estrogen, either elevated or normal. Static level of estrogen, through negative feedback mechanism on hypothalamic–pituitary–adrenal axis (HPA), inhibits adequate release of pituitary FSH. Low level of FSH results in inadequate growth and development of follicles. Tonic elevated level of estrogen, through "positive feedback" effect on HPA, results in release of elevated tonic level of LH. There is no LH surge and therefore, no ovulation. AIs, by inhibiting estrogen synthesis temporarily, release hypothalamic-pituitary block, thereby normalizing the pulsatile release of pituitary FSH and ovulation. The hypoestrogenic state is quickly reversible due to the short half-life of letrozole (48 hours). There is no antiestrogenic effect on endometrium. Also, there is temporary elevation of testosterone to an optimum level, which is beneficial as it increases the follicular sensitivity to endogenous gonadotropins. Letrozole also increases the biosynthesis of endometrial receptivity markers such as integrin.

Efficacy

- *Ovulation rate*: 75%[15]
- *Pregnancy rate*: >25%.[15]

In a systematic review and meta-analysis of seven studies with 1,833 PCOS patients, live birth and pregnancy rates were

statistically significantly better with letrozole compared to CC, with no differences in multiple pregnancy, miscarriage, and ovulation rates. It was concluded that letrozole was superior to CC when considering live birth and pregnancy rates in women with PCOS.[16] In yet another meta-analysis of 26 randomized controlled trails (RCTs), with 5,560 women, letrozole was found to improve live birth and pregnancy rates in subfertile women with PCOS compared to CC.[17] In a more recent double-blind RCT comparing letrozole 2.5 mg and CC 50 mg for anovulatory PCOS, women receiving letrozole achieved statistically higher pregnancy rate of 61%, compared to 43% in the CC group. Letrozole group showed a live birth rate of 48.8%, compared to 35.4% in the CC group. However, the live birth rates were not statistically different between the two treatment groups. This study implied that letrozole may be superior to CC as a primary ovulation induction agent in women with PCOS.[18] A recent systematic review and meta-analysis of 57 trials with 8,082 participants compared the effectiveness of first-line treatment options for anovulation in the WHO group II women.

It was found that compared to clomiphene alone, both letrozole and combination of clomiphene and metformin showed higher ovulation and pregnancy rates. Letrozole was the only treatment with significantly higher live birth rates compared to clomiphene alone.[19]

Side Effects

- Bone pain (20%)
- Hot flushes (18%)
- Back pain (17%)
- Nausea (15%)
- Dyspnea (14%)

Safety

There were safety concerns raised when letrozole was used for ovulation induction, the main being teratogenic and bone loss due to hypoestrogenism.

An abstract presented at the American Society for Reproductive Medicine (ASRM) meeting way back in 2005 eventually led to a ban on letrozole use for ovulation induction in India in 2011.[20] In the years following, good evidence suggested that letrozole is not associated with higher than normal teratogenic risk.

Tatsumi T et al. studied 3,136 natural cycles and 796 letrozole cycles for miscarriage and stillbirth rates, neonatal outcome, and congenital anomalies. The risk of miscarriage was found to be significantly lower in the letrozole cycles. No significant differences were observed in the overall risk of congenital anomalies between natural and letrozole cycles. The study concluded that letrozole reduces miscarriage rates, with no increase in the risk of major congenital anomalies or adverse pregnancy or neonatal outcomes when compared with natural cycles.[21]

Sharma S et al. studied 623 children born to infertile women who conceived naturally or following CC or letrozole induction. Congenital malformations and chromosomal abnormalities were found in 2.9% babies conceived naturally, in 2.5% babies in letrozole group and 3.9% babies in CC group. No statistical difference in overall rate of congenital malformations was found among children conceived naturally or after letrozole and CC induction.[22]

Gonadotropins

Historical Perspective

The word "gonadotropin" is derived from the Greek word, *trope*, which means turning on. In 1920s, with the surgical technique of hypophysectomy in animals, it was realized that removal of pituitary gland led to loss of reproductive function, and that it could be restored by administering exogenous pituitary gland extracts.[23] Zondek described the two gonadotropins extracted from the blood and urine of women as prolan A and B, which are now known to us as FSH and LH, respectively.[24] The first practice of exogenous gonadotropin for ovulation induction was achieved in 1950s with pituitary extracts from cows, swine, and sheep.[25] They were either used alone or in conjunction with pregnant mare serum gonadotropins (PMSGs). Follicular stimulation in women using PMSG was first attempted in 1931. Animal-origin gonadotropin, initially found to be effective, resulted in development of neutralizing antibodies, which rendered the ovaries unresponsive to these hormones over time. Human pituitary gonadotropins were isolated in 1958 and were successfully used to stimulate ovulation. They were forced off the market by mid-1980s after the unfortunate events of death and dementia caused by Creutzfeldt–Jacob disease (CJD).[26] Human menopausal gonadotropins (hMGs) were extracted from the urine of postmenopausal women in 1960s.[27] There was a continuous improvement in the extraction and purification techniques to remove impurities. Despite the best efforts, the active ingredients constituted only 1–2% of the final product. Finally, with the deoxyribonucleic acid (DNA) recombinant technology, recombinant gonadotropins were created, which are extremely pure, highly specific, and have a limitless supply. At present, both urinary and recombinant products are available for use **(Fig. 1)**.

Gonadotropins in Ovulation Physiology

A physiological ovarian cycle involves the growth of a cohort of synchronous primordial follicles to the preantral stage. With the rising FSH levels in the early follicular phase, the follicle most sensitive to FSH enlarges and becomes more and more receptive to FSH. Androgenic substrates are delivered to the granulosa cells, which convert them to estradiol. As the estradiol levels rise, FSH secretion from the pituitary is

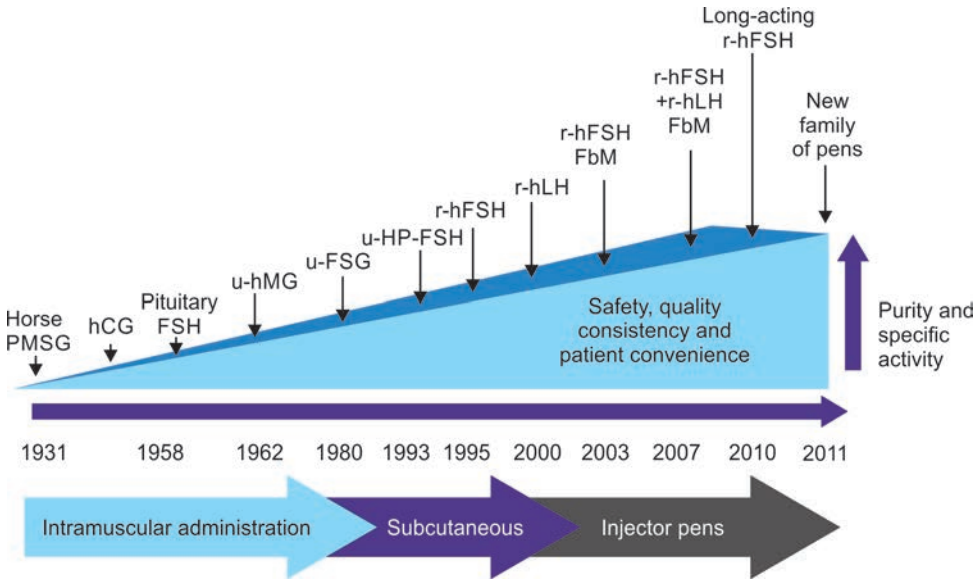

Fig. 1: Evolution of gonadotropins.
(PMSG: pregnant mare serum gonadotropin; hCG: human chorionic gonadotropin; FSH: follicle-stimulating hormone; u-hMG: urinary-human menopausal gonadotropin; u-HP-FSH: urinary-highly purified-follicle-stimulating hormone; r-hFSH: recombinant human follicle stimulating hormone; r-hLH: recombinant human leutinising hormone)

suppressed through a negative feedback. Despite the falling FSH concentrations, the "dominant" follicle continues to grow and develops LH receptors. The rest of the follicles, however, cannot keep pace and stop growing. The dominant follicle prevents the growth of its fellow follicles, maintaining a monovulatory cycle in humans. The use of gonadotropins in IVF, on the other hand, supports the growth of the entire cohort of developing preantral follicles. Of note, the earlier stages of follicle recruitment and development are gonadotropin-independent. Gonadotropins are either used to restore physiological monovulation or to induce superovulation or controlled ovarian hyperstimulation, where all the synchronized follicles are induced to grow to yield 6–10 oocytes.

Role of LH in ovulation: FSH and LH act in concert to complete follicle maturation and ovulation through a menstrual cycle. At 8–12 mm size, follicles develop LH receptors under the influence of FSH. Mid-cycle LH surge induces ovulation, resumption of meiosis, formation of corpus luteum, luteinization of theca and granulosa cells, and early production of progesterone **(Table 2)**.

TABLE 2: Role of luteinizing hormone in ovulatory cycle.

Early follicular phase	*Late follicular phase*

Urinary Menotropins or hMG: Gonadotropin treatment for ovulation induction in anovulatory women began in 1960s and for superovulation in 1980s.

Human menopausal gonadotropin or Menotropin was derived initially from the urine of postmenopausal women from a single nunnery in Italy. The collection was later expanded to various centers worldwide to meet the mounting demand. The earliest preparations were only 5% pure and contained FSH and LH in equal proportions with varying proportions of hCG. hMG preparations contain up to five different isomers of FSH and up to 9 LH isomers. Purification techniques led to the standardization of FSH and LH activity to 75 IU for each type of gonadotropin, but unfortunately, non-gonadotropin proteins such as tumor necrosis factor-binding protein I (TNF-BP-I), transferrin, Tamm–Horsfall protein, and epidermal growth factors (EGF) continued to exist. Despite all the extraction and purification methods, gonadotropin constituted only 1–2% of the final product.[28] The presence of non-gonadotropin proteins causes local side effects such as pain and allergic reactions.[29]

The LH activity of the gonadotropins extracted from menopausal urine is only about one-third of that of the FSH activity in terms of IU, and this makes it necessary to supplement LH activity through hCG derived from the urine of pregnant women to reach an LH:FSH ratio of 1:1. With time, it became clearer that most women needed FSH rather than LH for follicular growth, and consequently, there was a shift toward purer FSH products.

Purified and highly purified FSH: Removal of LH with antibodies resulted in a biologically pure urinary FSH preparation, urofollitropin. With the use of monoclonal antibodies specific to FSH, highly purified FSH (HP-FSH) was produced in 1990s with <0.1 IU LH and <5% of urinary proteins.[30] This HP-FSH was better suited for patients with high endogenous LH, as it was known by this time that FSH

alone could induce folliculogenesis and that LH was also responsible for complications like ovarian stimulation.[31] The enhanced purity and specific bioactivity of HP-FSH made it possible to administer this gonadotropin through subcutaneous route.

Recombinant Gonadotropins

Recombinant DNA technology opened a new horizon for the production of recombinant human gonadotropin. Recombinant gonadotropin were developed by inserting the desired gene sequences for alpha and beta subunits of gonadotropin into expression vectors. These vectors are then transfected into immortalized Chinese hamster ovary (CHO) cell lines. Sereno laboratories produced the world's first recombinant follitropin alpha in 1988 and Organon laboratories produced the first follitropin beta in 1996. Though the names are different, both these FSH preparations contain one alpha and one beta chain. It is the post-translational glycosylation and purification that results in varied sialic acid residue compositions, and hence, different names. The clinical performance, nonetheless, is similar.[32] Follitropin alpha and beta are now available as prefilled pens which deliver a highly precise dose.[33] The FSH content of the recombinant FSH preparations can be quantified as mass in μg, contrary to urinary FSH, whose FSH content is quantified by bioactivity using Steelman–Pohley bioassay.

Recombinant LH (r-LH), Luveris, has been available for clinical use since 1993. It is used to enhance follicular growth with FSH in patients with profound LH deficiency, like that seen in hypogonadic hypogonadism. r-LH has also been found to improve implantation and clinical pregnancy rates when used in combination with r-FSH in patients older than 35 years and women with diminished ovarian reserve.[34]

A combination of recombinant FSH and LH in a ratio of 2:1 is also available as Pergoveris for use in suitable patients. Recombinant hCG is available as Ovitrelle or Ovidrel as 250 μg syringe, which is equivalent to 6,500 IU of hCG.[35]

Recombinant gonadotropins have some advantages over the urinary products in terms of purity, batch-to-batch consistency, limitless source and supply, predictable bioactivity, and safety. However, the pregnancy rates and reproductive outcomes are similar.[32]

Designer Recombinant Follicle-stimulating Hormone

Pushing the envelope of genetic engineering has led to the development of designer recombinant molecules. Long-acting formulation, corifollitropin alpha, or FSH-carboxy-terminal peptide (FSH-CTP) was created in 1992 by Fares FA et al.[36] Recombinant DNA technology was utilized to fuse the CTP of hCG beta-subunit to the FSH beta-subunit, resulting in a hybrid β chain. The resulting FSH analog has identical receptor-binding and biological activities as wild-type FSH (WT-FSH), but an increased circulating half-life. The serum elimination half-life of FSH-CTP is 65 hours, which is twice that of r-FSH.[36] FSH-CTP was designed with the idea of making stimulation more patient-friendly, as a single injection of FSH-CTP gives a sustained FSH level for 1 week.

The latest to be granted marketing authorization in the EU is follitropin-δ (FE 999049) which has been derived from human fetal retinal origin. The amino acid sequences of both subunits are the same as that of natural FSH but the sialic acid content is lower. It has a longer elimination life of 30 hours and induces stronger ovarian response. Follitropin-δ cannot be dosed according to bioactivity or specific bioactivity as other follitropins and is instead dosed by mass (μg).[37]

Orally active small peptides with FSH action are still a distant dream, but if realized, would be a big boon as it would avoid the need for painful injections altogether. One oral FSH agonist has been evaluated in females but it did not produce any follicular development.

Human Chorionic Gonadotropin

The most consistently used gonadotropin in assisted reproduction is hCG. It is used as a surrogate for mid-cycle LH surge. LH is necessary for final oocyte maturation, resumption of meiosis, development of corpus luteum, and production of progesterone. Because of 85% sequence similarity in the β subunit, both LH and hCG bind to the same receptor. Both have a molecular weight of approximately 30 kDa, identical α unit, and high cysteine content. CTP of the β subunit of hCG makes it different and confers a longer half-life due to slower metabolic clearance.[38] Long serum half-life of hCG, a sustained luteotropic effect, multiple corpora lutea development, leading to ovarian hyperstimulation syndrome (OHSS), supraphysiological levels of estradiol and progesterone synthesis leading to implantation failures and early pregnancy loss, and delayed ovulation of small follicles leading to multiple pregnancies are some of the disadvantages of hCG administration as a surrogate for LH surge **(Table 3)**.[39-42]

The minimal effective dose for triggering oocyte maturation and ovulation is 5,000–10,000 IU of hCG. There is no difference between r-LH, recombinant chorionic gonadotropin (r-CG), and urinary hCG in achieving final oocyte maturation, ovulation, pregnancy, and OHSS rates.[43] 5,000–6,000 IU of urinary hCG is equivalent to 250 μg of recombinant CG.[44] It takes around 36 hours for the completion of meiosis, and ovulation happens roughly 4 hours later **(Table 4)**.

Indications[45-50]

- Ovulation trigger
- Follicular stimulation along with FSH
- Luteal support
- hCG priming in in vitro maturation
- Hypogonadal hypogonadism.

TABLE 3: Luteinizing hormone (LH) versus human chorionic gonadotropin (hCG).

Characteristics	*LH*	*hCG*
Molecular weight (Daltons)	28,000	38,000
Secreted by	Pituitary	Embryo and placenta
Accumulation	Slight	Significant with LH receptor downregulation
Equivalence	6–8 IU of LH	1 IU of hCG
Physiological role	Support follicle development and induce ovulation	Support implantation and pregnancy
Potency and receptor affinity	Less	More
Sialic acid carbohydrate residues	1–2	20
β subunit	115 amino acids	145 amino acids
Circulatory half-life	38–60 minutes	6–8 hours

Lutropin beta	0	75	Unknown	Recombinant from transfected CHO cells	SC

(CHO: chinese hamster ovary; FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin; hMG: human menopausal gonadotropin; IM: intramuscular; LH: luteinizing hormone; SC: subcutaneous; IU: international units)

Structure of Gonadotropins

Gonadotropins are composed of an α and a β chain. The α subunit is common to all three gonadotropins and thyroid-stimulating hormones (TSHs), and contains 92 amino acids (A/A) and 10 cysteine residues. It is the β subunit that actually differentiates the hormones.

Follicle-stimulating Hormone

The β subunit of FSH contains 111 A/A and 12 cysteine residues. The molecular weight of FSH is 34 kDa. The carbohydrate content of FSH determines its half-life, proper folding, secretion, target cell-binding, and signal transduction.[51] Human FSH circulates as a mixture of isoforms separated on the basis of charge. The various isoforms differ in their biological activity. The more acidic an isoform, the lower is the receptor-binding and bioactivity, but longer is the half-life.

Luteinizing Hormone

The β subunit of LH compromises of 121 A/A. The molecular weight of LH is 28 kDa.

The initial and terminal half-lives of endogenous LH are 0.6 and 10 hours, respectively and of r-LH are 0.8 and 11 hours, respectively. The pituitary LH is more sulfated and r-LH more sialylated.[52]

Human Chorionic Gonadotropin

The β subunit of hCG contains 145 A/A. hCG has a molecular weight of 38 kDa. The presence of CTP makes the subunit different form the β subunit of LH.

Success Rates and Complications of Using Gonadotropin[53-55]

- The cumulative live birth rates are of the order of 89% after six treatment cycles with gonadotropin.

- The incidence of severe OHSS is <1% and that of multiple pregnancies is 30%.
- The rate of major and minor malformations with the use of gonadotropin was found to be 54.3/1,000, which is similar to that of the general population.

Indications for Gonadotropin Use

- *Gonadotropin for ovulation induction (Fig. 2A)*: Gonadotropins are used for ovulation induction when other simpler, safer, and economical approaches such as CC, letrozole, ovarian drilling, and metformin have failed. Since our aim in ovulation induction is monovulation, low doses of FSH are used. Treatment must be individualized, monitored, and started with the lowest effective dose after a thorough patient counseling. A starting dose of 37.5–75 IU/day is given for at least 5–7 days, and dose increment done only after 7–14 days if ovarian response is not optimum. This is to ensure low rates of OHSS and multiple gestation.[53,56]
- *Gonadotropin for superovulation in intrauterine insemination and controlled ovarian stimulation (COS) in IVF/intracytoplasmic sperm injection (Figs. 2B and C):* The goal of superovulation is to induce more than one follicular development. In COS, the entire cohort of preantral follicles is recruited and stimulated to yield 6–10 oocytes, while controlling the endogenous LH surge by pituitary downregulation. Starting doses of gonadotropin depend on patient's age, ovarian reserve, sensitivity to gonadotropin, and previous ovarian response, if any. Ovarian reserve-guided stimulation protocols significantly improve IVF outcome, while reducing cost and risks. Pretreatment counseling about the potential complications and multiple gestations is warranted.

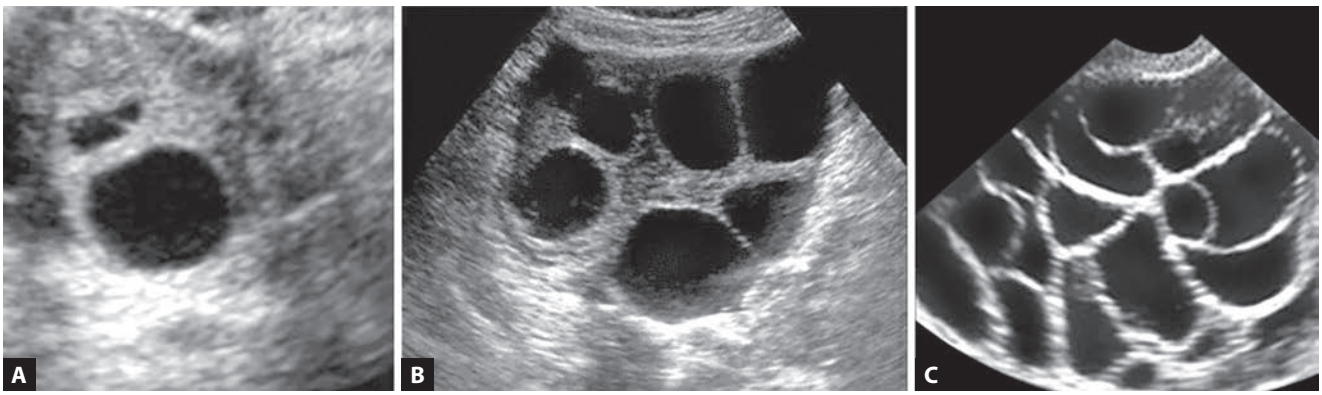
For soft stimulation in IVF, starting doses of 150 IU/day are advocated.[57] La Marca et al. created a model for ovarian stimulation based on age, antral follicle count (AFC), and day 3 FSH. Using the normogram based on age, FSH, and AFC, the most appropriate gonadotropin dose for a woman of 30 years of age with normal day 3 FSH, AFC of 16, or AMH of 4 ng/mL (predicted hyper-responders) is 150 IU/day.[58] Older patients and those with diminished ovarian reserve may require higher doses of 300–450 IU/day.[59,60] Increasing gonadotropin dose beyond a particular limit in such patients does not make the oocyte yield better. On the contrary, high gonadotropin doses worsen the oocyte quality, endometrial receptivity, implantation, and pregnancy rates.[61] Gianaroli et al. found that the number of euploid oocytes is directly proportional to mature oocytes and establishment of clinical pregnancy and inversely proportional to age and the number of FSH units used per oocyte and per mature oocyte.[62]

Indications for Luteinizing Hormone Use in Assisted Reproduction Technology

- Hypogonadotropic hypogonadism
- *r-LH cotreatment with r-FSH for poor responders*: In a systematic review and meta-analysis of 14 trials with 2,612 women, r-LH supplementation to r-FSH was found to have a beneficial effect in poor responders and patients with history of pregnancy loss.[63]
  - *Patients with advanced reproductive age*: Hill MJ et al. evaluated the effect of r-LH in assisted reproduction technology (ART) cycles in patients of advanced reproductive age in a systematic review and meta-analysis. They concluded that implantation and clinical pregnancy rates were higher in the r-LH-supplemented group.[34]
  - *Poor responders*: The benefits of r-LH supplementation in specific subpopulations was confirmed in a large meta-analysis of 40 randomized controlled trials of 6,443 patients treated with either r-LH/r-FSH or FSH only, in women aged 18–45 years or older. Significantly, more oocytes were retrieved in poor responders in the r-LH supplemented group compared to r-FSH alone group. A significantly higher clinical pregnancy rate was seen with the r-LH/R-FSH group.[64]

Gonadotropin-releasing Hormone Analogs

Gonadotropin-releasing hormone, first discovered in 1971, is a decapeptide with a structure that is common to all mammals. Its action is similar in both males and females.



Figs. 2A to C: (A) Ovulation induction; (B) Superovulation; and (C) Controlled ovarian stimulation.

It is released from the hypothalamus in a pulsatile manner, with pulses ranging between 71 minutes in late follicular phase to 216 minutes in late luteal phase.[66,66]

Gonadotropin-releasing Hormone Agonist

Gonadotropin-releasing hormone agonists (leuprolide, triptorelin, and goserelin) are parenterally administered to prevent gastrointestinal degradation. Buserelin and nafarelin are available as extremely effective intranasal sprays, but require very frequent dosing due to rapid elimination. Long-term depot preparations are available for maintaining therapeutic levels for 28–35 days.[67]

Action: With the initial administration, there is an expected flare-up effect increasing gonadotropin secretion. With prolonged use, GnRH receptors are downregulated and internalized via receptor-mediated endocytosis and dissociated.[68] For achieving pituitary suppression, 7–14 days of daily administration is required.

Safety and side effects:[69,70]

- Hot flushes
- Vaginal dryness
- Loss of libido
- Reduced breast size
- Emotional instability
- Significant but reversible bone loss.

Gonadotropin-releasing Hormone Antagonist

Gonadotropin-releasing hormone antagonist (GnRH-ant) acts by directly blocking the receptors competitively and suppressing the gonadotropin secretion from the pituitary within 8 hours of administration. There is no initial flare-up as is seen with the use of agonists. The first- and second-generations of antagonists resulted in histamine release and consequent anaphylactic reactions. The third-generation antagonists that are being clinically used at present and include ganirelix, cetrorelix, abarelix, antarelix, and iturelix have not caused any major local or systemic reactions in thousands of treated patients worldwide. However, nausea, malaise, fatigue, and headache are reported with their use.[71] The highest pregnancy rates are achieved when a daily dose of 0.25 mg of the antagonist is used. Higher dose was found to lower implantation rates due to its possible direct effects on embryos.[72]

A meta-analysis of 45 RCTs with nearly 7,500 women comparing GnRH agonists and antagonists for COS in ART cycles did not show any difference in the live birth or ongoing pregnancy rates but significantly lower incidence of OHSS with the antagonist use.[73] GnRH antagonists are particularly beneficial in anticipated hyper-responders.

Long-acting GnRH antagonist, degarelix, was introduced for prostatic cancer treatment. Its use in ART seems to address the flexibility issue with the antagonist protocols. A single injection in luteal phase is effective enough to promote LH suppression and maintain low estradiol levels.[74]

TABLE 5: GnRH agonist versus GnRH antagonist.

GnRH agonist	***GnRH antagonist***
Receptor blockage	Initial activation followed by downregulation
Competitive inhibition	Desensitization
Dose-dependent immediate suppression	Initial flare-up
Rapid reversibility	Slow reversibility

(GnRH: Gonadotropin-releasing hormone)

Differentiations between GnRH agonist and GnRH antagonist are depicted in **Table 5**.

Deep understanding of the physiology of reproduction and pharmacokinetics and pharmacodynamics of the ovulation stimulant drugs goes a long way in achieving optimum reproductive outcome. Individualized and patient-tailored treatment yields the best reproductive outcome with maximum safety.

Gonadotropins are the most essential and effective drugs for controlled ovarian hyperstimulation and superovulation in ART. The source of gonadotropin does not make much of a difference in the pregnancy rates. However, rational and judicious use of gonadotropins is important for patient safety and good results.

CHAPTER 47

Ovulation Induction and Ovarian Stimulation Protocols

Rutvij Dalal, Sonal Agarwal

OVULATION INDUCTION AND SUPEROVULATION

This section attempts to summarize the latest evidence regarding various agents currently used for ovulation induction. A brief review about the origin of ovulation induction and the relevant physiology is mentioned.

INTRODUCTION

Normal menstrual cycle is under the control of various paracrine and endocrine mechanisms through neuro-endocrine system via hypothalamic-pituitary-ovarian axis (HPO axis). Changes occur both in ovary and uterus, which result in egg production and preparation of endometrium, which is utmost important for reproduction.[1] Induction of ovulation in an-ovulatory women is a landmark achievement in the history of reproductive endocrinology. The last century has seen major advancement in the field of infertility and the discovery of various medical and surgical methods of ovulation induction has changed the face of treatment worldwide. Earlier women who had little hope of normal menstruation can now successfully ovulate and bear children. Ovulation induction is the treatment of choice in anovulatory infertility. Anovulation and oligo-ovulation are the etiological factors for almost 21% of infertile couples. Ovulation induction and superovulation terminology is used interchangeably quite often but these two have different concepts behind it. Ovulation induction is development of a follicle in an anovulatory patient. The aim is to combat any subtle fault in ovulatory function and luteal phase defect (LPD) that are not detected with recent investigations. Superovulation has been useful in conditions such as mild to moderate male factor infertility, transient anovulation, minimal-to-mild endometriosis, cervical factor, and unexplained infertility. It is done in women already ovulating with subtle defects.

CATEGORY OF PATIENTS BENEFITING FROM OVULATION INDUCTION

Patients belonging to WHO class 1 and 2 benefit the most. WHO classification of ovulatory disorders is enlisted in **Box 1**.

WHO type I ovulatory dysfunction (hypothalamic pituitary failure or hypothalamic amenorrhea or hypogonadotropic hypogonadism) are characterized by low gonadotropin levels, low estrogen levels, and normal prolactin levels and account for 10% of all ovulatory disorders. Amenorrhea is present which is un-responsive to progestin challenge test.

WHO type II ovulatory dysfunction (hypothalamo-pituitary dysfunction) comprises of women with gonadotropin disorder and normal estrogen levels accounting for 85% of patients with ovulatory dysfunction. Other causes of anovulation include hyperprolactinemia, hypothyroidism, pituitary tumors, etc. In these conditions, it is always prudent to treat the cause first.

BOX 1: WHO classification of anovulation.[2]

Class 1: Hypogonadotropic hypogonadal anovulation
- FSH low/normal
- Estradiol low
- Pituitary is less or unresponsive to GnRH

Class 2: Normogonadotropic normoestrogenic anovulation
- Pituitary-ovarian dysfunction
- FSH normal
- Estradiol normal
- 70–80% are PCOS, rest are other hyperandrogenic disorders

Class 3: Hypergonadotropic hypoestrogenic anovulation
- FSH high
- Estradiol low
- Suggestive of ovarian failure/insufficiency

Class 4: Hyperprolactinemic anovulation
- High prolactin levels
- Normal FSH
- Low estradiol

Brief Review of Evolution of Ovulation Induction

Before 1960s, treatment of anovulatory infertility was restricted to psychological support and proper timing and frequency of intercourse. In 1961, Greenblatt and colleagues published their first experience of successful induction of ovulation and results with clomiphene. Sixty years have passed and clomiphene still remains the first-line treatment for polycystic ovary syndrome (PCOS) and this simple and inexpensive treatment has resulted in innumerable pregnancies. Gemzell in 1958 and Bettendorf in 1961 achieved a major leap forward with successful induction of ovulation using human pituitary gonadotropins. They were independently able to achieve successful pregnancies in hypophysectomized individuals. In 1963, Lunenfeld and coworkers isolated gonadotropins from urine of postmenopausal women and reached another landmark since this inexpensive source helped in isolating large quantities of the hormone for widespread use. Insler and Lunenfeld were able to achieve pregnancies in large number of amenorrheic women. Gonadotropin-releasing hormone (GnRH) was isolated and synthesized in the laboratory in 1978, but it was Knobil in 1980 who demonstrated its clinical efficacy by pulsatile administration of the drug. Though these were the foremost milestones in the history of ovulation induction, management has indeed come a long way today with advent of controlled ovarian stimulation (COS) and GnRH agonists (GnRHa) and antagonist protocols used in assisted reproduction.

PHYSIOLOGY OF OVULATION

Folliculogenesis and ovulation occur because of a complex interplay between cellular, endocrine, and paracrine factors.[3] Germ cells or oogonia that migrate from the genital ridge to the fetal ovary undergo mitosis and reach their maximum number of 6–7 million at midgestation. Onset of meiosis and follicular atresia result in decline in their number after birth and at puberty only about 300,000 oocytes are left. The final development of ovarian follicles begins about 3–6 months before ovulation. Over a period of 3–6 months these follicles acquire follicle-stimulating hormone (FSH) and luteinizing hormone (LH) receptors and the follicle forms antrum.[4] The antral follicles are dependent on gonadotropins as depicted in **Figure 1**. Oogonia are transformed into primary oocytes after the first meiotic division and are arrested at prophase of the first meiotic division until just before ovulation.

As the levels of estradiol, inhibin A, and progesterone decrease with regression of the corpus luteum in the latter part of the cycle, the concentrations of FSH and LH rise. When this intercycle rise of FSH exceeds the critical level, it activates the largest antral follicles (2–5 mm) present at this time. This activation involves induction of key enzymes like aromatase and appearance of LH receptors. LH stimulates the production of androstenedione from the thecal cells. Androstenedione diffuses into the granulosa cells and are here converted to estradiol by the action of aromatase, the production of which is stimulated by FSH. The emerging dominant follicle produces increasing amounts of estrogen and inhibin A and this induces a negative feedback of FSH. The fall in FSH prevents further recruitment of follicles.

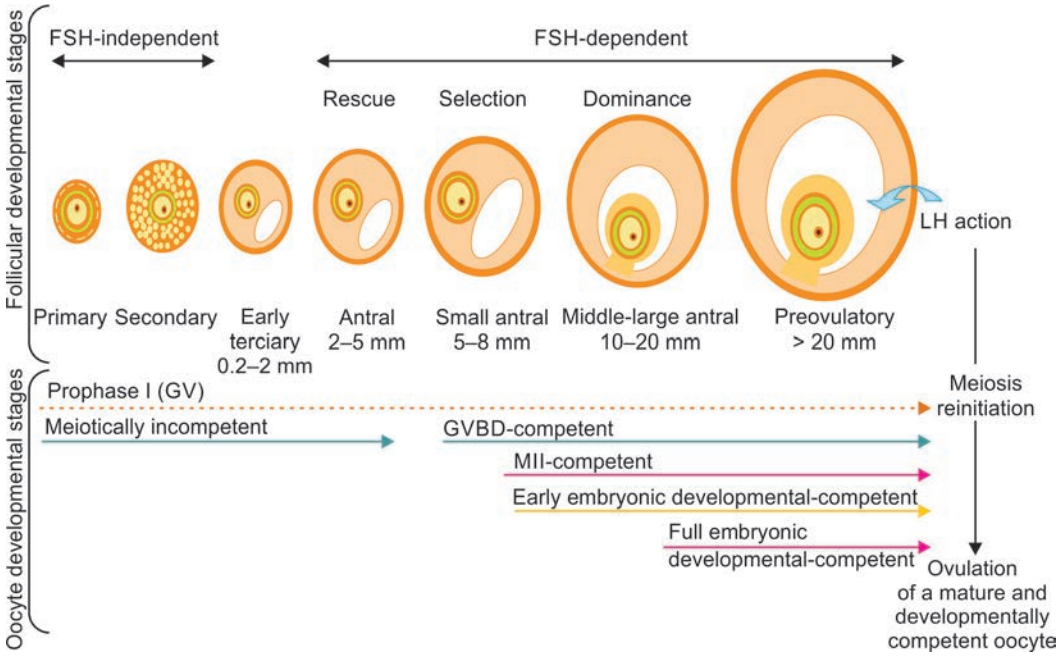

Fig. 1: Folliculogenesis and oogenesis.
(FSH: follicle-stimulating hormone; GV: germinal vesicle; GVBD: germinal vesicle breakdown; LH: luteinizing hormone; MII: metaphase II).

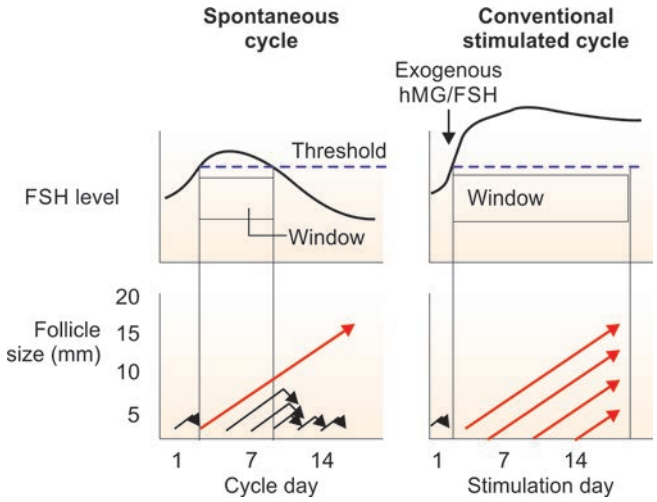

Fig. 2: Follicle-stimulating hormone threshold and window in spontaneous and stimulated cycle.
(FSH: follicle-stimulating hormone; hMG: human menopausal gonadotropin)

BOX 2: Concept of LH threshold and ceiling.[5]

- Suppression of granulosa cell proliferation
- Oocyte development compromised
- Follicular atresia
- Premature luteinization

LH ceiling

Normal follicular growth and development

- Paracrine signaling activated by FSH and LH
- Adequate granulosa cell proliferation

] LH Window

- Functional maturation
- Androgen and estrogen biosynthesis
- Oocyte maturation

LH threshold

No paracrine signaling between granulosa cells and theca cells
Androgen and estrogen biosynthesis hampered
Impaired oocyte maturation
Improper granulosa cell proliferation
Decreased activation of aromatase activity by LH.

As the follicle further acquires LH receptors, it matures and at LH surge, the first meiotic division is completed and it transforms into a secondary oocyte. The two cell-two gonadotropin theory states that FSH concentration must exceed a certain threshold before follicular development will proceed. The duration for which the FSH level exceeds the threshold is called the "FSH window" and it is the short duration of this window in normal ovulation that permits monofollicular selection.

The physiological principles of ovulation induction include either increasing the number of antral follicles available in the ovary at the time of selection, releasing the ovary from inhibitory influences, or by maintaining the level of FSH above the threshold level for longer either by enhancing endogenous gonadotropins or administration of exogenous gonadotropins. This effect is illustrated in **Figure 2**.

Dominant follicle should have LH exposure for particular period of time and concentration for final follicular maturation. LH threshold and ceiling concept has been described in **Box 2**.

MANAGEMENT OPTIONS FOR OVULATION INDUCTION[6]

- Lifestyle modifications in form of diet and exercise
- Medical management with:
  - Antiestrogens
  - Aromatase inhibitors (AIs)
  - Insulin sensitizers
  - Gonadotropins
  - Dopamine agonists
  - Gonadotropin-releasing hormone
  - GnRH agonists and antagonists
- Surgery.

Lifestyle Modification for Obesity-related Infertility

Obesity has been known to have an adverse effect on ovarian function and fertility.[7] Defined as a body mass index (BMI) of over 25 kg/m^2, obesity is associated with lower fertility rates, both at natural conception and ovulation induction; higher doses of ovulation inducing drugs, and higher miscarriage rates.[8] Obesity is also an important arm of the PCOS triad and is seen in 50% of women with PCOS. 80% of obese patients are insulin-resistant as well. These women have a higher tendency to multifollicular response even on low dose FSH and a greater tendency for cycle cancellation and ovarian hyperstimulation.

Obesity evidently expresses and exaggerates the signs and symptoms of insulin resistance. Weight loss can be achieved either through exercise, diet, or both. Studies have shown that a weight loss of just 5–10% through diet or exercise restores reproductive function in 55–100% of individuals within a period of 6 months. Reduction in weight results in a 30% fall in visceral fat restoring ovulation and reducing the markers for metabolic disease. Weight loss in patients with PCOS has been observed to decrease elevated androgen and LH levels, enhance insulin sensitivity, re-establish mono-ovulation, and improve response to ovulation inducing agents.[9]

Exercise helps in weight loss, improving insulin resistance, and restoration of reproductive function. Exercise burns visceral fat more than subcutaneous fat. Aerobic exercise should last for at least 20–30 minutes thrice a week sufficient to cause sweating to be effective. A diet that is low in calorie, fat, and carbohydrate with a low glycemic index is recommended.[10] Thus, weight loss is an intervention that is effective, inexpensive, and without adverse effects. It has an added advantage in decreasing the long-term complications

of diabetes and cardiovascular disease. Since a minimal 5–10% reduction in weight is sufficient to reinstate ovarian function, it should be advised as the first line of treatment in obese subjects. In patients with a BMI more than 28–30 kg/m^2 who would respond poorly to ovulation induction, it is wise to advise weight loss prior to treatment.[11]

Medical Management

Antiestrogens

In normogonadotropic anovulation, administration of small amounts of FSH will induce ovulation. This can be achieved by antiestrogens, pulsatile GnRH or low-dose gonadotropins. Clomiphene citrate (CC) and tamoxifen are the two antiestrogens [SERM (selective estrogen receptor modulator)] used. It is the best treatment for ovulatory dysfunction and normal estrogen levels (WHO type II). Combined with intrauterine insemination (IUI), CC enhances fecundity in unexplained infertility.[12]

Chemical structure and pharmacokinetics: Clomiphene citrate is a nonsteroidal triphenylethylene derivative and a competitive nonselective estrogen receptor modulator. It has both agonistic and antagonistic actions at the level of estrogen receptors (ERs).[13] It binds to the nuclear ER in the hypothalamus for extended periods (weeks rather than hours) and depletes ER concentrations by interfering with the normal process of ER replenishment. It thus blocks the negative feedback effect of estrogen, alters the pulsatile release of GnRH, and stimulates gonadotropin secretion from the pituitary gland. In ovulatory women, it increases the GnRH pulse frequency and in anovulatory women, it increases the amplitude. LH surge occurs when estrogen is secreted from growing follicle.[14] Exogenous hCG is not given in CC- induced cycles.[15]

Pharmacokinetics: Clomiphene citrate has a low clearance rate and has a long half-life of 5 days.[16] It has two distinct isomers: (1) enclomiphene that is more potent and responsible for the ovulation inducing action of CC and (2) zuclomiphene that is less active, longer lasting, and cleared more slowly from the body. The euclomiphene levels rise rapidly and fall to insignificant levels after a few days (**Table 1**). The starting dose of CC is 50–100 mg and CC can be begun from day 2–5 of a normal period or a withdrawal bleed without any impact on outcome. If there is no response in three cycles, the dose is increased as women who do not respond to 50 mg, two-thirds will not do so in the first cycle. The maximum dose should not be more than 150 mg as higher doses do not enhance ovulation and pregnancy rates and only add to side effects. CC treatment generally should be limited to the minimum effective dose and to no more than six ovulatory cycles per attempt and not more than 12 total cycles. Failure to conceive after successful CC-induced ovulation is indication for further evaluation to exclude other contributing causes of infertility. CC is excreted through stools and cleared mainly by the liver.

TABLE 1: Differences between two isomers of clomiphene.[17]

Enclomiphene	***Zuclomiphene***
62% concentration	38% concentration
Antiestrogenic action is more	Less antiestrogenic and more estrogenic
Potency is more than zuclomiphene	Less potent
T1/2 of 2.5–11.8 hours	T1/2 of 14.2–33.4 hours

Caution has to be exerted as CC treatment is futile in women with elevated FSH values, hypogonadotropic hypogonadism, tubal factor, male factor, and uterine factor infertility. It is also prudent to confirm tubal patency before embarking on any ovulation induction regime.

Monitoring response: Response to treatment should be monitored by the measurement of basal body temperature, serum progesterone levels (day 21 and 28), urinary LH levels, or ultrasound.[18] No studies have evaluated the advantage of using more intensive monitoring methods like ultrasound to assess treatment response. But ultrasound when available should be used to monitor IUI cycles and preferably the first cycle to determine the minimum effective dose.[19]

About 20–25% of women fail to ovulate despite maximum doses of clomiphene and this is called "clomiphene resistance". This commonly occurs in obese, hyperandrogenic, and insulin-resistant women with high LH levels. Failure to conceive despite successful ovulation is called "clomiphene failure".[20]

Results with treatment: Ovulation rates following treatment with clomiphene in properly selected patients is usually 70–85% and conception rates are 40–50%.[21] The cycle fecundity in patients who respond to clomiphene is approximately 15%. Three-fourths of the pregnancies reportedly occur in the first three cycles. Cumulative pregnancy rates can be as high as 60% after six cycles and may reach almost 97% after 12 cycles. 20% of pregnancies that occur due to clomiphene may end in a spontaneous abortion and the estimated risk of multiple pregnancies is about 8–13%; majority being twins. The discrepancy between ovulation and pregnancy rates is commonly due to lack of persistence of therapy or other associated causes of infertility. The reasons for the relatively low pregnancy rate are unclear, but may be related to high LH levels, the antiestrogenic effects of clomiphene, and to adverse effects on the oocytes. Because of the long half-life of clomiphene isomers, they may exert an antiestrogenic effect on the quality and quantity of cervical mucus and growth and maturation of the endometrium. These effects are thought to occur with prolonged therapy and at larger doses. Traditionally the antiestrogenic effect of CC on the

endometrium has been implicated to be responsible for the discrepancy in ovulation and pregnancy rates. Successful implantation depends on adequate endometrial thickness and a receptive endometrium. A reduction in endometrial thickness below the minimum, thought to be necessary for pregnancy to occur, was seen in 30% of patients on clomiphene. Another study found the endometrium to be deleterious to implantation in clomiphene-induced cycles because of having a reduction in glandular density and presence of vacuolated cells.[22] Due to the inability to define a minimum endometrial thickness necessary for pregnancy to occur and tremendous individual variability in the antiestrogenic effect of CC, the significance of these effects is difficult to quantify.[23] The antiestrogenic effect of CC on the cervix has been reported to occur in about 15% of cases, and if demonstrated, the adverse effect can be circumvented by IUI.[24]

A systematic review of four cross-over randomized controlled trials (RCTs), that compared CC with placebo in patients with PCOS, found that all doses of CC were associated with increased pregnancy rates per treatment cycle [odds ratio (OR) 3.41, 95% confidence interval (CI) 4.23–9.48] and increased ovulation (OR 4.6, 95% CI 2.84–7.45). Life-table analysis demonstrates upto 22% conception rate.[25-27]

Routine administration of hCG adds little to improving conception rates. It is indicated only when there is an absent or delayed LH surge or for timing IUI or intercourse. Both recombinant and urinary hCG are equally effective though urinary hCG is reported to have more local reactions. Steroids have been tried as adjunctive agents with CC in women with elevated dehydroepiandrosterone (DHEAS) levels (>200 µg/dL). Dexamethasone helps to decrease the adrenal production of androgens and increases ovulation rates by reducing the inhibitory effect of local androgens. It suppresses the action of estradiol on the pituitary gland and increases serum growth hormone and IGF-1 levels. It is usually administered at a dose of 0.5 mg at bedtime for 1 month (low dose), or prednisolone that is administered at a dose of 5 mg. Long standing use of oral steroids demands caution in view of their adverse effects. An increased appetite and weight gain would further deteriorate the metabolic profile of any patient with PCOS. High-dose, short-course regimen has also lately been tried in clomiphene-resistant women but with normal DHEAS levels with successful outcome.[28]

Clomiphene resistance: Failure to ovulate after three cycles of CC treatment with maximum dose of 150 mg is called clomiphene resistance. Resistance to CC treatment occurs in obese, hyperandrogenic, and insulin-resistant individuals with elevated LH levels. Alternatives to management include higher doses of CC, weight reduction, extended CC therapy for 8 days, pretreatment with oral contraceptive pills (OCPs) (to lower LH levels), concomitant use of GnRH agonist to suppress LH, and adjunctive therapy with dexamethasone or insulin-sensitizing agents. Alternative drugs such as AIs and gonadotropins can be tried.[29]

Clomiphene failure: Failure to conceive despite successful ovulation for six cycles calls for seeking other causes for infertility. Combinations and alternative strategies can be attempted. Lack of pregnancy, despite 12 successful ovulatory cycles, in the absence of other causes is usually an indication for assisted reproduction.

Indications of antiestrogens:[8]

- Anovulation
- Luteal phase deficiency
- Unexplained infertility
- Hypothalamic or pituitary dysfunction
- IUI or in vitro fertilization (IVF)—mild stimulation
- Endometriosis—stage 1 and 2.

Prerequisites for clomiphene citrate:

- Male partner evaluation
- History and physical examination
- Age, duration, and cause of infertility
- Normal thyroid and prolactin function
- Normal functioning of pituitary.

Adverse effects:

- Vasomotor flushes are temporary and seen in about 10% of patients. They cease once treatment ends
- Mood swings and nausea
- Blurred vision, double vision, scotoma, light sensitivity, and optic neuropathy (severe and persistent). Visual disturbances (<2%) are mostly uncommon and reversible. In the eventuality of persistent or severe complications, treatment needs to be stopped, and alternative methods should be considered.[12]
- Breast tenderness (2–5%)
- Pelvic discomfort
- Effect on endometrium and cervical mucus[30]
- Multiple pregnancies are lowest with CC. The incidence of multiple pregnancies can be further reduced by ultrasound monitoring and withholding hCG and IUI when there are more than two follicles more than 18 mm. The earlier notion that CC-induced successful pregnancies have a higher incidence of spontaneous abortions has not been proved in any study. Recent reports have shown that abortion rates are not increased compared to normal (20%).[15]
- *Ovarian cancer:* Some case reports and epidemiological studies have suggested an association between epithelial ovarian cancer and fertility drugs. But there is little evidence for an increased risk of invasive epithelial ovarian cancer in women exposed to fertility treatment. Those studies that have found higher rates of the disease report a two-fold increased risk at the most, although this has rarely been statistically significant.

These facts must be viewed in context of considerable methodological difficulties that frustrate these studies. There is a clear need for larger studies employing longer periods of follow-up, detailing precisely the types, doses, and duration of treatments patients have received, and controlling for potential confounding reproductive factors.

- *Ovarian hyperstimulation syndrome (OHSS):* Mild OHSS is relatively common but severe OHSS rarely occurs.

Contraindications:

- Suspected pregnancy
- Hypersensitivity to drug
- Liver failure and dysfunction
- Functional ovarian cysts
- Visual disorders.

Other selective estrogen receptor modulators:

Tamoxifen: Tamoxifen has been useful in patients with anovulation even in failed CC treatment cycles. One recent study has shown comparable results of ovulation and pregnancy rates when efficacy of tamoxifen with that of CC was tested. Some studies suggest superiority of tamoxifen as it has no effect on endometrium.[31] Raloxifene has recently been tried in trials but not in use presently.

Aromatase Inhibitors

The two compounds currently being used for ovulation induction are the selective nonsteroidal AIs namely—letrozole and anastrozole.[32] Aromatase is a microsomal cytochrome P450 hemoprotein-containing enzyme that catalyzes the rate-limiting step in estrogen biosynthesis. Aromatase enzyme activity is found in the ovary, adipose tissue, brain, muscle, liver, and breast tissue.

Three generations of AIs have been developed over the past three decades but the first two-generation drugs were clinically not found useful owing to significant adverse effects and low potency. Generations of AIs are given in **Table 2**. Till recently, they were approved for the use in treatment of postmenopausal breast cancer; but letrozole has been lately approved for use as an ovulation-inducing agent.

Classification:

- *Steroidal:* Competes with endogenous androstenedione and testosterone for P450 causing irreversible enzymatic inhibition.
- *Nonsteroidal:* Competes with endogenous substrates for cytochrome P450 forming a reversible bond.

TABLE 2: Classification of aromatase inhibitors.

Generation	*Nonsteroidal/Reversible*	*Steroidal/Irreversible*
First	Aminoglutethimide	None
Second	Fadrozole	Formestane
Third	Anastrozole/Letrozole/ Exemestane	Exemestane

Aromatase inhibitors are also classified as:

- *First generation of AI:* Induces hepatic enzymes and inhibits cortisol, aldosterone, thyroxine, and aromatase.
- *Second generation of AI:* Potency twice than first generation.
- *Third generation of AI:* Inhibits aromatase enzyme only. Potency is 3–4 times more than that of second-generation AI.

Mechanism of action:

- Aromatase inhibitors block conversion of androgens to estrogens and thus cause an increase in testosterone levels.
- Block inhibitory feedback of testosterone on hypothalamo-pituitary-gonadal (HPG) axis and converts into more potent estrogen without any increase in circulating estrogens and estradiol (E2) receptor modulators.[33]

Letrozole and anastrozole are competitive, potent, and reversible AIs and reduce estrogen levels by 97–99%. They inhibit release of estrogen from various sources, namely ovarian, adipose tissue, and locally produced estrogen in the brain and thus release the hypothalamo-pituitary axis from the negative feedback effect of estrogen.[34] The consequent increase in the release of gonadotropins stimulates follicular growth. Unlike CC, which has a prolonged duration of action and causes depletion of ERs, letrozole does not deplete ERs resulting in intact central feedback. As the dominant follicle grows, it produces estrogen that exerts negative feedback at the center and decreases FSH release. Suppression of FSH secretion results in atresia of smaller follicles and monofollicular growth. Studies have also proposed peripheral mechanisms of action. Inhibition of aromatase in the ovary would result in the temporary accumulation of androgens. It has been postulated that this increased androgen level stimulates follicular growth by increasing its sensitivity to FSH. By decreasing follicular estrogen levels, the ER levels in the endometrium are upregulated leading onto a rapid endometrial growth once the drug is stopped and estrogen secretion resumes. This results in a thicker and more receptive endometrium in patients receiving AIs. In patients with PCOS, FSH production in the early follicular phase may be blunted because of high androgen levels being aromatized to estrogen in the brain and exerting a negative feedback. Thus, AIs may be particularly useful in PCOS patients. A recent study has evaluated expression of HOXA10 and integrin α(v)β(3)

in rat endometrium exposed to either letrozole or clomiphene. This study found that letrozole affects HOXA10 expression but not integrin in uterine endometrium and concluded that clomiphene suppresses endometrial receptivity more than letrozole.[35]

Pharmacokinetics: Letrozole is used in a dose of 2.5–5 mg orally from day 2–3 of the cycle for 5 days. These compounds are completely absorbed after oral administration with a

TABLE 3: To show various evidences on clomiphene and letrozole.

(*: randomized trials; CC: clomiphene citrate; PCOS: polycystic ovary syndrome; L: letrozole)

mean terminal half-life of about 30–60 hours. It is eliminated from the circulation rapidly and do not continue to exert their action after cessation of the drug.

Evidence from controlled studies (Table 3): Theoretically and by earlier studies, evidence emerged that letrozole use is associated with monofollicular response, lower multiple pregnancy rates, thicker and more receptive endometrium, and consequently better pregnancy rates.

Though earlier studies did show a thicker endometrium and a trend toward higher pregnancy rates, evidence accumulating from recently published randomized studies is conflicting. Studies have shown greater follicular number and estradiol levels with CC on the day of hCG and no significant difference in pregnancy rates, endometrial thickness, and ovulation rates.

Aromatase inhibitors have been tried in patients with clomiphene failures either alone or in conjunction with gonadotropins. In patients with CC failures, letrozole alone has shown 75% ovulation rates and 20–25% pregnancy rates. In comparative studies with gonadotropins and letrozole in patients with CC failure or advanced age, gonadotropins have been found to have better pregnancy rates. When used in a sequential regime with gonadotropins, women who received letrozole and FSH had fewer follicles, and E2 levels on the day of hCG, similar or higher endometrial thickness, equivalent pregnancy rates, and lower multiple pregnancy. In comparison with gonadotropins alone, similar pregnancy rates could be achieved with 40–50% lower gonadotropin usage and lower multiple pregnancy rates. Recently one double-blinded randomized trial by Amer et al.,[39] has shown higher pregnancy rates with letrozole as compared to CC but live birth rates were not statistically significant among them.

Indications for use:
- Clomiphene failure cases[40]
- Persistent thin endometrium with clomiphene cases
- Ovarian stimulation in women having breast cancer as it does not cause high estrogen levels but give good oocyte yield.[41]

Advantages over clomiphene citrate:
- No antiestrogenic effect on endometrium and cervical mucus.
- Absence of ER depletion.
- Better uterine blood flow.
- Rapidly eliminated from body due to short half-life of 45 hours.
- Limited follicles.[42]
- Reduced multiple pregnancy rates.[43]
- Decreased chances of OHSS.[44]

Adverse effects:
- Vasomotor symptoms such as hot flushes.
- Nausea and fatigue.
- Alopecia.
- Vaginal bleeding after long-term use in cases of breast cancer.

Contraindications:
- Women at risk of endometrial hyperplasia and endometrial neoplasia.
- Osteoporosis.

Insulin Sensitizers

Insulin sensitizers are discussed in chapter on "Role of Adjuvants in Ovarian Stimulation".

Evidence: Metformin has been better than a placebo for ovulation rate and pregnancy rate in PCOS women, but there was significant statistical heterogeneity in that.[45] Combined analyses of all women demonstrated a benefit of metformin over placebo without statistical heterogeneity for pregnancy rate. Metformin induced more minor gastrointestinal-related adverse events compared to placebo. Metformin therefore improves ovulation and pregnancy rates, but there is currently inadequate data for an effect on live birth rates. It is generally recommended, if using metformin, that doses are initiated at 500 mg daily and increased by 500 mg daily every 2 weeks. There is considerable controversy over when metformin should be ceased, if pregnancy occurs. In general, there is inadequate evidence to support continuing metformin following conception with more research needed. There was no benefit of metformin over CC for live birth rate, and CC was better than metformin for live birth rate in those with a BMI more than or equal to 30 kg/m^2. Metformin, therefore, did not result in improved reproductive outcomes compared to CC.

Current evidence-based guidelines recommend intensive lifestyle modification, particularly in those with a BMI more than or equal to 30 kg/m^2, including frequent multidisciplinary engagement for 3–6 months as first-line therapy—level of evidence 1B. This recommendation was underpinned by RCTs, which found that there was no benefit of metformin over lifestyle.

Gonadotropins

Exogenous gonadotropins are used in the treatment of WHO type-I infertility and WHO type-II infertility who have failed to conceive with antiestrogens despite ovulation (clomiphene failure) or have failed to ovulate with CC (clomiphene resistance). Gonadotropins are more effective than CC but are expensive, require parenteral administration, and have higher risk for ovarian hyperstimulation and multiple pregnancies. The principle of gonadotropin induction of ovulation is to mimic the normal physiological cycle of follicular selection, maturation, and ovulation. To use gonadotropins successfully for ovulation induction requires a sound knowledge of the normal endocrinologic processes that govern ovulation. Ovarian hyperstimulation, multiple follicular developments, and multiple pregnancies are serious complications that could occur with uncontrolled stimulation.

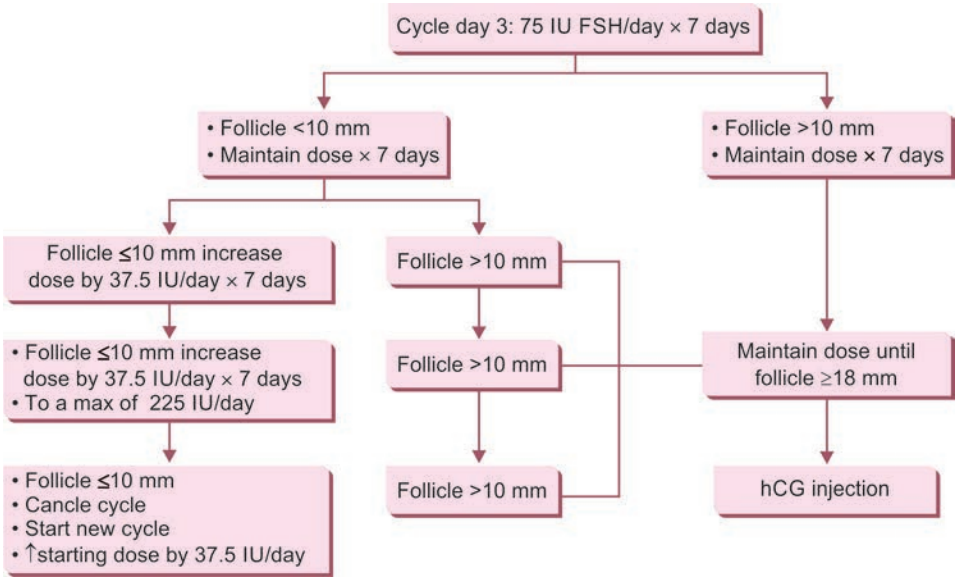
As mentioned earlier, it is the duration of the "FSH window" during which the FSH levels are above the threshold required to stimulate the growing follicles that determines the number of follicles that will be recruited. The essence of monofollicular achievement in gonadotropin induction of ovulation is to identify that FSH threshold dose that results in the selection of a single follicle. Administration of an FSH dose higher than the threshold for a period of time inevitably results in multifollicular recruitment. Earlier higher dose conventional gonadotropin stimulation was in vogue but had associated with it a higher incidence of hyperstimulation and multiple pregnancies. It involved starting with a dose of 2 ampoules (150 IU) of gonadotropins and increasing the dose every 3–5 days by 75 IU. Though ovulation rates were high, this regime was associated with high complication rates. Currently used protocols are—low-dose step-up regime, step down, or sequential regimen.

These aim to increase the FSH concentrations gradually to reach the threshold level and at the same time avoid an explosive ovarian response.

Low-dose step-up protocol: This has been the preferred method of gonadotropin induction in PCOS patients. This is based on a threshold concept that initiation of follicular growth requires only a 10–30% increase in dose of exogenous FSH. This small dose increase is done at weekly intervals. This protocol begins with 75IU daily for 7 days as low starting dose.[46] An ultrasound is done at the end of 1 week and if the dominant follicle is more than 10 mm in diameter, the same dose is continued and if it is less than 10 mm, the same dose is maintained for another week. At the end of the second week, if the follicular size is still less than 10 mm, the dose of gonadotropin is increased by half ampoule weekly up to a maximum of 225 IU/day **(Flowchart 1)**. This regime has the disadvantage that it is prolonged and requires multiple injections. But studies have shown that it maintains fair pregnancy rates (20%) and incidence of complications like multiple pregnancies (6%) and OHSS (0.14%) are low.

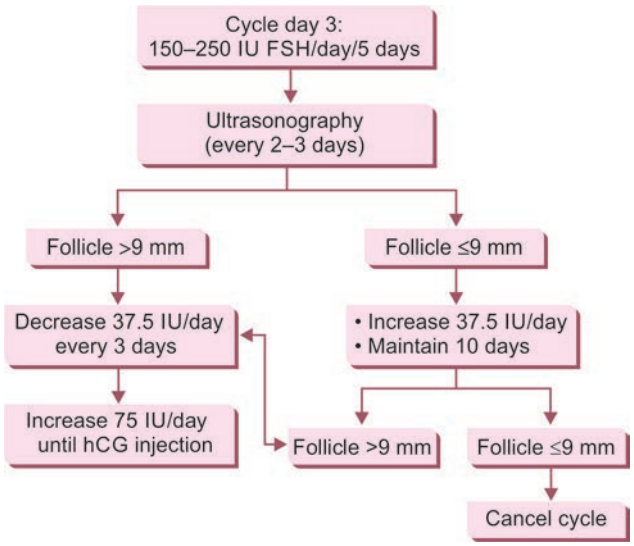
Step down protocol: This protocol aims to mimic the normal physiological rise of FSH in the early follicular

Flowchart 1: Chronic low-dose step-up protocol.



(FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin)

Flowchart 2: Step down protocol.



(FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin)

phase and subsequent decreasing dependence of the dominant growing follicle toward FSH. The starting dose is higher than the step up protocol and once a follicular response is seen on ultrasound, the dose is reduced to a baseline level that is persisted with till it reaches 18 mm. This protocol warrants experience and judgment to determine the effective starting dose that should neither be administered high or long enough to stimulate multifollicular growth. It thus calls for more stringent monitoring. The duration of treatment is smaller. It is depicted in **Flowchart 2**.

Oral ovulogens when used with gonadotropins, they result in almost equivalent pregnancy rates as gonadotropins alone and have the advantage of reducing gonadotropin use by 45–55%, lower cost per cycle, and no antiestrogenic side effects.[47]

Dopamine Agonists

Study and understanding of pathophysiology of OHSS has explained the use of cabergoline as dopamine agonist. It reduces vascular permeability, hemoconcentration, and ascites. With proper informed consent, it can be used in high risk situations.[48]

Mechanism of action: Dopamine agonists decrease receptor expression for vascular endothelial growth factor (VEGF) which is responsible for causing OHSS.[49]

Dosage and risks: It should start on day of trigger at a dose of 0.5 mg daily for 8 days. No significant risk is seen with administration for 8 days at low dose. Most common side effects are headache, nausea, and dizziness. With long-term treatment, valvular heart disease was rarely observed with doses higher than 0.5 mg with incidence of 3/1,000 cases.

Gonadotropin-releasing Hormone

Pulsatile GnRH therapy can be given when pituitary gland is present in women, idiopathic hypogonadotropic hypogonadism, and weight loss-related amenorrhea. It can be given with computerized mini-pump at pulse intervals of 60–180 minutes. More than 90% ovulation rates can be achieved after six cycles. Incidence of multiple pregnancy rates is about 17.4%.

Disadvantages:

- Pump needs to be connected to the body at all times.
- Development of antibodies.
- Allergic skin reactions.

Gonadotropin-releasing Hormone Analogs

Structure, preparations, and mechanism of action is been dealt in the chapter on "Gonadotropin-releasing Hormone Analogs". They are seldom used for ovulation induction treatment.

Surgical Methods

Stein and Levinthal in 1935 first performed ovarian wedge resection in infertile patients with PCOS. Though it was followed by promising results, the procedure was soon abandoned in view of extensive postoperative adhesions, tissue loss, and emergence of easier medical methods for ovulation induction. The introduction of minimally invasive surgery or laparoscopy created resurgence of interest in surgical methods. The process of laparoscopic ovarian drilling has been controversial and evolving and its current status must be evaluated in the context of newer theories of pathogenesis of PCOS, newer definition of the disease, and the growing popularity of insulin sensitizers.

The first-line of treatment in PCOS still remains CC or letrozole. Options to treat women who are clomiphene resistant are insulin sensitizers, ovarian drilling, and gonadotropic induction. Ovulation induction with gonadotropins is expensive, requires experience since response can be explosive in later stages and is associated with higher rates of multiple pregnancies. Ovarian drilling relatively is a more invasive procedure and is associated with irreversible complications like adhesion formation and poor ovarian reserve.

Laparoscopic ovarian drilling with either electrocautery or laser causes reduction in the volume of ovarian stroma and reduction in androgen production. This leads to lesser peripheral aromatization and elevated FSH levels and re-establishment of HPO axis. Controversies continue to persist as to whether electrocautery is better than laser; the type of laser preferred the number of holes per ovary, duration, strength, and nature of current to be used. In a review by Saleh et al., in 2004 involving 18 articles, the authors concluded that there was no difference in rates of ovulation between electrocoagulation and laser. This topic has been explained in detail in chapter on "Polycystic Ovarian Syndrome".

STIMULATION PROTOCOLS IN ART

INTRODUCTION

The first successful human IVF was a natural cycle IVF. Soon, there was a shift to ovarian stimulation to get an increased number of oocytes, embryos, and thus improve the pregnancy rates. The goal of assisted-reproductive technique (ART) is mainly to achieve a live birth safely in a patient friendly but at the same time in a cost-effective manner.

The concept of COS for multiple follicular developments is to generate multiple embryos and increase pregnancy rates.[6] Number of oocytes directly correlates with ongoing pregnancy rates but patients may not respond similar to each other with same protocol. This has brought the concept of individualized controlled ovarian stimulation (i-COS).[50]

INDIVIDUALIZING APPROACH TOWARD PATIENT FOR COS

Recently, a joint venture of discussion amongst American Society for Reproductive Medicine and the European Society of Human Reproduction and Embryology (ESHRE) has given the concept of "patient-tailored stimulation". It should be a result of shared-decision making (SDM) process. In expert committee opinion, Dr Politi[51] told that SDM is important in situations where decisions are being made between treatment options with "similar outcomes from a medical standpoint" and patients' preferences for the possible risks and benefits. Decision making help is provided to assist patients decide their treatment regarding number of embryos to be transferred but no such aids are still there for deciding the approach to COS.[52]

Objectives of I-COS

- Tailoring of protocol for each woman separately with no compromise on the quality.
- To achieve a sufficient number of fertilizable oocytes of good quality so that at least two or three superior quality embryos can be selected for transfer and the remaining embryos can be cryopreserved for a subsequent freeze-thaw cycle.
- To avoid multiple pregnancy.
- Eliminate risk of OHSS as it is iatrogenic cause.
- Reduce risk of cycle cancellation to minimal rate.[53]
- Increase the pregnancy rate.
- Endometrial environment should be suitable for implantation.
- Appropriate plan and calculation of dosage for expected poor responders.
- Drop-out rates and costs should be as less as possible to reduce financial burden of patients.

In this era of personalized medicine, moderate ovarian stimulation targeting 8–15 oocytes is the best way to optimize IVF outcome safely.

TABLE 4: Markers of ovarian response.

Clinical	*Investigational*
Age	FSH
Smoking status	AMH[54]
Menstrual cycle	AFC[55]
BMI	Ovarian volume
Previous response to stimulation	
PCOS	

(AFC: antral follicle count; AMH: anti-Müllerian hormone; BMI: body mass index; FSH: follicle-stimulating hormone; PCOS: polycystic ovary syndrome)

Factors which decide personalized approach are:

- Availability of different drugs and options of making small changes of even 12.5 IU for decision of optimum dosage for a patient.
- Embryology laboratory conditions.
- Endocrine and clinical profile of the couple.
- Ovarian response markers **(Table 4)**.

The International Society for Mild Approaches in Assisted Reproduction (ISMAAR) has given a physiological, lower risk, lesser drug-oriented and more patient friendly approach. Main emphasis in this classification has been given on clinical aspects of assisted reproduction.[56] Recent trials have shown comparable results of mild stimulation versus conventional stimulation protocols. This approach will help to promote mild, affordable, and safe techniques.[57] Concerns related to poor oocyte and embryo quality with conventional stimulation and its effect on endometrial function can be dealt in a better way. The ISMAAR consensus on terminology of stimulation for IVF is given in **Table 5**.

Classification of Patients According to Their Ovarian Response

- *Normal responder:* 8–15 follicles/eggs.
- *Poor responder:* 1–4 follicles/eggs.
- *Hyper-responder:* Not more than 15 follicles/eggs.

Number of eggs in IVF is a surrogate for clinical success. Results in study by Sunkara et al.,[58] has shown a nonlinear relationship between the number of eggs and live birth rates. The number of eggs to maximize the live birth rate is ~15, plateaus between 15 and 20, and declines beyond 20 eggs. Depending on clinical characteristics and ovarian response,[59] they can be divided into three types **(Table 6)**.

Two separate consensuses are there for poor responders. ESHRE consensus gave Bologna criteria for poor responders having following features:[60]

Two of the following three features must be present:

1. Advanced maternal age more than or equal to 40 years or any other risk factor for poor ovarian response.
2. A previous poor ovarian response less than or equal to three oocytes with a conventional stimulation protocol.

TABLE 5: ISMAAR consensus on stimulation for in vitro fertilization.

Terminology	*Aim*	*To replace*	*Method used*
Natural cycle IVF	1 oocyte	No stimulation	No medication
Modified natural cycle IVF	1 oocyte	Semi-natural, controlled natural cycle IVF	hCG only
Mild IVF	2–7 oocytes	Soft minimal stimulation, "friendly" IVF	Low dose Gn, oral ovulogens and GnRH antagonist
Conventional IVF	>/=8 oocytes	Standard, routine IVF, COS IVF	GnRH agonist or antagonist with conventional hMG/FSH dose

(COS: controlled ovarian stimulation; FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropin; GnRH: gonadotropin-releasing hormone; hMG: human menopausal gonadotropin; IVF: in vitro fertilization)

TABLE 6: How to identify different types of ovarian response.

Poor responder	*Normal responder*	*Hyper responder*
Regular or short cycles	Regular cycles	Regular/irregular cycles
Obese/thin	Normal built	Thin or obese built
Age >37 years	Age <37 years FSH <12 mIU/mL	Age <37 years
FSH >12 mIU/mL	AMH 1.5–3.5 ng/mL	LH/FSH >2 mIU/mL
AMH <5–1.4 ng/mL	AFC 8–15	AMH >3.5 ng/mL
AFC <8	Previous normal response to stimulation	AFC >15
Previous poor response to stimulation		Previous hyper-response to stimulation

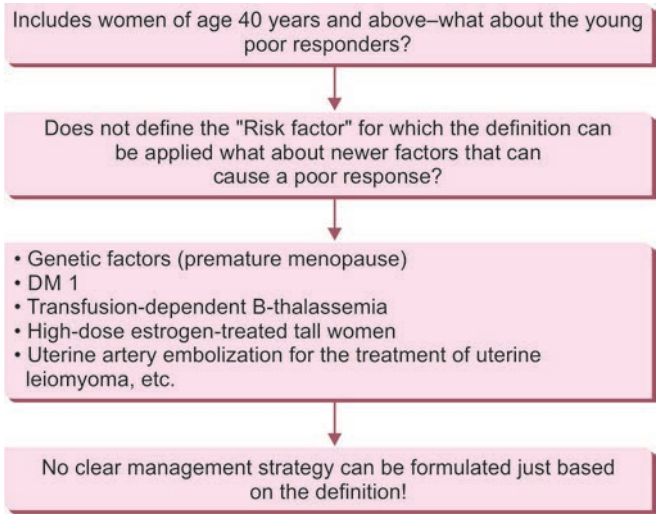
(AFC: antral follicle count; AMH: anti-Müllerian hormone; FSH: follicle-stimulating hormone; LH: luteinizing hormone)

3. An abnormal ovarian reserve test [antral follicle count (AFC) <5–7 follicles or anti-Müllerian hormone (AMH) <0.5–1.1 ng/mL].

But this criterion had many shortcomings[61] and pitfalls **(Flowchart 3)**. After years of criticism, the Bologna criteria was not appropriate and thus came the second stratification by Patient-Oriented Strategies Encompassing IndividualizeD Oocyte Number (POSEIDON) group in patients with reduced ovarian reserve or unexpected sub-optimal ovarian response to exogenous gonadotropins.[62] Four groups have been made based on both qualitative and quantitative parameters **(Fig. 3)**. Management of all four groups based on their parameters is given in detail in chapter on "Poor Responders".

Identification of protocols based on reserve parameters is described in **Table 7**.

Flowchart 3: Criticism of Bologna criteria.



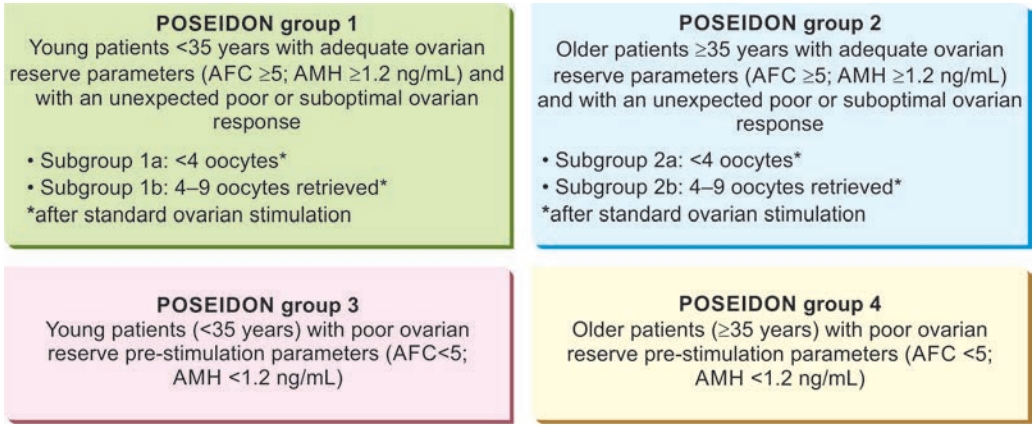


Fig. 3: Four groups of "low prognosis patients" in assisted reproductive technology according to the POSEIDON's stratification based on oocyte quantity and quality.
(AFC: antral follicle count; AMH: anti-Müllerian hormone)

TABLE 7: Identification of protocol based on reserve parameters.

Parameters	*Principle*	*Protocol/adjuvants*	*Gonadotropin dosage*	*Advantages/disadvantages*
AMH</-0.1 AFC 0–2	Very low reserve so less chances of follicles	Minimal/mild Pretreatment with: • Androgens (DHEA 75 mg/day 3 months before) • Testesterone gel previous month 12.5 mg. Sunkara meta-analysis.[63] Both these interventions do not improve outcome • E2 priming or antagonist in previous luteal phase (crash protocol) for synchronous cohort in a systematic review and meta-analysis by Bosdou et al.[64] Transdermal testosterone pretreatment seems to increase clinical pregnancy and live birth rates in poor responders undergoing ovarian stimulation for IVF. There is insufficient data to support a beneficial role of rLH, hCG, DHEA, or letrozole administration in the probability of pregnancy in poor responders undergoing ovarian stimulation for IVF. Growth hormone supplementation (Cochrane Duffy et al)[65] Increases pregnancy rate OR: 5; Dose: 4–8 IU daily from day 2 till hCG	150–225 IU	• Less cost • Better quality as compared to quantity • Better compliance • Less success
AMH 0.7–1.3 AFC 5–7	• Downregulation may cause profound suppression • Self phase FSH and LH to be utilized	Antagonist/short flare	300 IU	• Higher success rates with antagonist protocol • Substantial reduction in cancellation rates • Agonist trigger can be used • Increased yield • Compliance good
AMH 1.4–3.5 AFC 8–14	As reserve is good, will respond to either of the protocol	GnRH downregulation/antagonist	225 IU	• Good yield • Decision depends on patient compliance
AMH >3.5 AFC >15	Risk of OHSS, so to keep the option of agonist trigger open	Antagonist • Metformin (1500–2000 mg/day)— increased clinical pregnancy rates and decreased risk of OHSS (Tso, 2014)[66] • Addition of dopamine agonist in the luteal phase	150 IU	• Less days of stimulation • Decreased chances of OHSS • Higher pregnancy rates

(AMH: anti-Müllerian hormone; AFC: antral follicle count; DHEA: dehydroepiandrosterone; E2: estradiol; rLH: recombinant luteinizing hormone)

INDIVIDUALIZATION OF GONADOTROPIN PREPARATION AND DOSAGE

Different preparations of gonadotropins are given in **Table 8**.

- *Normoresponders:* Highly purified (Hp) human menopausal gonadotropin (hMG) or recombinant (r) FSH should be used.
  - Less than 30 years: 75 IU
  - 30–35 years: 150 IU
  - More than 35 years: 225 IU
- *Poor responders:* Hp hMG or rFSH + rLH should be used.
  - Less than 30 years: 225 IU
  - 30–35 years: 300 IU
  - More than 35 years: 300–450 IU

TABLE 8: Gonadotropin preparations.[67]

Gonadotropin preparations	*Contents and properties*
hMG	FSH and LH are present in equal proportion
uFSH	FSH with nongonadotropin protein content of >95%
Pure FSH	FSH with nongonadotropin protein content of <5%
Recombinant FSH	High purity and does not have LH activity
Recombinant LH	High purity and greater specific LH activity
Corifollitropin alfa[66]	Subcutaneous depot preparation, sustained long half-life

(FSH: follicle-stimulating hormone; hMG: human menopausal gonadotropin; LH: luteinizing hormone)

- *Hyper-responders:* rFSH should be used.
  - Less than 30 years: 75 IU
  - 30–35 years: 75 IU
  - More than 35 years: 150 IU

To start or add LH in the following circumstances:

- Advance age more than 35 years
- Poor responder
- Plateau response on day 6.

After the introduction of GnRH antagonists and strategies to reduce multiple births such as single embryo transfer, now there is a developing interest in natural cycle and mild stimulation in IVF. Natural and mild IVF are patient friendly, cost-effective, and reduce patient discomfort and multiple pregnancies.

Models for Predicting Dose of Gonadotropins

Many models are there which combine different parameters of age, ovarian reserve, hormonal parameters, ultrasound findings, BMI, and smoking status. Popovic-Todorovic et al., model included age, AFC, smoking status, and ovarian stromal blood flow. La Marca et al., model has used age, AFC, and AMH to predict response to gonadotropin dose. Pivot et al., model has included AMH, AFC, age, BMI, and smoking habits. This normogram has helped in making even very small dose changes in the stimulation protocols.

Which Gonadotropin is Better?

The rFSH is more potent than urinary hMG or FSH preparations.[68] The rFSH produces significantly more oocytes than urinary with lower doses and shorter time.[69] In a study by Peter Plateau et al. (merit study), the findings of this integrated analysis demonstrated that ovarian stimulation with Hp-hMG, following a long downregulation protocol, in IVF cycles results in significantly more live births than stimulation with rFSH alone. In the Cochrane review by Van Wely M,[70] there was no evidence of a difference in live births when rFSH was compared with FSH-P or when rFSH was compared with FSH-Hp. Thus, the clinical choice of gonadotropin should depend on availability, convenience, and costs. Differences between urinary gonadotropins were considered unlikely to be clinically significant.

DIFFERENT PROTOCOLS FOR STIMULATION

- *Agonist protocols:*
  - Long protocol
  - Stop protocol
  - Short protocol
  - Ultrashort protocol
  - Microflare
- *Antagonist protocol:*
  - Fixed
  - Flexible
- *Mild stimulation protocol*
- *Special cases:*
  - Ultra long protocol
  - Double stimulation protocols
  - Stair step and chronic low-dose step-up protocols.

GONADOTROPIN-RELEASING HORMONE AGONIST

The introduction of GnRHa in the late 1980s was a great boon in the field of ovarian stimulation in ART. They provided the ability to downregulate endogenous pituitary gonadotropin secretion and thereby prevent a premature LH surge during exogenous gonadotropin stimulation.

Mechanism of Action

The GnRHa molecule is derived from the native GnRH by amino acid substitution at 6th and 10th position, which leads to an increase in FSH and LH. It has a flare effect lasting for 5–7 days and on continuous administration, there is suppression of the HPO axis because of receptor downregulation and desensitization, thus decreasing the circulating levels of gonadotropins and sex steroids and finally receptor internalization occurs.

Route

They are available as daily injections, depot preparation (monthly or 3 monthly), and nasal sprays (multiple daily doses, which mimic the natural pulses). They can be administered intramuscular (IM), subcutaneous (SC), or intranasal. SC route is the most commonly used. Daily SC injections are preferred for use in IVF. However, depot preparations (leuprolide 3.75 mg, goserelin 3.6 mg or 11.8 mg) are used in patients with endometriosis prior to IVF for downregulation. **Tables 9 and 10** illustrate various preparations and their half-lives.

Uses

- Pituitary suppression prior to ovarian stimulation
- Used as trigger in antagonist protocol or in modified natural protocol.

TABLE 9: Gonadotropin-releasing hormone agonist preparation.

Nonapeptides	***Decapeptides***
Leuprolide[71]	Nafarelin
Buserelin	Triptorelin (Decapeptyl)
Goserelin (Zoladex)—only available as a depot	
Histrelin	
Deslorelin (not been used in human in vitro fertilization)	

TABLE 10: Bioavailability and half-life of different agonist preparations.

Drug	*Bioavailability*	*T max*	*Half-life*
Leuprolide	94%	2–6 hours	3 hours
Decapeptyl	100%	45 minutes	3–5 hours
Cetrorelix	85%	1 hour	5 hours
Ganirelix	91%	1–2 hours	13 hours

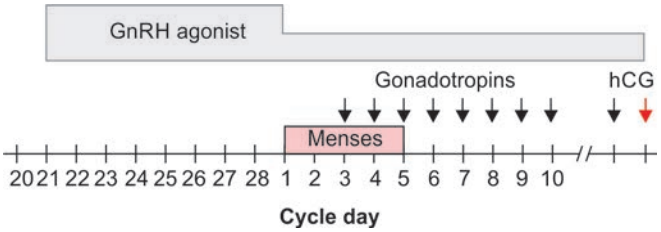

Fig. 4: Long protocol.

- Prevention of premature LH surge
- Luteal phase support (LPS)
- Prevention of OHSS
- Breast cancer patients
- Central precocious puberty
- Endometriosis
- Fibroids
- Hirsutism.

Advantages

- Synchronization of follicular growth
- Flexibility in IVF programming
- Favors batch IVF
- *Abolition of spontaneous LH surge:* A meta-analysis of RCTs has shown that the use of GnRHa has not only reduced cancellation rates but has also increased the number of oocytes and embryos, allowing better selection so that, on an average, the outcome in terms of pregnancy rates was improved.
- Less expensive than antagonist.

Disadvantages

- Less "patient friendly"
- Stressful due to longer treatment cycles (3–4 weeks for GnRHa)
- Less safe
- Increased gonadotropin doses
- Only hCG can be used as trigger
- Increased risk of OHSS
- Overall costly due to increased gonadotropin usage
- Slow follicular growth
- Luteal phase defect.

Side Effects

- Hot flushes
- Vaginal dryness
- Transient frontal headaches
- Arthralgia
- Myalgia
- Insomnia
- Headaches
- Loss of libido
- Hypoestrogenic state
- Excessive suppression.

PROTOCOLS FOR AGONIST

Long Protocol (Fig. 4)

It is the first protocol used to prevent premature LH surge. It was the gold standard till the introduction of GnRH antagonist. The GnRHa is started in the midluteal phase of the preceding menstrual cycle or in the early follicular phase, but the time required to achieve pituitary downregulation is longer and the prevalence of cystic follicles is higher in the latter. No evidence of a significant difference between depot and daily GnRHa use for pituitary downregulation in IVF cycles using the long protocol is there, but substantial differences could not be ruled out.[72] Since depot GnRHa requires more gonadotropins and a longer duration of use, it may increase the overall costs of IVF treatment. Injection lupride 1 mg is started from midluteal phase of the preceding cycle for 10 days or until the onset of menses.

To confirm downregulation:

- Ultrasonography (endometrial thickness of less than 5 mm and no cysts more than 10 mm)
- Serum estradiol levels less than 50 pg/mL
- Serum LH less than 5 mIU/mL
- Serum progesterone less than 0.5 ng/mL.

Exogenous gonadotropins and GnRH agonists (reduced dose of GnRH agonists in mini dose long protocol) are continued till the day of hCG administration. The goal is to have at least two follicles measuring 17–18 mm in mean diameter, ideally with a few others in the 14–16 mm range when the hCG trigger of 10,000 IU is given to achieve final follicular maturation. A Cochrane review by Maheshwari et al.,[73] concluded that the number of oocytes retrieved and the pregnancy rate was higher in the long protocol. There was no difference in the live birth rate; however, this outcome is reported in only three studies. There was no evidence of a difference in the outcomes among various long protocols; nor that stopping or reducing GnRHa at the start of stimulation were associated with a reduced pregnancy rate. Comparison was long protocol versus short or ultrashort protocol.[74]

Disadvantages

- Increased dose of gonadotropins
- Increased overall cost
- Increased chances of OHSS in hyper-responder

- Luteal phase support also needs to be given
- Profound pituitary suppression
- Functional cyst formation—combined OCP and agonist prevents cyst formation.

Stop Protocols

It has two types of protocols namely menstrual early cessation and follicular early cessation protocols as depicted in **Figures 5 and 6**.

Short or Flare Protocol (Fig. 7)

Rationale

The flare effect of the agonist releases the stored FSH and LH, which augments the folliculogenesis, which has already been started. Main use is in poor responders.

Disadvantages

The flare effect causing the surge of LH in the initial phase of folliculogenesis may have adverse effects on the developing follicles. Also, this is commonly associated with significant increases in serum progesterone and androgen levels, which may be due to the late corpus luteal rescue. This may be deleterious to the oocyte and may hamper the fertilization and pregnancy rates.

Microdose Flare Protocol (Fig. 8)

Pretreatment with OCPs for 14–21 days should be done in the preceding cycle.[75] Injection leupride 40 μg twice a day from day 2 of withdrawal bleed is given till day of hCG trigger. Gonadotropin stimulation 300–450 IU/day started from day 3 of withdrawal bleed till day of hCG trigger (criteria for hCG trigger same as that for long protocol).

Advantages

No increase in serum progesterone or androgen because:

- Decreased GnRH agonist dose.
- The preliminary OCP pretreatment.

This protocol may be useful in previous poor responders in whom it has been observed to stimulate increase in serum FSH (not attributable to exogenous gonadotropin treatment)

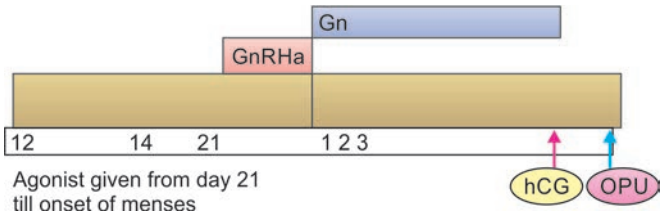

Fig. 5: Menstrual early cessation agonist protocol.

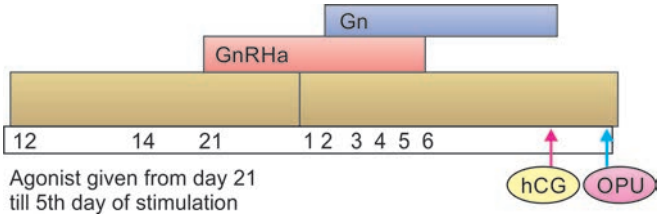

Fig. 6: Follicular early cessation agonist protocol.

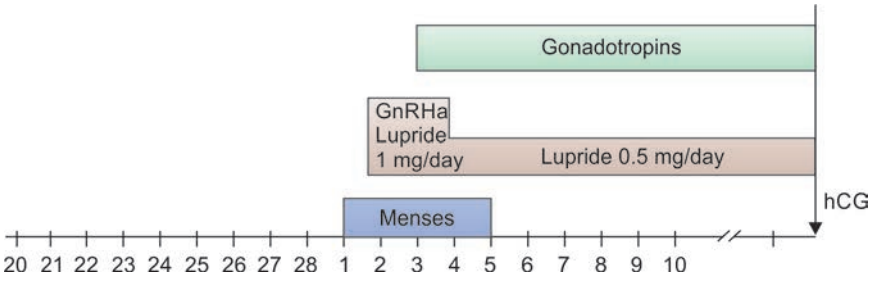

Fig. 7: GnRH agonist short protocol.
(GnRHa: gonadotropin-releasing hormone agonist; hCG: human chorionic gonadotropin)

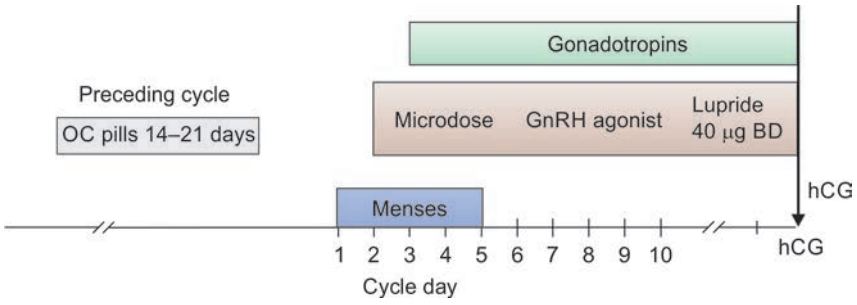

Fig. 8: Microdose Flare protocol.
(GnRH: gonadotropin-releasing hormone; hCG: human chorionic gonadotropin; OC: oral contraceptive)

and lower cancellation rates and good clinical and ongoing pregnancy rates. Long GnRH agonist and antagonist regimens offer a suitable choice for poor responders, whereas the short agonist regimen may be less effective because of fewer eggs retrieved.[76]

Ultrashort Protocol

In this protocol, the GnRHa is administered only for 3 days. The short regimens have the advantage of a shorter duration of stimulation, with the use of fewer ampoules of gonadotropins and therefore lower costs.[77]

Safety of GnRH Agonists

Lahat et al.,[78] reported a high incidence of attention deficit hyperactivity disorder (ADHD) in long-term follow-up of children inadvertently exposed to GnRH agonists in early pregnancy.[12]

GONADOTROPIN-RELEASING HORMONE ANTAGONISTS

The GnRH antagonists earlier were not very popular because of their histamine releasing capability and associated systemic edema.[79] However, the development of third generation antagonists—cetrorelix and ganirelix was a major breakthrough in the field of reproductive medicine because of their metabolic stability and histamine induced reduced allergic side effects.

Structure

Amino acids at 1, 2, 3, 6, and 10 positions play a significant role in structure and function of native GnRH molecule (decapeptide). Sixth position is involved in enzymatic cleavage. Positions 1, 6, and 10 are important for three-dimensional structure of the molecule and position 2 and 3 are important for gonadotropin release.[80]

Mechanism of Action

The antagonists block the GnRH receptor in a dose-dependent competitive fashion and they have no flare effect. There is immediate suppression of pituitary gonadotropin release. This is in contrast to the long-acting agonists, which first stimulate and later inhibit pituitary gonadotropin secretion by desensitization and receptor downregulation. After the GnRH antagonist is discontinued, there is a short recovery phase of 2–4 days.

Preparations

Third-generation GnRH antagonists: Cetrorelix and ganirelix.

Doses and Route

No adjustment in dose of obese women for cetrorelix. Half-life of cetrorelix 3 mg dose is 62.8 hours, 0.25 mg 20.6 hours, and ganirelix 0.25 mg is 16.2 hours.

PROTOCOL FOR ANTAGONIST PROTOCOL

- Single-dose antagonist protocol and multiple-dose antagonist protocol
- Fixed antagonist and flexible antagonist protocol.

Single-dose Antagonist Protocol (Fig. 9)

Cetrorelix 3 mg is given on day 7 in fixed protocol (French Protocol). A single injection prevents LH surge for 96 hours.

Multiple-dose Antagonist Protocol

Common protocol. Both cetrorelix/ganirelix can be used. In the *fixed protocol* **(Fig. 10)**, GnRH antagonist is started on day 6 of stimulation and is continued till the day of hCG trigger.[81] In the *flexible protocol* **(Fig. 11)**, GnRH antagonist is started once the leading follicle is more than 14 mm. Flexible protocol is a more cost-effective approach, as it avoids unnecessary injections. Statistically significant reduction found both in number of antagonist ampoules and amount of gonadotropin used in the flexible protocol. No statistically significant difference found in pregnancy rate between flexible and fixed protocols.[82]

Advantages

- More physiological
- More patient friendly
- Less stressful due to shorter treatment cycles
- Safer

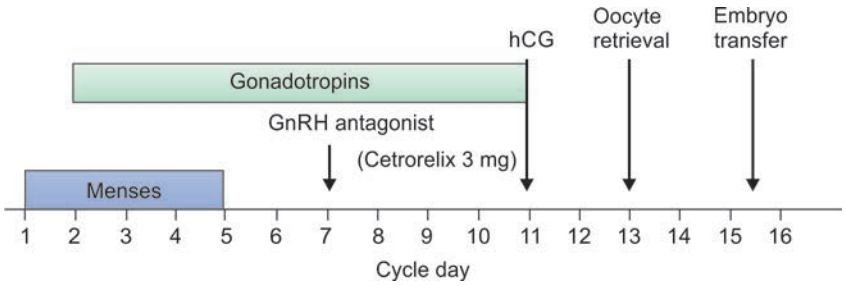

Fig. 9: Single dose antagonist protocol.
(GnRH: gonadotropin-releasing hormone; hCG: human chorionic gonadotropin)

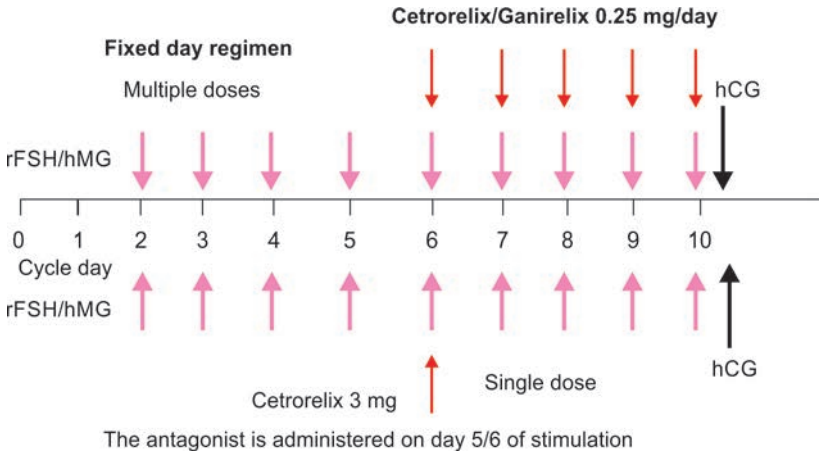

Fig. 10: Fixed dose antagonist protocol.
(rFSH: recombinant follicle-stimulating hormone; hMG: human menopausal gonadotropin; hCG: human chorionic gonadotropin)

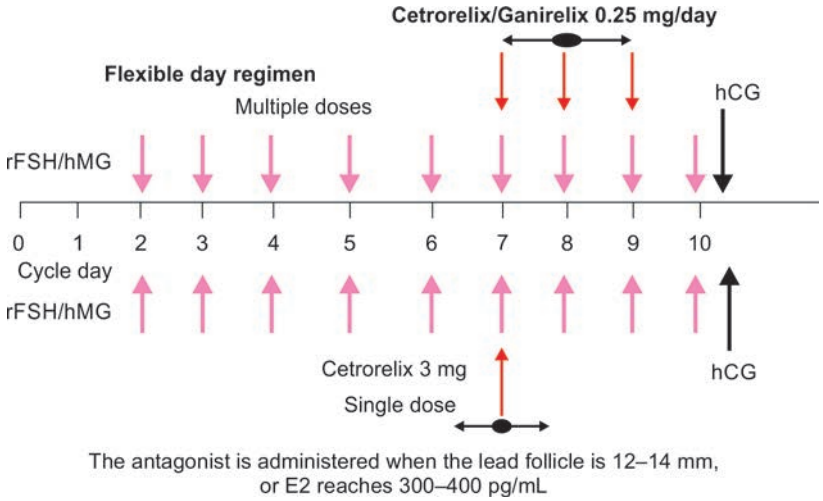

Fig. 11: Flexible dose antagonist protocol.
(rFSH: recombinant follicle-stimulating hormone; hMG: human menopausal gonadotropin; hCG: human chorionic gonadotropin; E2: estradiol)

- Decreased dose of gonadotropins
- Minimal ovarian stimulation
- Agonist trigger can be used
- Negligible chances of OHSS
- Cost friendly
- Flexible protocols.

Disadvantages

- Does not suppress raised LH levels in early phase of stimulation
- Does not allow flexibility in IVF programming
- Does not favor batch IVF
- Drug per se is more expensive than GnRH agonist.

GNRH AGONIST VERSUS ANTAGONIST[83]

Cochrane analysis suggests that there is significant reduction in the incidence of OHSS (by more than 50%) with the use of antagonists. However, this analysis has been criticized by Orvito et al. who say that GnRH agonist still have demonstrable superiority over antagonists in terms of ongoing pregnancy rates and live birth rates.

Differences between GnRH agonists and antagonists are given in **Table 11**.

TRIGGER

List of triggers:

- hCG: 5,000 IU SC or IM
- R hCG: 250 µg SC ↭ 6,000–7,000 IU hCG
- R GnRH agonists:
  - Leuprolide: 500–1,000 µg SC
  - Triptorelin: 200 µg SC
  - Buserelin: 500 µg SC

Youssef[84] concluded that urinary hCG remains the best choice for final oocyte maturation triggering in IVF and intracytoplasmic sperm injection (ICSI) treatment cycles due to availability and cost (Youssef 2011).

In high responder patients, avoiding hCG and using GnRH agonist (0.2 mg triptorelin) as the trigger almost eliminates OHSS. A meta-analysis showed lesser pregnancy rates in fresh embryo transfer with agonist trigger.[85] Griesinger G et al.,[86] proposed frozen thawed cycle.

In 2014, Youssef et al., found lower live birth rate and higher miscarriage rate in women who received a GnRHa with reduced OHSS rates.[87]

NATURAL CYCLE IN VITRO FERTILIZATION

In vitro fertilization is carried out in a spontaneous menstrual cycle. No medication is given with aim to collect one naturally selected oocyte at least expenses.[88]

TABLE 11: Comparison between GnRH agonist and antagonist.

Agonist	*Antagonist*
Initial flare followed by pituitary desensitization	Immediate Gn suppression by competitive block of GnRH receptors
More ampoules of gonadotropin needed	Lesser ampoules required
Longer duration of stimulation	Shorter duration of stimulation
Slow recovery of pituitary function	Quick recovery of pituitary function
hCG as trigger	GnRH agonist or hCG can be used as trigger
More oocytes for IVF and cryopreservation	Fewer oocytes, but also less OHSS
Risk of OHSS is more	Significantly lesser risk of OHSS
Symptoms of E2 deprivation are more	Symptoms of E2 deprivation are less
More programmable IVF procedures	Less programmable IVF, but greater patient convenience
Gold standard in normoresponders	Particularly advantageous in hyper and poor responders. Can also be used in normoresponders

(E2: estradiol; GnRH: gonadotropin- releasing hormone; hCG: human chorionic gonadotropin; IVF: in vitro fertilization; OHSS: ovarian hyperstimulation syndrome)

Protocol

It has high-cancellation rates and low success rates. It is used in cancer patients where gonadotropins cannot be given. The timing of oocyte collection may be based on an optimum level of serum E2 and LH and/or ultrasound measurement of follicular diameter and endometrial thickness.[89,90]

MODIFIED NATURAL CYCLE IN VITRO FERTILIZATION

The aim is to reduce chances of cycle cancellation.

- Human chorionic gonadotropin as trigger +/– luteal support.
- GnRHa +/– Gn. hCG injection and luteal support are given.

Recent evidence suggests that it may be useful in poor responders.[91]

MILD IN VITRO FERTILIZATION (FIG. 12)

Gonadotropin (FSH or hMG) are administered at lower doses or oral compounds (antiestrogens or aromatase inhibitors) are used along with it. hCG injection and luteal support are also given.[92] The criteria for administration of hCG, IVF, and embryo transfer techniques are similar to those applied in other IVF protocols. Luteal support is given either in the form of hCG or progesterone.[93]

Advantages

- Less complex
- Less time-consuming
- Cheaper
- Reduced chances for complications
- Reduced chances for discomfort
- Reduced chances for drop-out
- Effects on oocyte quality
- Effects on endometrial receptivity
- Emphasize on maximizing chances for healthy children born per treatment started at reasonable cost, less patient discomfort and fewer chances of complications.

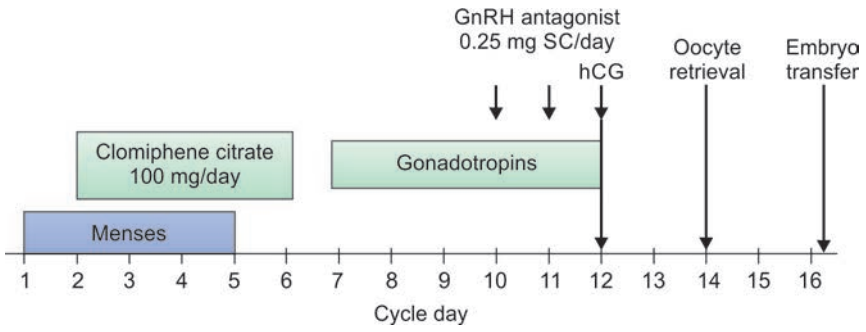

Fig. 12: Mild stimulation IVF.
(GnRH: gonadotropin-releasing hormone; hCG: human chorionic gonadotropin; SC: subcutaneous).

Disadvantages

- Lower pregnancy rates per cycle
- Lower success rates
- High-cycle cancellation rate
- Decreased number of oocytes and embryos
- Less margin for suboptimal laboratory performance
- Mild IVF not yet tested in women less than 38 years old
- Difficulty in programming the cycle.

KATO PROTOCOL

This minimal ovarian stimulation protocol **(Fig. 13)** has full advantage of the characteristics of CC. Administration of 50 mg CC is started on cycle day 3 and from day 8, patients receive 150 IU of FSH every other day. Once the size of the dominant follicle and the estradiol concentration reaches the predefined values, GnRH agonist is administered as the trigger. Oocytes are then retrieved 32–35 hours later.

Enclomiphene has a short half-life (24 hours) and therefore it is necessary to continue oral administration of CC until the day before maturation is triggered. In the large-scale retrospective study by Teramoto S and Kato O, of all 43,433 cycles initiated, the rates for oocyte retrieval and embryo cleavage were 83% and 64%, respectively.[94] The mean number of oocytes retrieved was 2.2. The rates for live births, miscarriages, and ectopic pregnancies, in relation to initiated cycles, including cases of frozen-thawed transfer, were 11.1, 3.4, and 0.2%, respectively. In view of this protocol being inexpensive and much more compatible, it can be expected to provide a huge benefit to infertile women especially in developing countries.

CONTROLLED OVARIAN STIMULATION WITH LETROZOLE SUPPLEMENTATION (COST-LESS PROTOCOL) (FIG. 14)

Day 2: Letrozole 5 mg/day till 48 hours before oocyte pick up.

Day 5: FSH 150–225 according to age, AFC, and weight. Antagonist to prevent LH surge along with agonist trigger.

After the oocyte retrieval, the patients restarted the letrozole regimen until their estradiol concentrations were less than 50 pg/dL.

Results: Patients had less E2 levels but similar oocyte yield as compared to conventional antagonist protocol. Letrozole versus anastrolzole versus tamoxifene, least peak E2 levels are seen with letrozole.[95]

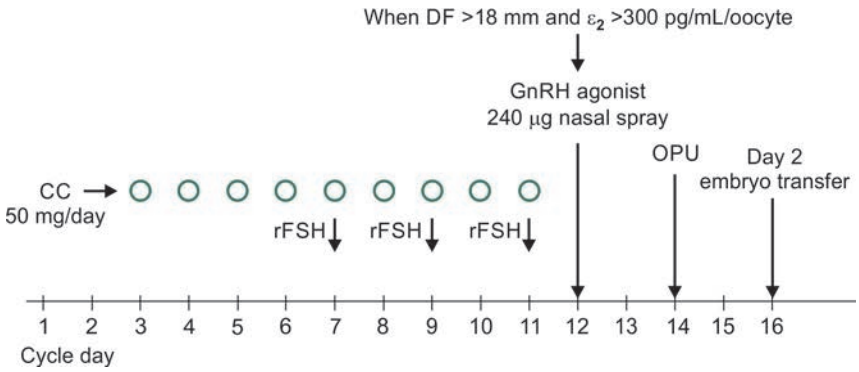

Fig. 13: Kato protocol.
(CC: clomiphene citrate; DF:dominant follicle; GnRH: gonadotropin-releasing hormone; OPU: oocyte pickup; rFSH: recombinant follicle-stimulating hormone).

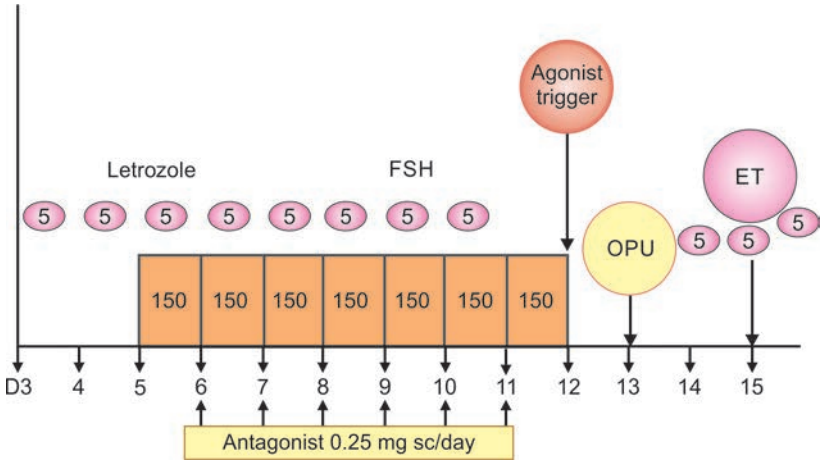

Fig. 14: Cost-less protocol with letrozole.
(ET: embryo transfer; FSH: follicle-stimulating hormone; OPU: oocyte pickup)

SHANGHAI PROTOCOL (KUANG ET AL.) (FIG. 15)

Double stimulations during the follicular and luteal phases of poor responders in IVF or ICSI programs in the same menstrual cycle provided more opportunities to retrieve oocytes with embryos of similar development potential. This approach is useful for cases with history of negative oocyte retrieval and also in cancer patients who need emergency fertility preservation.[96]

DUPLEX PROTOCOL (MOFFAT ET AL.)

It is also known as Dual ovarian stimulation. This protocol features dual stimulation, with the second stimulation starting immediately after the first oocyte retrieval. In this Duplex (DPX) protocol, both the first and second stimulations used a similar regimen consisting of a classical antagonist protocol using 300 IU of FSH per day, cetrorelix 0.25 mg starting on ovarian stimulation day 6, and GnRH trigger (triptorelin 0.2 mg) when follicular maturation was reached. The first and second stimulations provided a similar number of oocytes, zygotes, and blastocysts. The DPX protocol thus doubled the final blastocyst yield, compared with a classical single ovarian stimulation cycle. This approach can be used in fertility preservation and the desire to collect the largest number of oocytes can be possible.[97]

ULTRALONG PROTOCOL FOR ENDOMETRIOSIS (ESHRE 2013 GUIDELINES)

Depicted in **Figure 16**. It is discussed in detail in chapter on "Endometriosis".

Progestin–primed Ovarian Stimulation (PPOS)

Progestin-primed ovarian stimulation (PPOS) is a new protocol designed for ovarian stimulation **(Fig. 17)**. In this protocol instead of down-regulation with agonist or antagonist use, progesterone is used to prevent LH surge.[98] Meta-analysis by Guan et al., has showed that premature LH surge incidence, clinical pregnancy rate, live birth rate, and ongoing pregnancy rate in PPOS protocol is similar to nonPPOS cycles in all patient populations.[99] Another meta-analysis by Alexandru et al., also suggested effective role of progestins in prevention of LH surge.[100] PPOS protocol in PCOS patients have shown in lower incidence of OHSS as progestin reduces chances of OHSS in both follicular and luteal phase.[101] Retrospective study by Huang et al.,

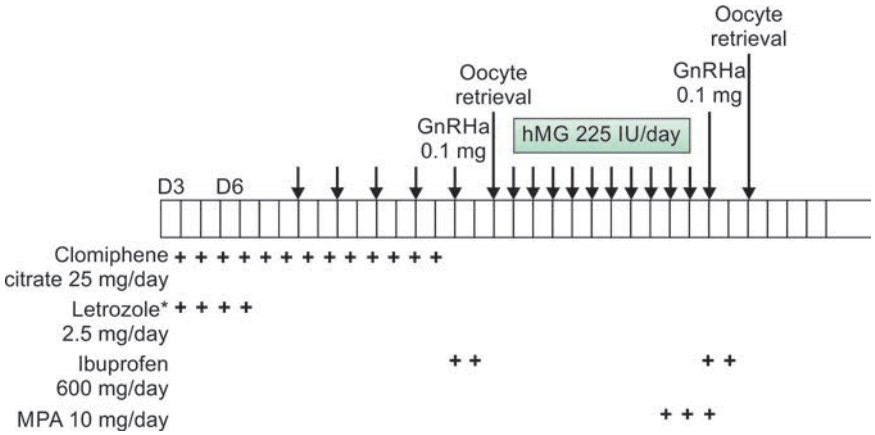

Fig. 15: Shanghai protocol.
(GnRHa: gonadotropin-releasing hormone agonist; hMG: human menopausal gonadotropin)

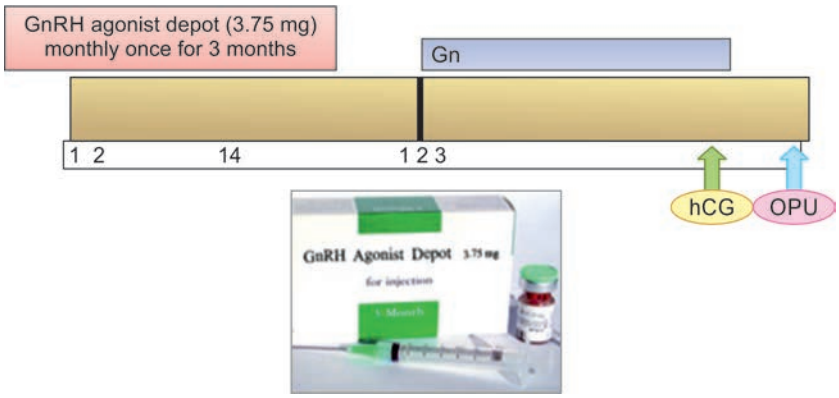

Fig. 16: Ultralong protocol for endometriosis.
(hCG: human chorionic gonadotropin; OPU: oocyte pickup)

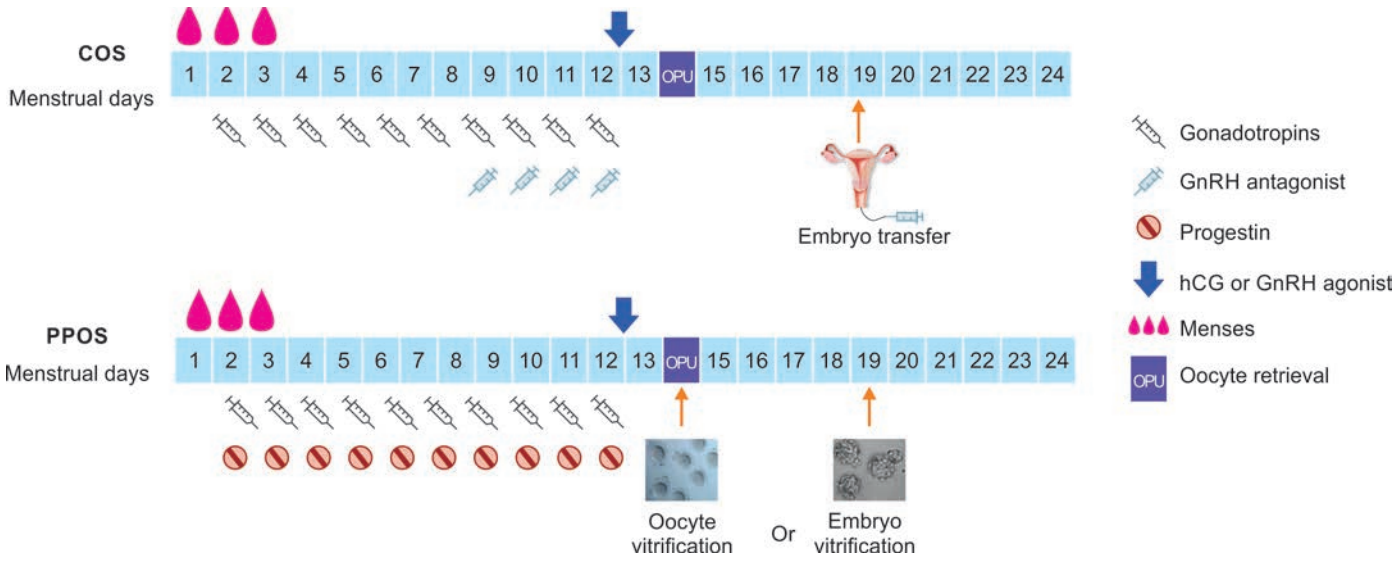

Fig. 17: Progestin-primed ovarian stimulation (PPOS) protocol.
(GnRH: gonadotropin releasing hormone; hCG: human chorionic gonadotropin)

have demonstrated similar neonatal outcomes when PPOS was compared to short antagonist protocol.[102] The only drawback so far is that fresh embryo transfer cannot be done as early exposure to progesterone results in endometrial advancement.[103]

ICMR Guidelines for Recommencing ART Services during COVID-19 Pandemic 2021

ICMR designed a step-wise module for ART clinic to be followed:[104]

(A) *Patient information and counseling:* COVID-19 pandemic might have effect on treatment and pregnancy outcomes in couples undergoing ART procedures, so couples should be properly counseled and informed about symptoms, social distancing, and situations where treatment may be stopped in between due to high-risk clinical situation.

(B) *Consent:* Specific consent form related to COVID-19 infection should be taken.

(C) *Risk Assessment triage:* Risk is assessed by following factors—clinical history and possibility of contact with suspected or positively infected individuals.

Group I: Couple low risk and asymptomatic: RTPCR test should be done before starting ART treatment and before oocyte retrieval or HCG trigger.
- If RTPCR negative: Continue the treatment
- If RTPCR positive: Postpone the treatment.

Group II: Couple recovered from COVID-19 infection: RTPCR test done prior to starting ART treatment and before oocyte retrieval or HCG trigger.
- If RTPCR negative: Continue the treatment
- If RTPCR positive: Postpone the treatment.

Group III: Any one partner with symptoms before starting ovarian stimulation for IUI/IVF: RTPCR test should be done prior to starting ART treatment
- If RTPCR negative: Continue the treatment
- If RTPCR positive: Postpone the treatment.

Group IV: COVID-19 symptoms arising during ovarian stimulation in IUI/IVF cycle: RTPCR test before further treatment like oocyte retrieval or HCG trigger.
- If RTPCR negative: Continue the treatment
- If RTPCR positive: Postpone the treatment.

Group V: COVID-19 symptoms arising after oocyte retrieval in IVF cycle: RTPCR test before further treatment.
- If RTPCR negative: Continue the treatment
- If RTPCR positive: Freeze all embryos, if positive after oocyte retrieval and before embryo transfer.

(D) *Modification of ART clinic layout and services:*
- Specific COVID-19 sanitization procedures, staff training, provision of PPE, and sanitation equipment.
- Use of Aarogya setu app.
- Limited persons at one time with division of staff into mini teams accompanying proper social distancing protocols.
- Follow up of patients 14 days after ART procedure to look for COVID-19 patients.
- Teleconsultations instead of direct interactions.
- Collaboration with nearby centers to refer patients in case own center gets closed due to any COVID-19 positive case detection or other emergencies.
- Adapt freeze all policy in suspected or COVID-19 positive patients during embryo culture.

(E) *Individualized treatment:*
- Individualized treatment.
- Telemedicine with avoidance of unnecessary visits.

- Provision of psychological counseling and education to couples as such patients are at increased risk of mental health deterioration and behavioral disorders during corona pandemic.

STUDIES DONE IN COVID-19 ERA

Orvieto et al.,[105] studied COVID-19 infection effect on IVF treatments in nine couples. They found that IVF treatment was resumed within 8–92 days after recovery from COVID-19 infection. All stimulation and embryological variables were similar before and after the infection with significantly lesser number of top-quality embryos recoveries. It is thereby suggested that IVF treatment should at least be delayed for 3 months after recovery from COVID-19 infection, so that recruitment of healthy gametes could occur.

Bhattacharya et al.,[106] used a prediction model to assess impact of COVID-19 infection on different age group women. It was noticed that older women with known cause of infertility had lesser live birth rates while couples with unexplained infertility even conceived naturally while waiting for the treatment.

Orvieto et al.,[107] assessed 36 couples who received IVF treatment within 7–85 days after receiving mRNA SARS-CoV-2 vaccine and concluded that the vaccine did not have any effect on either ovarian reserve or stimulation characteristics during the cycle.

KEY NOTES

- With recent evolution of various oral ovulogens, ovulation induction and superovulation has become easier and importance to occurrence of negligible or no complications is possible now.
- Concentration should be on the quality output and not only on quantity output so as to increase pregnancy rates.
- One size does not fit all. Our endeavor should be to customize the treatment as per our patient's individual needs.
- The goals of iCOS are to achieve optimum success, reduce complications like OHSS, and to achieve a singleton pregnancy.
- Recombinant versus urinary gonadotropin for ovarian stimulation in ART cycles: All available gonadotropins are equally effective and safe. The choice of the product will depend upon its availability, the convenience of its use, and the cost.[70]
- The short flare and the microdose flare GnRH agonist protocol can be used in patients with diminished ovarian reserve.
- The administration of GnRHa for a period of 3–6 months prior to IVF or ICSI in women with endometriosis increased the odds of clinical pregnancy by four-fold.[108]
- GnRH antagonists have rendered IVF, a patient friendly and safe procedure of high efficacy.
- One of the most important aspects of GnRH antagonist protocol is the option of triggering final oocyte maturation with GnRH agonist in high-responder patients, which thus helps in reducing the incidence of OHSS to practically zero.
- GnRH antagonists have stimulated thinking in developing new concepts in ovarian stimulation like modified natural cycle, mild IVF, agonist triggering, and cryopreservation of all 2PN oocytes, and re-initiation of antagonist in case of severe established OHSS.
- There was evidence of improved pregnancy outcomes with progestogen pretreatment and poorer pregnancy outcomes with a combined OCP pretreatment.[109]
- There was no evidence of a significant difference in pregnancy rates between natural cycle and standard IVF.[88]
- It is true that mild or minimal stimulation may not be the optimal treatment protocol for all patients but may be used in a certain group of patients like hyper-responders or in poor responders who have failed other treatments.
- Random start COS is as effective as conventional start COS in fertility preservation. This protocol would minimize delays and allow more patients to undergo fertility preservation and still proceed with cancer treatment within 2–3 weeks.
- COVID-19 era has impacted life of couples seeking treatment both physically and mentally. Future studies are required to understand the impact better.

CHAPTER 48

Role of Adjuvants in Ovarian Stimulation

Mirudhubashini Govindarajan, Ramya Jayaram

INTRODUCTION

Controlled ovarian stimulation (COS) is the principal step of current assisted reproductive technology (ART) procedures. Gonadotropins are administered in ART in order to maximize the number of good quality oocytes obtained. Along with gonadotropins gonadotropin-releasing hormone (GnRH) analogs are used to prevent unwarranted luteinizing hormone (LH) surge during COS. In some women, the response to standard stimulation is abnormal, either poor response yielding very few or poor quality oocytes or very high, leading to ovarian hyperstimulation syndrome (OHSS). In order to optimize these adverse outcomes, various add-ons have been proposed. Adjuvants have been clinically used in poor responders to improve the number and quality of oocytes, and in hyper-responders to lessen the chances of hyperstimulation.

ADJUVANTS FOR OVARIAN STIMULATION IN POOR RESPONDERS

A poor responder is generally identified by factors such as age, abnormal ovarian response tests [anti-Müllerian hormone (AMH) and antral follicle counts (AFC)], previous ovarian surgery, and endometriosis. Poor ovarian response (POR) is still one of the major challenges in controlled ovarian hyperstimulation (COH). Incidence of POR is reported to range from 5.6 to 35.1% (Jenkins et al. 1991). "Bologna" criteria were proposed by The European Society of Human Reproduction and Embryology (ESHRE) in 2011 (Ferraretti and Gianaroli) to define poor responders. Humaidan et al. have modified and subclassified POR into "POSEIDON" (Patient-Oriented Strategies Encompassing Individualized Oocyte Number) subgroups in 2016. POSEIDON subgroups I and II are basically women with normal ovarian reserve and are more likely to respond to modifications in the stimulation protocols. POSEIDON subgroups III and IV have abnormal ovarian reserve tests and are less likely to respond. Numerous adjuvants have been tried in poor responders over the last few years to potentially optimize the quality and quantity of oocytes and thereby improve the pregnancy rates. However, majority of published studies so far have not classified their patients according to POSEIDON subgroups.

Growth Hormone

Probable Mode of Action

- Growth hormone (GH) enhances ovarian response to follicle-stimulating hormone (FSH) and thereby stimulates ovarian steroidogenesis and follicular development. This hypothesis was proposed as early as 1986.[1]
- GH and its intermediary insulin-like growth factor-1 (IGF-1) promote the health and proliferation of granulosa cells which are critical to the nourishment and health of the oocyte.[2]
- Both IGF-1 and IGF-2 are present in the follicular fluid and are believed to play a crucial role in cytoplasmic maturation and in potentiating the actions of FSH.[3,4]

Literature Evidence

- 2010 Cochrane review indicated that the addition of GH in ovarian stimulation of poor responders resulted in statistically significant difference in both live birth rates (25 vs. 8%) and pregnancy rates without increasing the adverse events. However, the results of this review needs to be interpreted with caution as the number of included trials were few and the sample size was small.[5]
- Meta-analysis by De Ziegler also concluded that GH supplementation improved pregnancy and live birth rates by threefold to fourfold, but did not increase the number of oocytes.[6,7]
- Network meta-analysis and systematic review published in Human Reproduction Update in 2020 by Zhang et al. shows that adjuvant treatment with GH was the optimal strategy in terms of outcome measures, i.e., oocyte and embryo numbers.

Dosage and Timing

- There is no consensus between majority of studies on the dosage and the timing of GH administration.[8]
- GH was started concomitantly with gonadotropins in most of the studies. In a study by Kucuk et al.,[9] it was initiated on day 21 of the previous cycle.

Conclusion

Current network meta-analysis suggests that the response to GH addition appears to be beneficial;[10,11] however, it may vary in different subgroups. Much larger studies may be necessary to accurately determine the treatment effect on different subgroups before recommending the *routine* use of GH in *all* poor responders undergoing *in vitro* fertilization (IVF).

Androgens and Androgenic Drugs

Testosterone

Mode of action:

- Testosterone (T) increases both antral follicle numbers and granulosa cell proliferation. It also reduces apoptosis in subhuman primates.
- Androgens act directly via the androgen receptors. Androgen receptor messenger ribonucleic acid (RNA) correlates positively with granulosa cell proliferation and negatively with granulosa cell apoptosis.[12]
- Androgens also have an indirect effect by their conversion to estrogens and 3-beta-diol that can activate the estrogen receptor.
- Testosterone has been shown to cause a marked increase of ovarian response in women who had a consistently poor response to repeated ovarian stimulation for IVF.[13]

Literature evidence:

- Testosterone increases follicular response by increasing FSH-receptor activity and by stimulating IGF-1.[14]
- Application of transdermal testosterone resulted in a significant improvement in number of follicles recruited, oocytes retrieved, implantation rates, clinical pregnancy rates, and a decrease in cycle cancellation rates.[15,16]
- Two meta-analyses showed that the transdermal testosterone significantly reduced the doses of FSH required and increased live birth rate.[16,17]
- Meta-analyses by Sunkara et al. however did not find the available evidence on androgens sufficient enough to support the use of androgen supplementation to improve live birth outcome in poor responders undergoing ART.[18]
- Current network meta-analysis by Zhang et al. using exogenous androgens [dehydroepiandrosterone (DHEA) and transdermal testosterone] had demonstrated beneficial effects. DHEA had the best clinical pregnancy rates while testosterone produced the highest numbers of embryos.

Conclusion: More evidence from randomized controlled trials (RCTs) with large sample size is required before advocating the *routine* use of testosterone in *all* poor responders.

Dehydroepiandrosterone

Mode of action:

- Oral DHEA has been used to increase ovarian androgens and thereby the ovarian response in poor responders. DHEA is the prohormone for follicular fluid testosterone. Circulating DHEA levels decrease by about 50% between ages 25 years and 45 years. 50% of follicular fluid testosterone is derived from circulating DHEA. Both serum testosterone levels and number of oocytes retrieved decrease with age. Using multivariate analysis, baseline testosterone levels were found to independently correlate positively with the number of oocytes retrieved.[19]
- Casson et al. in 2000 were the first to report positive effect on supplementation of DHEA in women with diminished ovarian reserve.[20]

Literature evidence:

- In a study using the patient's prior cycles as their own controls, the number of oocytes retrieved increased significantly from 3.4 to 4.4 after an average of 4 months of 25 mg three times daily of oral DHEA.[21]
- In a prospective randomized study, Wiser et al. found significantly increased live birth rates (23.1 vs. 4.0%) in patients with diminished ovarian reserve on DHEA supplementation. This study was criticized for severe methodological and statistical problems.[22]
- However, two meta-analyses[16,17] found no significant difference in clinical pregnancy and live birth rates between patients who received DHEA and those who did not, deserving further evidence.

Conclusion: In the current meta-analysis, adjuvant treatment using exogenous androgens (DHEA or transdermal testosterone) had beneficial effects. DHEA resulted in the best clinical pregnancy rate, and testosterone produced the highest number of embryos. Pretreatment with transdermal DHEA or testosterone has been proposed as a safe and effective means to increase the concentration of intraovarian androgens (Balasch et al., 2006; Casson et al., 2000). Theoretically, intraovarian androgens promote cellular sensitivity to FSH in growing follicles (Hillier and De Zwart, 1981; Vendola et al., 1998) and may thereby increase oocyte yield and oocyte maturity during ovarian stimulation, subsequently improving the pregnancy rate. Although estradiol levels on the human chorionic gonadotropin (hCG) day were low in the DHEA groups, the clinical pregnancy

rate was highest, and the cycle cancelation rate was lowest. A previous meta-analysis review demonstrated that pretreatment with transdermal testosterone, but not DHEA, increased clinical pregnancy and live birth rates (Bosdou et al., 2012). Two papers included in the present review showed that testosterone significantly increased clinical pregnancy rates, although only DHEA had a better prospect for improving pregnancy probability.

Human Chorionic Gonadotropin-recombinant Luteinizing Hormone

Human chorionic gonadotropin and recombinant luteinizing hormone (rLH) have long been used as adjuvant agents for increasing the production of endogenous intraovarian androgens (through the addition of LH activity). In the only eligible study in the present network meta-analysis, hCG obtained the highest number of retrieved oocytes. However, neither rLH nor hCG was associated with better clinical outcomes, including the clinical pregnancy rate, the number of embryos, and the cycle cancelation rates. These results are consistent with those of several previous meta-analyses (Bosdou et al., 2012; Gizzo et al., 2015), although the RCTs included in those meta-analyses were very different. However, these results are inconsistent with the results obtained from studies on exogenous androgens (transdermal testosterone and DHEA). This inconsistency may be because the two different interventions have overall differential effects or because different adjuvant agents act through different molecular mechanisms.

Coenzyme Q

Coenzyme Q (CoQ) data is available from only one study, which has claimed that the addition of CoQ10 may have a beneficial effect on the ovarian response (Xu et al., 2018). In the current network meta-analysis, CoQ10 treatment had the lowest cycle cancelation rate and achieved the second highest clinical pregnancy rate, indicating that the prospects are possibly good for using CoQ10 in POR. However, these results need to be confirmed in further prospective studies.

Letrozole/Clomiphene as Adjuvants

Mild COS protocols combining clomiphene or letrozole with gonadotropins have been implemented as an effective alternative for conventional COS, in normal responders swell as in POR (Verberg et al., 2009). Clomiphene acts by blocking hypothalamic estrogen receptors, thereby blocking the negative feedback effect of circulating endogenous estrogen and subsequently increasing the release of GnRH, FSH, and LH (Dickey and Holtkamp, 1996). Letrozole reversibly binds and prevents aromatase from producing estrogens. With the growing demand for patient-friendly COS protocols for ART, there is a valid interest in milder protocols involving the addition of clomiphene or letrozole to COS with the aim of retrieving fewer and better quality oocytes without compromising endometrial receptivity. Based on the results in some meta-analysis earlier, a mild ovarian stimulation strategy involving clomiphene or letrozole addition obtained pregnancy outcomes similar to those of conventional COS protocols[23] (Bosdou et al., 2012; Song et al., 2016).

In the current network meta-analysis, although there were no significant differences compared with the control group, surface under the cumulative ranking curve (SUCRA) values showed that cotreatment using clomiphene or letrozole with gonadotropin, especially clomiphene, led to the worst clinical outcomes, including the lowest pregnancy rates, the lowest oocyte numbers, the lowest embryo numbers, and the highest cycle cancelation rates. Therefore, using clomiphene or letrozole for mild stimulation regimens as the first-line adjuvant treatment for patients with POR cannot be recommended.

Estrogens and Oral Contraceptives

Adjuvant hormonal drugs such as oral contraceptive pills (OCPs) and estrogens have been used for synchronization of follicular growth in poor responders. They are also utilized for scheduling of the ART cycles. The increased homogeneity of the follicular cohort induced by steroid pretreatment is thought to improve the synchrony of follicular growth during stimulation. This can result in an increase in both oocyte yield and gamete quality leading to an increase in pregnancy rates.[24]

Estrogen Pretreatment

Oral estrogen has been used to schedule ovarian stimulation cycles using 4 mg daily of estradiol-valerate beginning in the midluteal phase of the previous menstrual cycle. Ovarian stimulation was started on the day following discontinuation of estrogen.[25] No adverse events have been noted with usage of estrogen for cycle programming.

Previous studies have proposed that luteal phase estradiol priming may improve the synchronization of the pool of follicles available for COS, resulting in more favorable responses to COS (Fanchin et al., 2003, Fanchin et al., 2003b). In the current network meta-analysis, estradiol pretreatment increased the oocyte number significantly. As only one RCT was included in the present network meta-analysis, more rigorous RCT studies are still needed to determine whether adjuvant treatment with estrogen is beneficial.

Combined Oral Contraceptive Pills Pretreatment

Mode of action: Combined oral contraceptive (COC) pills suppress endogenous gonadotropins. COC when given

prior to ovarian stimulation aids in synchronization of follicular development, reduces cyst formation, prevents spontaneous LH surge, and shortens the length of GnRH analog treatment.[26]

Literature evidence:

- Cochrane review on COC treatment prior to antagonist protocol for ovarian stimulation in unsegregated patients found fewer clinical pregnancies and higher amount of total gonadotropin dosage.[27]
- Some studies have found an increase in the miscarriage rates in antagonist cycles using OCP pretreatment.[28]

Conclusion: Combined oral contraceptives and estrogens are commonly used agents for programming ART cycles and obtaining uniform cohort of follicles. Decreased pregnancy rates and increased miscarriage rates have been noted with usage of OCPs in some studies. No adverse outcomes have been noted with usage of estrogens for programming.

ADJUVANTS FOR HYPER-RESPONDERS

Women with polycystic ovary syndrome (PCOS) are hyperinsulinemic with a large number of antral follicles, and higher incidence of OHSS when exposed to conventional protocols.

Metformin

- The use of metformin in PCOS improves insulin resistance and intraovarian hyperandrogenism thereby reducing the risk of OHSS. Meta-analysis of five RCTs with adjunctive use of metformin in PCOS have shown a dramatic reduction in OHSS [odds ratio (OR) 0.21, confidence interval (CI) 0.11-0.41, $p < 0.00001$).[29]
- Metformin appears to improve the odds of pregnancy in women with PCOS undergoing ovarian stimulation. Meta-analysis of 17 RCTs has shown both increased ovulation (OR 4.39, CI 1.94–9.96) and pregnancy rates (OR 2.67, CI 1.54–4.94) when metformin was added to clomiphene citrate. This effect of metformin was found to be statistically significant in obese women with PCOS (OR 10.9), whereas it failed to reach significance in nonobese PCOS women.[30]
- Palomba et al. conducted a randomized, double blind, placebo-controlled trial with metformin supplementation in patients who had previous cancelled IVF cycles due to a high risk of OHSS. The incidence of OHSS was significantly reduced by approximately 70% [relative risk (RR 2.9)] with a number needed to treat (NNT) of 5.[31]
- Metformin has also been associated with an improved pregnancy rate in PCOS women undergoing ART.[32,33] However when all RCTs were combined, the increase in pregnancy rate (29%) was not statistically significant.[33]

ADJUVANTS TO ORAL OVULOGENS

Dexamethasone

- Dexamethasone was found to improve response to ovarian stimulation when combined with clomiphene citrate. An RCT showed a higher rate of ovulation with clomiphene citrate when 0.5 mg of dexamethasone was given continuously.[34]
- In another two RCTs where women failed to ovulate with up to 150–250 mg of clomiphene citrate, adjunctive use of dexamethasone increased ovulation rate by 4–5-fold and pregnancy rate by 8–10-fold. In these studies, a higher dose of 2 mg of dexamethasone was given, but only during the 5 days of clomiphene citrate and for the following 5 days.[35,36]

Dexamethasone may enhance ovulation in situations of clomiphene citrate resistance in ovulation induction.

Conclusion

All adjuvant treatment groups used a lower dosage of gonadotropin for ovarian stimulation. Studies have shown that a higher dosage of FSH has a detrimental effect on egg and oocyte quality, increasing the incidence of chromosomaly abnormal embryos and significantly decreasing live birth rates (Baart et al., 2007). Moreover, a higher dosage of gonadotropins may increase the total consumption of ovarian follicles, which is not beneficial for patients with POR. Indeed, clinical studies have confirmed that higher dosages of FSH resulted in an increased number of follicle recruitments but low-quality embryos (Hohmann et al., 2003). The optimal COS protocol for patients with POR is most likely supplementation with appropriate adjuvant agents to improve clinical outcomes rather than simply increasing the FSH dosage.

Based on the available evidence, for patients with POR, COS protocols that used adjuvant treatment with DHEA, CoQ10, and GH produced better clinical outcomes in terms of pregnancy. A lower dosage of gonadotropin was required for ovulation induction than what was used in the control group. Adjuvant treatment using clomiphene led to the lowest pregnancy rates, even though the total dosage of gonadotropins was the most economical.

KEY POINTS

- Aggressive COS with higher dosage of gonadotropins in POR is associated with a variety of side effects, higher costs, and is less likely to succeed (Kailasam et al. 2004; Cheung et al. 2005). Higher dosage of FSH has detrimental effects on egg and oocyte quality, increasing the incidence of abnormal embryos and significantly decreasing live birth rates (Baart et al., 2007).
- Efficacy of natural cycle or minimal stimulation IVF for POR is also disappointing because of high cancellation rates.

- All adjuvant treatment groups use a lower dosage of gonadotropin for ovarian stimulation. The optimal COS protocol for patients with POR is most likely supplementation with appropriate adjuvant agents to improve clinical outcomes rather than just increasing the FSH dosage.
- Based on the available evidence, in poor responders, adjuvant treatment with DHEA, CoQ10, and GH produced better clinical outcomes in terms of pregnancy (OR 2.46, 95% CI 1.16–5.23) Zhang et al. HR update 2020.[37]
- CoQ10 supplementation resulted in lowest cancellation rates.

CHAPTER 49

Gonadotropin-releasing Hormone Analogs

Mamta Dighe

INTRODUCTION

Schally and coworkers first isolated and synthesized porcine gonadotropin-releasing hormone (GnRH) in 1971.[1-3] Since then the application of GnRH analogs has been used in various aspects of ovarian stimulation and newer analogs, both, agonists and antagonists, have been formulated.

The understanding of the molecular biology and mechanism of action of the GnRH analogs has proved its unique ability to both elicit the release and synthesis of gonadotropins with pulsatile administration or when administered in the initial phases as well as to downregulate the receptors and inhibit release of gonadotropins when administered over a prolonged period. This unique ability to both stimulate and inhibit gonadotropin release has permitted its use in ovulation induction, both for follicle development as well as to prevent luteinizing hormone (LH) surges. Its use has also been applied to treatment of diseases dependent on gonadal steroids.

Depending on its method of usage and the pharmacokinetics rationale behind, it could be used in different types of treatments as follows:

- *In ovulation induction:* It controls the effects of gonadotropin secretion in ovulation induction or in controlled ovarian hyperstimulation and in in vitro fertilization (IVF) techniques.
- *In hormone-dependent diseases:* By suppressing sex steroids in diseases where its progression is hormone-dependent, e.g., uterine fibroids, endometriosis, endometrial, and prostatic cancer.
- *In central precocious puberty:* To suppress the early appearance of GnRH pulsatility (central precocious puberty) or even to delay the normal onset of pubertal GnRH pulsatility, thus postponing epiphyseal closure and permitting bone growth to continue.

ENDOGENOUS GONADOTROPIN-RELEASING HORMONE

Gonadotropin-releasing hormone is originated and released from group of loosely connected neurons located in the medial basal hypothalamus. It is released in pulsatile fashion into the capillary system of the pituitary gland.[4] The GnRH binds selectively to highly specific receptors on the anterior pituitary gonadotropin cells leading to a cascade which causes release of gonadotropins from the anterior pituitary, thus helping in the process of ovulation. The GnRH pulse frequency alters throughout the menstrual cycle with pulses occurring less often in the luteal phase. Any alteration in the frequency or amplitude of the GnRH pulses causes disorder in the menstrual cycle.

Half-life of GnRH is 2–4 minutes as it is broken down by peptidase and cleared by glomerular filtration. Its rapid metabolic degradation and short half-life made it difficult to use native GnRH for therapeutic purposes. To stabilize the molecule against enzymatic degradation and increase its duration of action, various changes were made in its chemical composition leading to the development of GnRH analogs, both agonists, and antagonists.

GONADOTROPIN-RELEASING HORMONE AGONISTS

Development of Gonadotropin-releasing Hormone Agonists

Gonadotropin-releasing hormone agonists were evolved so as to put GnRH into clinical use. Replacement of glycine at number 10 at the C-terminus was the first major development leading to the increase in the potency of GnRH. Although 90% of biologic activity is lost doing this with the attachment of NH2–ethylamine to the proline of position 9, most of this activity is restored.[5] To slow down the enzymatic degradation, the next step was the substitution of the glycine at position 6 by D-amino acids. The combination of these two adaptations also exhibited higher receptor binding affinity. Introduction of larger and more hydrophobic and lipophilic D-amino acid at the position number 6 also prolonged the half-life. These changes in the chemical composition of the native GnRH protect the GnRH agonists against enzymatic degradation, stabilizing it, and increase its receptor binding

capacity and affinity. Thus in all GnRH agonists, position 6 is substituted with a D-amino acid.

The leuprolide, goserelin, and histrelin contain either thylamide or aza-glycine at position 10. These substitutions increase metabolic stability and potency.[6] Leuprolide in the ovulation induction test in the rat was 50–80 times more potent than the parent hormone. In the test, nafarelin, which contains hydrophobic amino acid at position 6, was 200 times more active than the endogenous hormone[7] **(Table 1)**.

The GnRH agonists have great affinity for the GnRH receptors and bind to them strongly, exerting an initial flare effect. All GnRH agonists increase secretion of gonadotropins upon acute administration. This is known as the flare effect. However, with sustained administration the receptor is downregulated as it is internalized via receptor-mediated endocytosis,[8] thus resulting in suppression of both the gonadotropin, the LH:follicle-stimulating hormone (FSH) ratio, and sex steroids.[5]

Routes of Administration

All GnRH agonists are small polypeptide molecules that have to be given parenterally, as they would otherwise be susceptible to proteolysis in the gastrointestinal tract. Administration routes of GnRH agonists are intramuscular or subcutaneous depot injection, or daily intranasal or subcutaneous administration.

The subcutaneous route is very commonly used, assures good bioavailability, and there is less interindividual variation. The intranasal route may cause variations in bioavailability and also needs more frequent administration.

The sustained release method allows a constant exposure to the hormone and delivers a steady state of suppression. Also the frequency of administration is limited, making it more comfortable for the patient. The depot preparations are used as once a month or once in 3 months injections. Though no difference in the outcome of pregnancy has been observed with depot versus daily injections, there was an increase in the dose of gonadotropins required after the depot injection, and stimulation time was increased. Hence, depot injections are not the first choice in terms of cost-effectiveness except in cases of endometriosis where the ultra-long protocol increases pregnancy rates.[9]

GONADOTROPIN-RELEASING HORMONE ANTAGONISTS

Development of Gonadotropin-releasing Hormone Antagonists

The antagonist analogs have an immediate and direct suppressive effect on the gonadotropin secretion. This inhibition or suppression is reversible, getting corrected once the antagonist administration is stopped. The GnRH antagonists act by competitive blocking of pituitary GnRH receptors. The search for antagonists suitable for therapeutic use encountered two major hurdles—low potency and low safety. Over the last 20 years, three generations of GnRH antagonists have been developed. In the third generation of antagonistic analogs, the risk of histamine release and anaphylaxis was significantly reduced making it suitable for clinical use and compounds such as cetrorelix and ganirelix were deployed for the use in stimulation protocols. In GnRH antagonists, substitutions have been made at multiple positions.[10-12] The substitution in the first three amino acids is what makes these compounds antagonists rather than agonists. In the third-generation antagonists, the substitutions at amino acid positions 8 and 10 have resulted in the elimination of the histamine release seen in the early antagonists **(Table 2)**.

TABLE 1: Structure of gonadotropin-releasing hormone (GnRH) and its agonists.

Compound	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
GnRH	Glu	His	Trp	Ser	Tyr	Gly	Leu	Arg	Pro	Gly-NH2
Leuprolide						Leu				NH-Et
Buserelin						Ser				NH-Et
Goserelin						Ser				AzaGly-NH2
Histrelin						D-His				AzaGly-NH2
Nafarelin						2Nal				Gly-NH2
Triptorelin						Trp				Gly-NH2

TABLE 2: Structure of gonadotropin-releasing hormone (GnRH) and its antagonists.

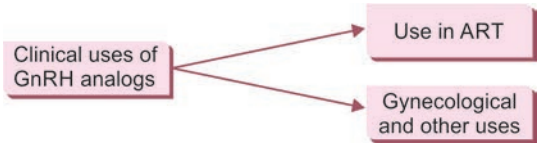
Compound	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
GnRH	Glu	His	Trp	Ser	Tyr	Gly	Leu	Arg	Pro	Gly-NH2
Cetrorelix	Ac-D-Nal	D-Phe	D/Pal	Ser	Tyr	D/Cit	Leu	Arg	Pro	D-Ala-NH2
Ganirelix	Ac-D-Nal	D-Phe	D/Pal	Ser	Tyr	D-hArg	Leu	L-h Arg	Pro	D-Ala-NH2

CLINICAL USES OF GONADOTROPIN-RELEASING HORMONE ANALOGS

Due to its ability to cause rapid desensitization of the pituitary gland after continuous and prolonged nonpulsatile administration leading to inhibition of ovarian steroidogenesis, many clinical applications were derived. Also, stopping administration of the analog leads to reversal of this condition and normal functioning of the ovary was resumed. This reversible state of hypogonadotropic hypogonadism was also termed as "medical gonadectomy" or "medical hypophysectomy".

Initially, the agonists offered a major advantage that was the efficient termination of the spontaneous LH surge. Without the use of a GnRH agonist, the incidence of premature LH surges and subsequent luteinization in cycles with exogenous gonadotropin stimulation, lead to an increased cancelation rate.[13] A meta-analysis of randomized controlled trials has concluded that the use of GnRH agonist has reduced cancelation rates and has also increased the number of oocytes and embryos, allowing better selection and increasing pregnancy rates.[14]

Wide scale clinical use of commercially available GnRH agonists have proved their efficacy in treatment of metastatic prostatic cancer,[15] breast cancer,[16] uterine fibroids and precocious puberty, and endometriosis.[17] The physically, psychologically, and socially impairing syndrome of central or true isosexual precocious puberty is another condition where GnRH analogs have found wide application.



Use of Gonadotropin-releasing Hormone Analogs in Assisted Reproductive Technology

Gonadotropin-releasing Hormone Agonist

Dosage and protocols: The most commonly used GnRH agonist protocols during controlled ovarian hyperstimulation are:

- *Long agonist or the downregulation protocol:* GnRH analog is started in the midluteal phase usually as a daily dose and continued throughout the stimulation to achieve suppression of the LH surge. The cycle may be spontaneous or induced by progestogen and/or estrogen compounds. A long GnRH agonist protocol can be used in combination with oral contraceptive pills and may be advantageous in prevention of functional ovarian cysts and also for the programming of IVF cycles. The rare possibility of an early pregnancy being there during the administration of GnRH agonist is also prevented by this approach.
- The long agonist protocol is useful in programming cycles and the administration of human chorionic gonadotropin (hCG) as the trigger required for final maturation prior to oocyte retrieval can be delayed, without any detrimental effect on IVF outcomes.[18,19]
- *Short agonist protocol:* Here the GnRH analog is started on day 2 of the menstrual cycle and continued throughout the stimulation. The initial administration helps in providing the flare effect and the release of pituitary gonadotropins helps to add to the stimulatory effect.[20] Continuous administration later helps to suppress the LH surge but not as effectively as in the long protocol. The immediate stimulatory action of GnRH agonist serves as initial stimulus for follicular recruitment (so called flare-up). On other hand, this short protocol might increase gonadotropin in early phase which induces enhanced ovarian androgen release. This is associated with the decreased oocyte quality and declined ongoing pregnancy rates compared to long protocol.[21]
- *Ultra-short and microdose protocols:* In the ultra-short protocol, the GnRH analog is administered only for the initial 3 days of the stimulation protocol. The gonadotropins are started 1 day after the initiation of the GnRH analogs. In the microdose protocol, doses of 60–80 μg are administered twice daily along with gonadotropins and it is especially useful in poor responders.

A meta-analysis that compared ultra-short, and long IVF protocols suggested a higher number of oocytes retrieved and higher pregnancy rates in long protocol, however more ampoules of gonadotropins were needed.[22] Nevertheless each protocol has its place and choosing the right indication for a certain type of protocol becomes beneficial **(Fig. 1)**.

GnRH agonists for triggering ovulation: The GnRH agonists can be used as an alternative way for hCG to trigger the endogenous LH and FSH surges and subsequent final maturation of the oocyte and ovulation. This is especially useful in the cases at risk of hyperstimulation as using hCG in these cases can aggravate the problem of ovarian hyperstimulation syndrome (OHSS).

Both LH and FSH levels rose over 4–12 hours and were elevated for 24–34 hours after GnRH agonists in comparison to approximately 6 days of elevated hCG levels after 5,000 IU hCG administration. The definite effect of single administration of GnRH analogs to trigger rupture of follicle in anovulatory women or in controlled ovarian

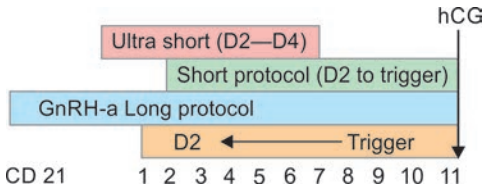


Fig. 1: Gonadotropin-releasing hormone agonist (GnRH-a) protocols. (hCG: human chorionic gonadotropin)

hyperstimulation is now well recognized.[23,24] However, use of GnRH agonist trigger leads to short luteal phases, in comparison to hCG cycles.[23-25]

The GnRH antagonists cause an immediate suppression of the LH surge and as long as sufficient antagonist is present, suppression of FSH and LH will continue. This property has helped in the development of various stimulation protocols that can utilize the effect of quick inhibition of the LH surge, right from the antagonist protocol to the minimal stimulation and luteal phase stimulation protocols.

GnRH agonists for luteal phase support: The concept of using GnRH agonist as luteal phase support (LPS) was introduced approximately in 2005. The hypothesis is that, GnRH agonist will amplify LH secretion from the anterior pituitary which supports the corpus luteum.

It has also been hypothesized to have effects on the endometrial GnRH receptors and even directly on the embryo.[26]

Routes of administration commonly used are single dose subcutaneous injection Decapeptyl 0.1 mg on day 5 or day 6 of oocyte retrieval or intranasal form with nafarelin 200 mg twice daily initiated on the evening of oocyte retrieval.

A Cochrane review by Van der et al. in 2015 suggested that there was an increased live birth rate and ongoing pregnancy rate with the use of GnRH agonist along with progesterone in the luteal phase, compared to using progesterone alone.[27]

Gonadotropin-releasing Hormone Antagonist

Dosage and protocols ***(Fig. 2)****:*

- *Single high-dose protocol (French protocol):* Gonadotropins are started from day of the cycle and a single high-dose of antagonist (3 mg) is administered on day 8 or when the estradiol levels are around 200 pg/mL or when the leading follicle is 14 mm. This single dose is expected to suppress the LH surge for 3 days.[28] In case the criteria for trigger have not been reached by then a daily antagonist dose can be administered. This protocol is rarely used in the clinical practice nowadays.
- *The fixed daily dose protocol (Lubeck protocol):* In a dose-finding series with doses of 3 mg, 1 mg, and 0.5 mg, cetrorelix a dose of 0.25 mg was recognized as minimal effective dose in the multiple dose protocol.[29] In the fixed protocol, gonadotropins are started from the second day of the cycle and antagonist is added on a fixed day (day 6 of stimulation) in a daily dose of 0.25 mg till the hCG trigger.
- *The flexible daily dose protocol:* Daily dose of 0.25 mg is started when the leading follicle reaches a size of 14 mm till the day of hCG trigger.
- *Timing the hCG trigger:* In the long agonist protocol, delaying the time of hCG trigger has not shown any detrimental effect on cycle outcome. However, a prospective randomized study studied patients on antagonist cycles who were randomized to receive hCG (10,000 IU) on the day when follicle reached 17 mm in size or 2 days later.[30] Doing this, the authors observed a significant improvement in cycle outcome with a greatly improved implantation rate in the early hCG group and trend toward optimized ongoing pregnancy rates. Whether this leads to an improvement in embryo quality or endometrial quality is still a matter of debate. This is an important step in achieving an optimal cycle outcome in GnRH antagonist's cycles.

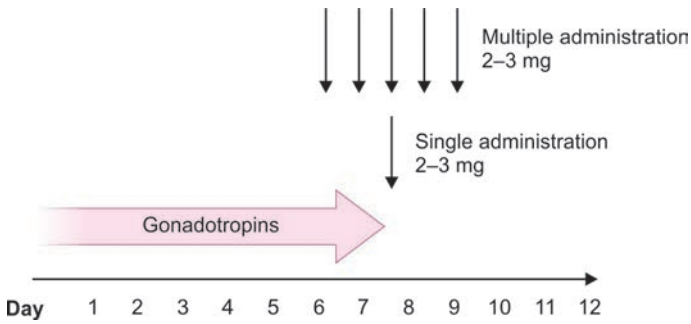

Fig. 2: Gonadotropin-releasing hormone (GnRH) antagonist dosage and protocols.

Newer treatments with antagonists: The advent of GnRH antagonists helped in formulating different protocols of ovarian stimulation where immediate suppression of LH surge could be applied when needed. Some examples are:

- *Modified natural cycle:* Here the antagonist is administered when follicle size reaches about 14 mm before hCG trigger. No stimulatory drugs are given prior to that; however, after addition of antagonist, FSH or LH could be given. It is used in poor responders, and if there is contraindication to stimulation.
- *Minimal and mild IVF:* The inception of GnRH antagonists has been a key to the development of these protocols. Here lower doses of FSH or human menopausal gonadotropin are used for stimulation at times along with oral ovulogens to obtain about eight or less oocytes.
- *Random start and luteal phase protocols:* Here the stimulation is started on any day of the menstrual cycle and the LH activity at that point is taken care of with the use of antagonists.

The introduction of GnRH antagonists in the field of ovarian stimulation has several advantages, such as:

- A more convenient method of ovarian stimulation with a shorter period of stimulation and no preceding pituitary suppression.
- A more physiologic way of ovarian stimulation integrated in a spontaneous menstrual cycle.
- Pituitary suppression is started when a prematuration LH surge threatens.

- The risk of OHSS can substantially reduce especially with the use of the GnRH antagonists cetrorelix.

The GnRH antagonists use differs in certain areas as compared to an analog, for example:

- Follicle cohort synchronization may be required so as to bring up good number of follicles.
- Timing of hCG may be a critical step and should happen at about 17–18 mm follicle size.
- LPS is necessary to achieve optimal outcome of the cycles.

The GnRH agonist trigger can be applied when at risk of OHSS or in donor stimulation and if freezing of all embryos is planned.

Clinical applications of GnRH analogs in the management of the infertile patients and in ovulation induction: In the management of the infertile patient, GnRH agonists can be used for various indications:

- To suppress the pituitary-ovarian axis before and simultaneously during ovarian stimulation and ovulation induction with exogenous gonadotropins.
- In endometriosis, for prolonged suppression of the pituitary-ovarian axis which is shown to improve IVF rates by fourfold.
- As an ovulation trigger, GnRH agonist trigger is used in IVF cycles using antagonist protocols. As mentioned previously, this is done in patients with polycystic ovary syndrome (PCOS) at the risk of hyperstimulation, in donor stimulation cycles and when freezing all embryos has been planned.
- The GnRH antagonists are used in combination with gonadotropins in many new stimulation protocols such as minimal and mild protocols, random start protocols, and the dual stimulation protocols where its ability to suppress LH immediately is utilized so that stimulation can be started at any point during the menstrual cycle.
- The choice of the GnRH analog to be used based on its delivery system, its mode of administration and its biological half-life, will determine the optimal gonadotropin treatment protocol.

With markers of ovarian reserve now available, patients are usually categorized into normal, poor or hyper-responders. Studies have identified protocols of GnRH analogs best suited for each of these categories in order to obtain optimal number of oocytes and prevent cycle cancellation or ovarian hyperstimulation.

Expected poor responders: In patients with an anti-Müllerian hormone (AMH) level of ≤0.1 and negligible antral follicles seen, no pregnancy was observed irrespective of the stimulation protocol used. These patients should be counseled regarding poor chances of success and using a modified natural cycle stimulation or minimal stimulation should be the goal in order to decrease the cost burden.

In patients with AMH levels between 0.5 and 1.3 ng/mL and antral follicles between 5 and 7, antagonist protocols were associated with a substantial fall in cycle cancellation and showed a trend toward higher pregnancy rates.[31] The short GnRH agonist protocols or the microdose flare protocols are also good options in these patients.

Advantages of antagonist protocol in poor responders are:

- The long downregulation protocol may have an unfavorable effect in poor responders as it may induce an excessive ovarian suppression that could result in decreased or absent follicular response.[32,33] The GnRH antagonists are not administered during the stage of follicular recruitment and hence suppression of endogenous gonadotropins secretion is not present at that time.
- The ovarian reserve is assessed by ultrasound on days 2–3 of the cycle to plan controlled ovarian stimulation (COS) and decide whether to initiate gonadotropins in the cycle, to predict and expect an optimal response.
- Second, with use of GnRH antagonist we can have recourse to a new gonadotropin, a hybrid molecule that has a prolonged half-life (corifollitropin alpha) and supports the cohort of follicle receptive to stimulation for 7 days.[34] The use of these long-acting gonadotropins causes a swift increase in the serum FSH concentration resulting in a remarkably higher exposure of the small antral follicles to constant high levels of FSH during the early follicular phase and significantly help in this category of patients.[35]

Expected normal responders: Women with AMH levels between 1.3 and 3.4 and antral follicle count (AFC) between 8 and 10 usually fall here. These patients would respond well to both the GnRH agonist downregulation protocol as well as the antagonist protocol. The aim would be to procure about 8–14 oocytes. The decision can be made depending on the patient compliance, time available for stimulation, and the comfort of the physician with the particular protocol.

Expected high responders: Recent studies have revealed that the use of antagonists is related to reduced occurrence of a high response and a significantly reduced incidence of OHSS or even of cycle cancellation because of the risk of OHSS.[36,37]

The days required for stimulation in an antagonist protocol were fewer in number than the GnRH agonist protocol (9 days vs. 13 days). It was also observed that in antagonist protocol there was reduced need for cryopreservation of embryos due to excess response and decline in hospitalization rate for OHSS (13.9% in the agonist group vs. 0.0% in the antagonist group).[38]

A significantly higher pregnancy rate was observed in antagonist protocol in higher responders (61.7 vs. 31.8%; p: 0.05).[38]

Finally, by using the GnRH antagonist protocol for COS, initiation of a LH surge when compared with that occurring physiologically at midcycle to trigger ovulation could be obtained by administering a single bolus of GnRH agonist.[39]

Gynecological and Other Uses of Gonadotropin-releasing Hormone Analogs

Clinical indications of use where gonadotropin suppression is desired are described here.

Endometriosis

Endometriosis is a complex disease and is characterized by the presence of ectopic endometrium. The growth and spread of endometriosis are established by the cyclic production of ovarian hormones. When the function of the ovary is suspended there is loss of cyclical hormone release, the uterine as well as ectopic endometria undergo atrophy, and endometriosis resolves. To control this course of the disease, temporary suppression of ovarian function is the principle of hormonal treatment in endometriosis. Endometriosis being a hormone-dependent condition, the possibility of selectively suppressing the ovarian secretion of estrogen by receptive GnRH administration causes reversible downregulation of gonadotropin secretion inducing a state of hypogonadotropic hypogonadism, pseudomenopause, or medical castration. Analogs are usually administered in monthly injections over 4–6 months. Undesirable symptoms of hypoestrogenism and decrease in bone density with long-term use can be tackled with the use of small doses of estrogen and progesterone. Several studies are underway to elicit the use of GnRH antagonists in endometriosis without the side effects of severe estrogen depletion. One study involved the use of 3 mg of cetrorelix administered weekly over 8 weeks. There was adequate control of symptoms and estradiol levels were maintained between 50 and 60 pg/mL preserving basic estrogen production.[40]

Recently an oral nonpeptide GnRH antagonist, elagolix, has been tried in women with endometriosis to reduce the symptoms of dysmenorrhea and pelvic pain. Elagolix has been tried in the dose of 15 mg daily (low dose treatment) and in the dose of 200 mg twice daily (high-dose treatment). However, both doses were associated with hypoestrogenic side effects.[41]

Uterine Fibroids

Fibroids are the most common tumors of female genital organs and probably the most common tumor in women. Fibroids may associate with infertility, menorrhagia, and/or dysmenorrhea. Management of patients who have sympathetic uterine fibroids has traditionally been myomectomy, i.e., surgical removal of the fibroid for those desirous of children or hysterectomy for women with large or multiple fibroids whose families are complete.

Luteinizing hormone-releasing hormone (LHRH) agonists, by creating a hypoestrogenic environment, have provided for the first time a medical treatment of uterine fibroids.[42] LHRH agonists significantly shrink these tumors in the majority of patients and cause their complete clinical disappearance in a majority of subjects.[43] In most cases, however, relief is temporary and regrowth to pretreatment size occurs within 3 months of cessation of therapy.

Preoperative treatment for 3 months may also help by improving the patient's preoperative status and providing concurrent symptom relief.[44] The 30–40% reduction in size may permit laparoscopic[45] or in cases of submucous myoma, hysteroscopic[46] removal of the myoma. However, the surgical plane may get altered making removal difficult.

The use of GnRH antagonists in fibroids is limited due to its short half-life and the nonavailability of the depot formulation, thus requiring repetitive dosing usually daily for most antagonists.

Precocious Puberty

The GnRH analogs remain the treatment of choice in central precocious puberty. The suppression of the pituitary-gonadal axis ceases sexual development, declines skeletal maturation, and decreases the growth rate without serious undesirable effects.

Benign Prostate Hyperplasia

Benign prostate hypertrophy affects males 60 years or older, and the treatment of choice is usually surgical removal. In patients with high surgical risk, the administration of GnRH agonists reduces the size of the prostate to 30% the original size, and improves the symptoms of urinary obstruction. GnRH antagonists can also be sued and its administration makes improvement last even after stopping medicine probably due to the direct effect of the antagonist on the prostatic epithelium or on some growth factors

Oncology

Cancers that depend on sex steroid hormones can be treated with GnRH analogs. These include prostate, breast, ovarian, and endometrial cancers. Prostate cancer, among all hormone-sensitive cancers, shows the best response to endocrine therapy. GnRH analogs can be used alone or in combination with antiandrogens such as flutamide. In breast cancer, GnRH agonists and antagonists have been tried both in pre- and postmenopausal women alone, or in combination with antiestrogens. GnRH receptors are located in the ovary; hence, GnRH antagonists may be of great value in the treatment of ovarian cancer by two mechanisms—through suppression of ovarian stimulation by gonadotropins and through direct inhibition of ovarian cells. In some cases of

TABLE 3: Comparison of gonadotropin-releasing hormone (GnRH) agonists and GnRH antagonists.

GnRH agonists	*GnRH antagonists*
Initial flare effect	No flare-up effect
Longer duration of stimulation	Shorter duration of stimulation
Increased gonadotropin requirement	Fewer ampoules of gonadotropin required
Small doses required	Need for higher doses
Pituitary response downregulated	Preserved pituitary response to GnRH
Asynchronicity of follicles rare	Asynchronous development may happen
Higher risk of OHSS	Lower risk of OHSS
Not used in mild or dual protocols	Used in natural, mild, and dual protocols
Slightly more oocytes obtained	Slightly less oocytes obtained

(OHSS: ovarian hyperstimulation syndrome)

recurrence of endometrial cancer, GnRH analogs provide prolonged relapse-free survival and better quality of life. This action can also be ancillary to steroid suppression or maybe due to an extrapituitary action of the analogs. The GnRH agonists and antagonists have also been known to preserve the gonad from the toxic effects of chemotherapy and radiotherapy on the germinal epithelium.

KEY POINTS

- The GnRH analogs are widely used in IVF to control the endogenous LH surge and achieve augmentation of multifollicular development. They also have widespread applications in many other areas as discussed above. The advent of GnRH antagonists has helped in devising newer stimulation protocols, making them more patient-friendly **(Table 3)**.
- The long GnRH agonist protocols give the highest pregnancy rates in the normal responders.
- There is some evidence that the short flare-up protocol is the treatment of choice for patients with diminished ovarian reserve (poor responders). Dose reduction might be the key point in optimizing pregnancy rates. Finally, GnRH agonists can be used to induce final maturation and ovulation as an alternative to hCG in assisted reproductive technology (ART).
- The GnRH-antagonist regimen (GnRH-ant) is effective in preventing a premature rise of LH and therefore results in a shorter and more cost-effective ovarian stimulation protocol compared to the long agonist protocol. However, there is a difference in the synchronization of follicular recruitment and growth in the GnRH-agonist (GnRH-a) and GnRH-antagonist regimens with better follicular growth and oocyte maturation seen with GnRH-a treatment.[47]

CHAPTER 50

Monitoring of Ovarian Stimulation

Snehal Dhobale Kohale

INTRODUCTION

The basic functional unit of the ovary is "follicle", which undergoes different morphologic and hormonal changes in the menstrual cycle. The concept that "the mammalian oocyte was enclosed within the ovarian follicle" was first put forward by Karl Ernst von Baer in 1827.[1] During follicular development, antral follicle passes through various gonadotropin-dependent phases such as recruitment, selection, and dominance before ovulation.[2] Ovulation may need to be induced in anovulatory cycles (e.g., polycystic ovary disease) or during timed intercourse (TI), intrauterine insemination (IUI), and in vitro fertilization (IVF) cycles. The aim of ovulation induction (OI) can be monofollicular growth or multifollicular growth [controlled ovarian stimulation (COS)]. Ovulation-inducing agents (tablets and gonadotropins) cause follicular growth as well as hormonal changes in the ovary.

NEED FOR MONITORING

- To obtain the optimum outcome of stimulation by modifying drug dosages
- To avoid complications of stimulation such as ovarian hyperstimulation syndrome (OHSS) and multiple births.

METHODS OF MONITORING

There are two methods of monitoring given in **Table 1**:

1. Biochemical or hormonal monitoring
2. Clinical monitoring.

TABLE 1: Methods of monitoring.

Biochemical/hormonal monitoring	***Clinical monitoring (follicular growth and endometrial assessment)***
• Home monitoring: – Basal body temperature – Cervical mucus test – Salivary ferning assessment – Electronic resistance evaluation of salivary and vaginal secretions – Urinary LH test • Blood hormonal assays of AMH, FSH, LH, estradiol, progesterone, inhibin B, etc.	• Transvaginal ultrasound 2D, 3D, color Doppler • Self-operated endovaginal telemonitoring (SOET)

(AMH: anti-Müllerian hormone; FSH: follicle-stimulating hormone; LH: luteinizing hormone)

STAGES OF MONITORING

Before Stimulation

It involves baseline assessment that helps in choosing the appropriate stimulation protocol so as to avoid poor response, cycle cancellation, or hyperresponse.

- *Transvaginal ultrasound:* For antral follicle count (AFC) and for ruling out other pathologies
- *Hormonal profile:* Anti-Müllerian hormone (AMH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyroid function test, and prolactin.

During Stimulation

- To confirm downregulation in gonadotropin-releasing hormone (GnRH) agonist long protocol
- To determine response to gonadotropins (poor response, hyperresponse, or no response)
- To determine the dose (step up and step down) and duration of gonadotropin therapy
- To detect premature LH surge
- To determine the optimal timing of trigger—human chorionic gonadotropin (hCG) administration
- To detect ovulation in OI or IUI cycles
- To assess the risk of OHSS in COS cycles so as to apply some strategies to prevent it (such as cabergoline use or GnRH agonist trigger instead of hCG in GnRH antagonist cycles).
- To determine the time of oocyte retrieval.

After Stimulation

- To establish ovulation
- To establish an optimal response to agonist trigger
- To identify complications of OI:
  - Luteinized unruptured follicle (LUF)
  - Retention or functional cyst
- To confirm pregnancy.

CHOOSING METHODS OF MONITORING

Monitoring should be easy, reliable, cost-effective, and patient-friendly.

Extent of monitoring will depend on:

- The aim of OI (monofollicular or multifollicular development)
- Drugs used for stimulation (oral medications or gonadotropins)
- Treatment planned (natural, IUI, or IVF) **(Table 2)**.

It is obvious that multifollicular development with gonadotropins in IVF cycles would need more intense and meticulous monitoring to avoid complications such as ovarian hyperstimulation.

TABLE 2: Optimum monitoring methods according to treatment planned.

Treatment planned	*Optimum monitoring*
Timed intercourse	Home monitoring (basal body temperature, cervical mucus assessment, salivary fering assessment, urinary luteinizing hormone kits) or Transvaginal ultrasound
Intrauterine insemination	Transvaginal ultrasound
In vitro fertilization	Transvaginal ultrasound and blood hormonal assays

Home Monitoring

Basal Body Temperature

- *Principle:* Thermogenic property of progesterone causes a rise in basal body temperature (BBT) by 0.5°F when progesterone levels are >3–5 ng/mL, 1–5 days after mid-cycle LH surge.
- *Method:* Temperature has to be measured each morning, on awakening, before arising from the bed with a special thermometer having an expanded scale of 96.0–100.0°F marked in tenths of 1°.
- Ovulatory cycles have a "biphasic response" (follicular phase: 97–98°F; on day of ovulation: nadir; and 0.4–0.8°F rise in luteal phase) as shown in **Figure 1**.
- *Advantages:* It is a low-cost, easy, and noninvasive method.
- *Disadvantages:* It is a retrospective diagnosis of ovulation. BBT readings can be affected by factors such as illness, infection, anxiety, stress, fatigue, jet lag, nightmares, insomnia, smoking, alcohol, exercise, and electric blanket use.

Cervical Mucus Assessment (Figs. 2A and B)

- *Principle:* It is based on the change in the characteristics of cervical mucus due to preovulatory estrogen rise.
- *Method:* Insler scoring system—It is a semiquantitative assessment of cervical mucus. The assessment parameters are the appearance of cervical os, mucus quantity, spinnbarkeit, and fering. In the modified

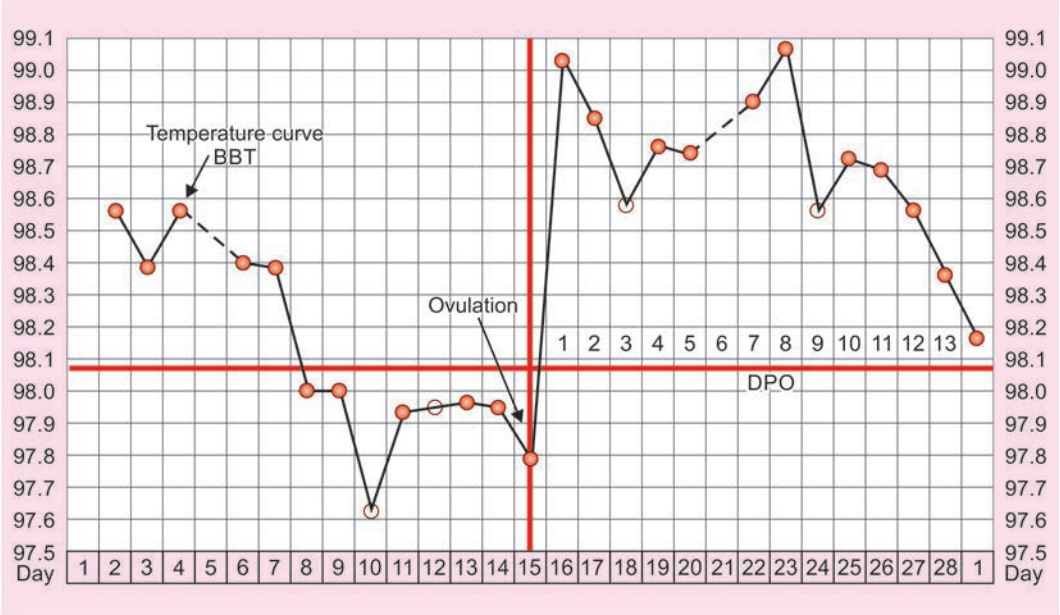

Fig. 1: Basal body temperature (BBT) chart in ovulatory cycle: Biphasic response. (DPO: days past ovulation)

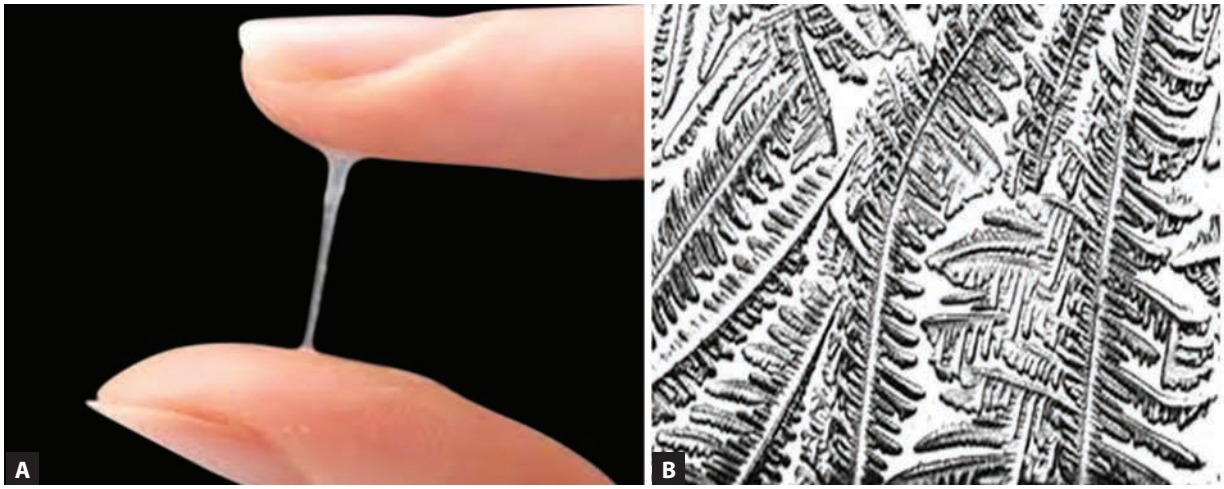

Figs. 2A and B: Cervical mucus: Spinnbarkeit and ferning patterns.

TABLE 3: Modified Insler scoring system.

	Score			
Parameters	***0***	***1***	***2***	***3***
Appearance of cervical os	Tightly closed, as pink as surrounding tissue	Beginning to open and redden	Intermediate between scores 1 and 3	Maximally dilated (6 mm diameter)
Mucus quantity	Not visible at external os and none aspirated (0 mL)	Not visible at external os but some aspirated (0.1 mL)	Visible at external os and can be aspirated (0.2 mL)	Definite cascade visible at external os (>0.3 mL)
Spinnbarkeit	No stretching	Stretches 1–4 cm before breaking	Stretches 5–8 cm before breaking	Stretches >8 cm before breaking
Ferning	Not visible	Less than half mucus starting to fern	More than half mucus showing good ferning (primary and secondary stem ferning)	All mucus showing good ferning (with tertiary and quaternary stem ferning)
Cellularity (leukocytes)	Full of leukocytes >20 per 40 × field or >1,000/mm	Many leukocytes 11–20 per 40 × field or 501–1,000/mm	Few leukocytes 1–10 per 40 × field or 1–500/mm	No leukocytes

Note: Score ≥12/15: Good ovulatory cervical mucus; score 10 or 11/15: Adequate ovulatory cervical mucus.

Insler scoring system, mucus cellularity is an additional parameter **(Table 3)**.

- *Disadvantages:* Less precision in determining exact ovulation time and individual variations in the response of the cervical glands to estrogen.

Salivary Ferning Assessment

During ovulation, with increased estradiol levels, saliva shows similar biochemical changes to cervical mucus. There is increase in salivary NaCl concentration, which results in crystallization, thus demonstrating a ferning pattern. There are commercially available kits that contain a handheld pocket mini microscope to demonstrate this ferning pattern. It has 78% specificity and 80% sensitivity to detect salivary ferning.

Electronic Resistance Evaluation of Salivary and Vaginal Secretions

The device called CUE Fertility Monitor provides a digital measurement of the electrical resistance of saliva (SER) and vaginal secretions (VL) using a computerized algorithm. Saliva and VL undergo NaCl and other electrolytic changes with LH rise; those can be measured by changes in electrical resistance by monitor. The data are stored and with computerized software, ovulatory window can be predicted with the use of oral probe for salivary assessment and vaginal sensor for VL.

- *Advantages:* Reusable monitors and easy to use at home
- *Disadvantages:* Costly device and conflicting data about the accuracy of this method.

Urinary Luteinizing Hormone Kit

- *Principle:* LH is having short half-life and is rapidly cleared in urine.
- Ovulation occurs 14–26 hours after LH surge detection, almost always within 48 hours.
- *Method:* Testing of late afternoon to early evening urine sample (4–10 PM).
- *Advantages:* It predicts ovulation in the next 24–48 hours of positive test result with >90% probability.
- *Disadvantages:* False-positive and false-negative results. Several diseases such as endometriosis, polycystic ovarian syndrome, premature ovarian failure, hyperthyroidism, renal failure, gonadotropin-producing neoplasia, and medications such as menotropins, danazol, clomiphene, hCG, hormone supplementation, and steroids can interfere with the accuracy of urinary LH test results. In women with irregular periods, LH surge can be missed even with daily testing. It cannot detect ovulation or complications such as LUF.

Ultrasound Monitoring

Real-time ultrasound is a frequently used method in the recent past for ovarian follicular development. "Follicular dynamics" is about the morphological and vascular response of the ovaries and uterus to the hormonal changes in the menstrual cycle.

- *Literature:* Visualization of follicles was first demonstrated by Kratochwil in 1972. A direct correlation between increasing follicular size and estradiol concentration in spontaneously ovulating women was demonstrated by Hackelöer et al. in 1979.[3,4] Several studies have demonstrated the correlation of follicle growth and changes in hormone levels in both stimulated and unstimulated cycles.[5,6]
- For real-time monitoring of ovarian function, the vaginal route is better than the abdominal route because of:
  - The smaller distance from the probe to the ovary
  - High resolution of the probes (5–7.5 MHz frequency)
  - The absence of a full bladder distorting pelvic organs
  - Improved convenience and patient compliance
  - The transvaginal scanning technique has been validated under normal, anovulatory, and gonadotropin-stimulated conditions.

Advantages of ultrasound for monitoring: Quick, easy, noninvasive method, and no known harmful effects to the oocyte or reproductive tract.

A few anatomical pelvic structures may look similar to the growing follicle on ultrasound. These include:

- Internal iliac artery and vein cross section
- Cross section of blood vessels around the uterus and ovary
- Bowel
- Hydrosalpinx
- Ovarian cysts.

Ultrasound provides information about:

- Uterus, ovary, and adnexa and their abnormalities
- Ovarian reserve (AFC and flow indices)
- Ovarian response (follicle and endometrial growth and blood flow)
- Time for trigger.

The qualitative information is assessed by color Doppler and the quantitative information by power Doppler.

Baseline scan: It is the first scan on day 2 or 3 of the cycle when no follicle is >9 mm. It demonstrates baseline pathology in ovary, uterus or adnexa, and ovarian reserve. Its purpose is to categorize the ovaries into a normal responder, poor responder, and hyperresponder and accordingly to choose the optimum stimulation protocol.

"*Ovarian reserve*" is assessed by AFC and ovarian volume. It is nothing but likely number of follicles that may develop or likely number of eggs that may be retrieved after stimulation.

"*Ovarian response*" is assessed by intraovarian flow indices. It is nothing but approximate doses required to produce dominant follicles.

Antral follicle count is the number of small antral follicles (2–10 mm) in both the ovaries **(Fig. 3)**.

Number of small antral follicles (2–6 mm) represents the "functional ovarian reserve" as it is significantly related to age. AFC correlates well with age, ovarian reserve, and response to stimulation. AFC is useful to predict the ovarian response, thus decreasing the chances of cycle cancellation.[7] A low AFC is considered to be total of 3–6 antral follicles [mean of 5.2 with standard deviation (SD) 2.11] and is associated with poor response to ovarian stimulation during IVF but does not reliably predict failure to conceive.[8] AFC >14 predicts hyperstimulation with sensitivity of 82% and specificity of 89%. AFC has good intercycle and interobserver reliability

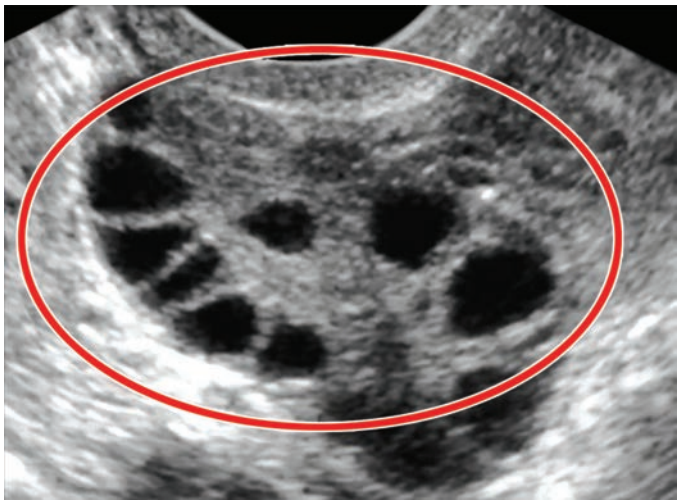

Fig. 3: Antral follicle count.

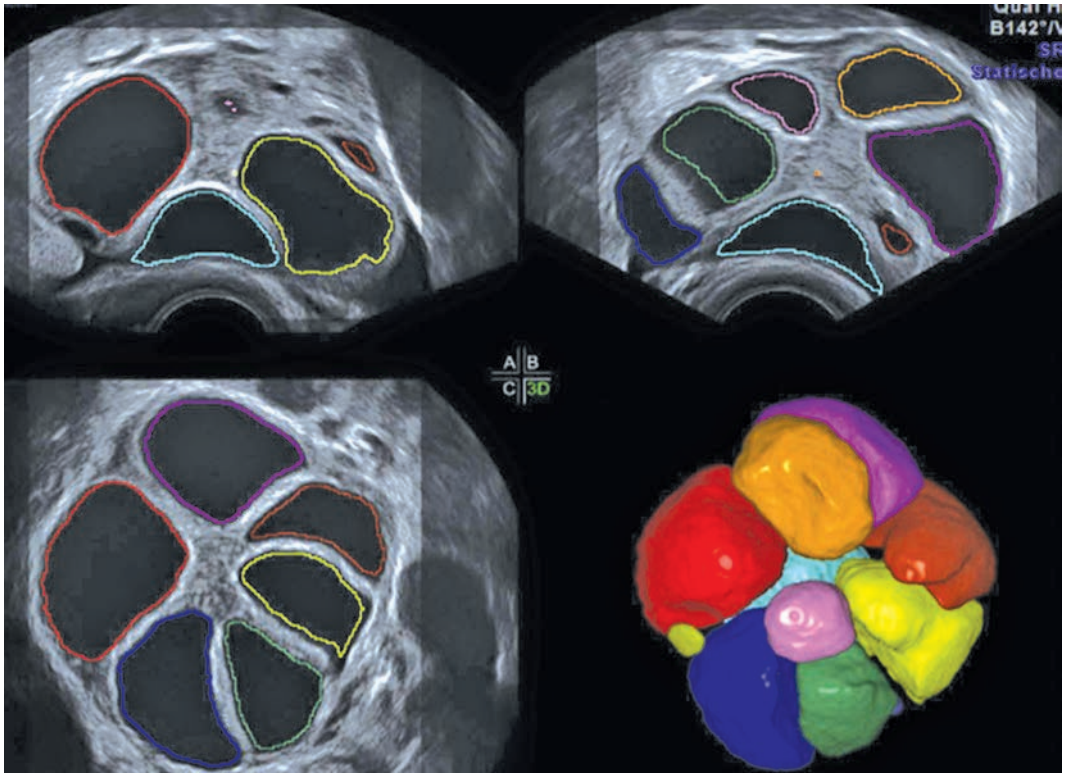

Fig. 4: Sonography-based automated volume calculation (SonoAVC).

in experienced centers.[9] Some variability is seen in younger women and those with high AFC. There is no impact of GnRH agonist used for pituitary downregulation on AFC, ovarian volume, and 3D power Doppler flow indices.[10] AFC can be evaluated by 2D, 3D, or 4D ultrasound.

Three-dimensional ultrasound is performed by manual measurement of follicle circumference through "virtual organ computer-aided analysis" (VOCAL) or by an automated ultrasound application, the "sonography-based automated volume calculation" (SonoAVC).[11,12] SonoAVC automatically identifies the boundaries of follicles. It measures the largest follicular diameters in "three orthogonal planes" **(Fig. 4)**.[11] A specific color is assigned to each follicle and it can be seen together with other follicles on the screen at the end. The "voxel" count within the identified hyperechoic area determines the follicular volume. It is the true measure of follicular volume even when its shape is irregular.[13,14] A good correlation has been demonstrated between the volume aspirated during oocyte retrieval and the SonoAVC calculated follicular volumes.[15] SonoAVC has more accuracy than traditional 2D measurements.[14] It also predicts the number of oocytes retrieved with a 60% retrieval rate.

Ovarian volume: Its is calculated by measuring each ovary in three planes with the formula of D1 × D2 × D3 × 0.52 cm^3/mL. The average volume of both ovaries gives mean ovarian volume. Poor response to stimulation is predicted by ovarian volume <3 mL, which has a high specificity of 80–90% and sensitivity of 11–80% **(Figs. 5A to C)**.[9]

Intraovarian flow indices **(Fig. 6)**: Ovarian stromal blood flow calculated at the time of starting stimulation shows good correlation with subsequent follicular response in IVF cycles.[16] Also, there is a good correlation between ovarian stromal flow index (FI) and the number of mature oocytes retrieved and pregnancy rate in the IVF cycle.[17]

Stromal flow index:

- *<11:* Poor responder
- *11–14:* Normal responder
- *>15:* Hyperresponder.

Stromal peak systolic velocity (PSV): Stromal PSV <10 after pituitary suppression is indicative of poor response. Stromal PSV >10 with unchanged resistance predicts the risk of hyperresponse.[18]

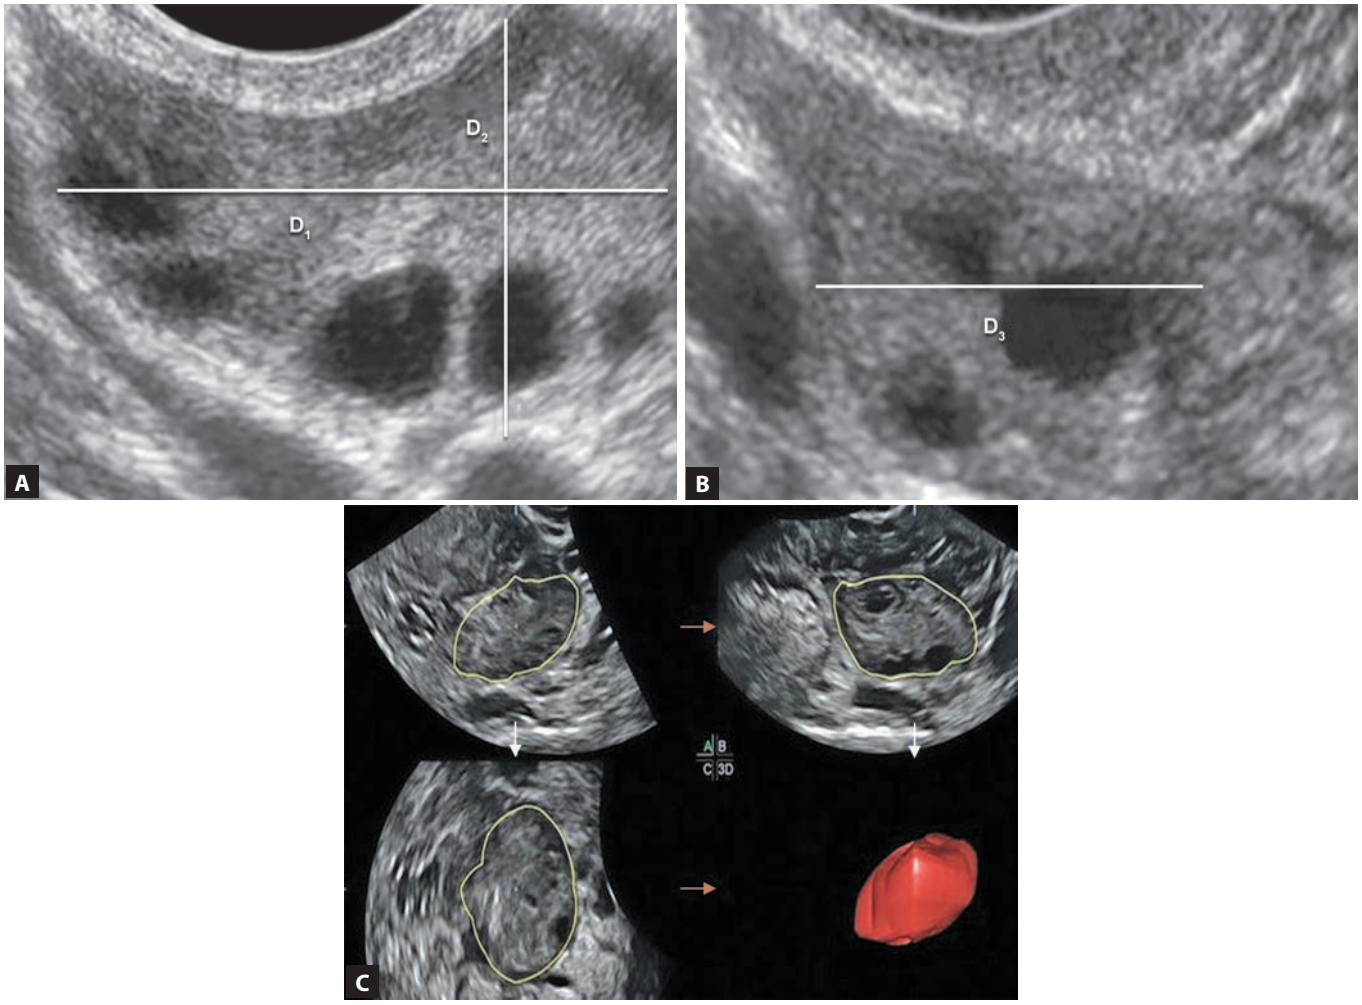
Uterine artery flow indices **(Fig. 7)**: Uterine artery resistance index (RI) >0.79 is associated with poor response and thus can predict the need of higher dosages of gonadotropins.[19] Lower uterine artery RI and higher PSV predict OHSS.

Ultrasound monitoring during ovarian stimulation includes assessment of:

- Follicular growth
- Endometrial thickness and patterns.

Assessment of Follicular Growth

Physiology: The first follicular structure that may be visualized on ultrasound is "secondary antral follicles" (2 mm), which



Figs. 5A to C: Ovarian volume 2D and 3D.

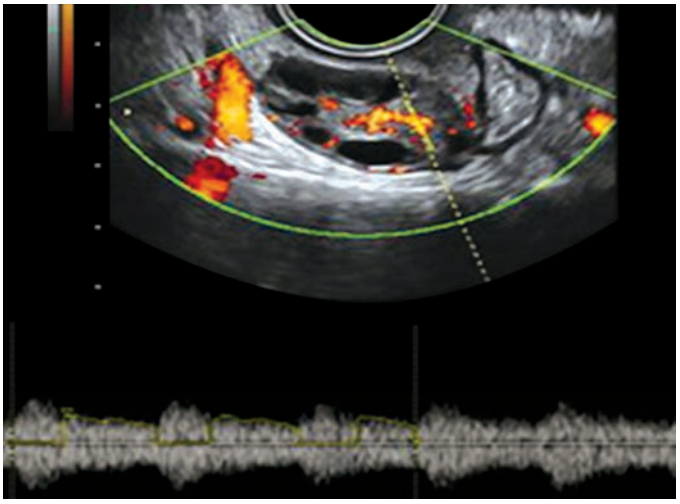


Fig. 6: Ovarian stromal flow index and peak systolic velocity.

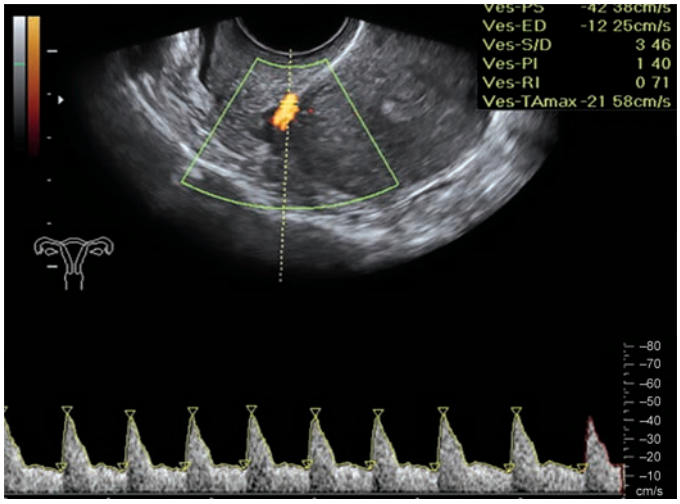

Fig. 7: Uterine artery flow indices.

are selected from the primordial follicular pool 80–90 days prior. There is a "selection" of dominant follicle by day 5. Between days 5 and 7, "dominance" of the follicle becomes apparent. Dominant follicle after 14 mm diameter has a growth rate of 1.5–2 mm/day until ovulation (20–25 mm diameter). Other follicles undergo atresia or developmental arrest.

Sonographically, the fate of the follicle can be decided by:

- Size
- Growth rate (as high as >2.3 mm/day in conception cycle)

- Wall thickness
- Internal echogenicity.

Prediction of ovulation:

- Increase in size (it is interesting to know that often the first largest follicle is not the largest follicle)
- Increase in granulosa cell thickness (growth rate 2–3 mm/day)
- Cumulus-like shadow 36 hours prior to ovulation[20]
- Sonolucent halo 24 hours prior to ovulation.[20] The vascularity of the theca cells is increased, and they become edematous after the LH surge. At the same time, separation starts between the granulosa cell and the theca cell layer. These changes are demonstrated as a line of decreased reflectivity around the follicle called "double contour" on ultrasound.
- Separation and folding of follicle lining 6–10 hours prior to ovulation.[20]

The "follicular growth pattern" rather than the follicular diameter has predictive value for anticipating the oocyte quality.[21] With the multifollicular growth in gonadotropin stimulation, it is difficult to identify changes in each follicle. The development of microvascular network around the follicle is responsible for proper follicular growth. The perifollicular blood flow (PFBF) indices are closely related to intrafollicular oxygen content and vascular endothelial growth factor (VEGF) concentrations **(Figs. 8A and B)**.[22] The oocytes retrieved from follicles with low oxygen content are frequently associated with mitochondrial dysfunction and abnormal chromosomal organization on metaphase spindle leading to segregation disorders and catastrophic mosaics in the embryos.[23] Thus, qualitative and quantitative analysis of PFBF by color Doppler and power Doppler is indicative of follicle competence. These ovarian flows also correlate well with the oocyte recovery rate.

By day 8 of the cycle, there is increase in the perifollicular vascularity in the theca cells of dominant follicle. The perifollicular RI starts falling from 2 days prior to ovulation and at the ovulation, it achieves the lowest value, which remains low for 4 days and then gradually starts rising to 0.5 by midluteal phase.

Perifollicular blood flow grading:

- *Grade 1:* Blood flow is <25% of follicle circumference
- *Grade 2:* Blood flow is ≥25% to <50% of follicle circumference
- *Grade 3:* Blood flow is ≥50% to <75% of follicle circumference
- *Grade 4:* Blood flow is ≥75% of follicle circumference.

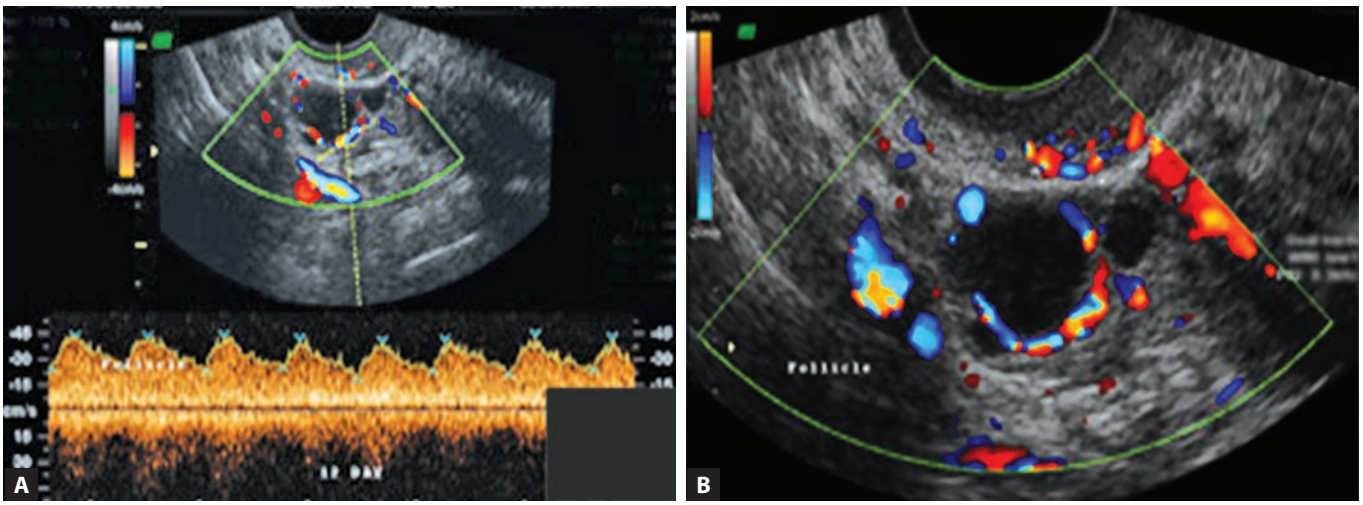
Follicles having >75% of surface perfusion, ovarian stromal PSV >10 cm/s, and RI <0.4–0.48 usually contain good quality oocytes, which develop into good embryos.[22] Oocyte from follicle with PSV <10 cm/s has a high chance of developing into abnormal embryos.

Nargund et al.[24] demonstrated the probability of developing grades I and II embryos that is 75% when perifollicular PSV is >10 cm/s, 40% when PSV is <10 cm/s, and 24% when there is no PFBF. Rising PSV with steady low RI indicates impending follicular rupture (an hour before ovulation, PSV can be as high as 45 cm/s).

Steady or decreasing PSV with rising RI indicates impending LUF.

Changes in PFBF with ovarian stimulation:

- Clomiphene citrate use reduces ovarian, especially perifollicular vascularization.[25]
- Letrozole use does not alter PFBF.
- PFBF is demonstrated to be higher with the use of menotropins (urinary products) than that of recombinant FSH due to LH activity.[26]
- In IVF stimulations, cases with good ovarian PFBF in early follicular phase demonstrate good PFBF even in late follicular phase and are thus associated with higher clinical pregnancy rates.



Figs. 8A and B: Perifollicular blood flow.

- Embryos derived from oocytes of highly vascularized follicles give higher clinical pregnancy rates. This has been demonstrated in the donor egg IVF cycles.[27]
- High perifollicular and uterine Doppler flow resistances are seen in poor responders.

Volume assessment of follicles by 3D ultrasound with Doppler consists of follicular volume, vascularization of cumulus, and perifollicular vascularization index (VI), FI, and vascularization flow index (VFI).

- 3D ultrasound is more accurate for assessment of the reliable parameter of follicle monitoring that is "follicular volume". In IVF cycles, follicles with a mean follicular diameter between 12 and 24 mm are associated with optimal oocyte recovery rate, fertilization rate, and cleavage rate, and it corresponds to the follicular volumes between 3 and 7 mL as stated by Wittmaack et al.[28]
- The chance of getting a mature oocyte from the follicle increases in the presence of cumulus, which can be detected by 3D ultrasound.[29]
- The perifollicular VI of 6–20 and FI >27 have higher pregnancy rates.[30]
- There is a strong correlation between 2D and 3D volume as well as 3D power Doppler angiography (PDA) indices as demonstrated in different studies.[31]

In practice, the follicular diameter is generally calculated by taking average of two or more measurements. Penzias et al.[32] found that the mean diameter of round and polygonal follicles accurately predicts the total follicular volume. But in cases of follicular crowding as may be seen in OI, especially with numerous ellipsoid follicles, the correlation between mean diameter and expected follicular volume and, presumably, oocyte maturity may be lacking.

Confirmation of ovulation: Although ultrasound does not allow precise timing or prediction of when ovulation will occur, it is an excellent technique for confirming ovulation once it has occurred. The ultrasound signs of ovulation are:

- Complete disappearance of the dominant follicle
- Decrease in the size of the follicle
- Irregularity of the follicular contour
- Central echoes within the follicle and formation of corpus luteum (echogenicity of the internal follicular area and that of the surrounding ovary becomes same)
- Presence of follicular fluid in the pouch of Douglas
- Hyperechogenic secretory endometrium.

Doppler of corpus luteum **(Fig. 9)**: It is the indicator of the functionality of corpus luteum. The normal value of RI of corpus luteum is 0.35–0.5. In the luteal phase deficiency (LPD), RI is 0.54–0.62, pulsatility index (PI) is 0.70–0.80, and PSV is 10–15.

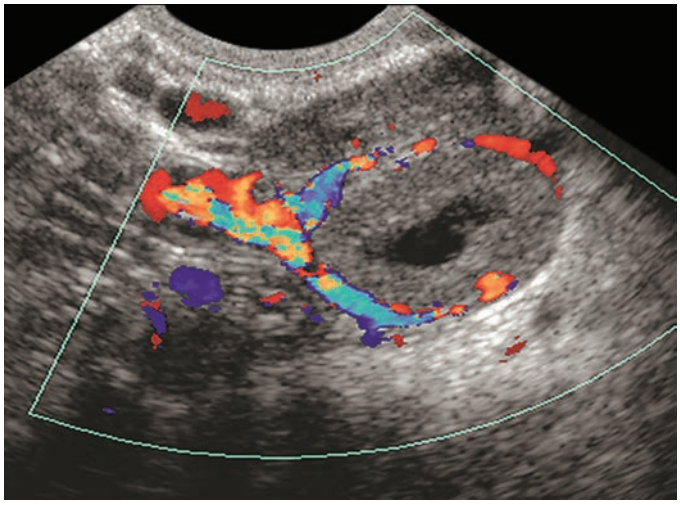


Fig. 9: Corpus luteum Doppler.

Uterine artery flow	

Assessment of Endometrium

The endometrium undergoes cyclical, morphological, and histological changes with typical sonographic patterns during the different phases of natural as well as stimulated cycles. These changes in the endometrium correlate with plasma estrogen and progesterone levels. Endometrial assessments have an important role in planning stimulation protocols, monitoring cycles, and predicting clinical outcomes **(Table 4)**.

Endometrial thickness is measured along the central longitudinal axis of the uterus. It is the maximum distance between the echogenic interfaces of the myometrium and the endometrium. The basal study of endometrial thickness should be started from cycle day 2 or 3 to look for proper shedding. The endometrium on this day should appear as a thin bright echogenic line or the cavity shows some blood with debris. A thick endometrium on basal scan (day 2) indicates improper endometrium shedding. The growth rate of endometrium in the proliferative phase is 0.5 mm/day and in the luteal phase, it is 0.1 mm/day. A thickness of >7 mm in the preovulatory period is associated with higher pregnancy rates **(Table 5)**.[33]

Smith's grading:

- *Grade A:* Bright endometrium—postovulation or the luteal phase
- *Grade B:* Endometrial reflectivity is similar to the myometrium—late follicular phase.

- *Grade C:* A solid area of reduced reflectivity appears as a darker area next to the lighter myometrium—mid-follicular phase.
- *Grade D:* Echoes are absent in the endometrium, but a bright central echo is seen, described as the triple line.

TABLE 5: Endometrial thickness and pattern in menstrual cycle.

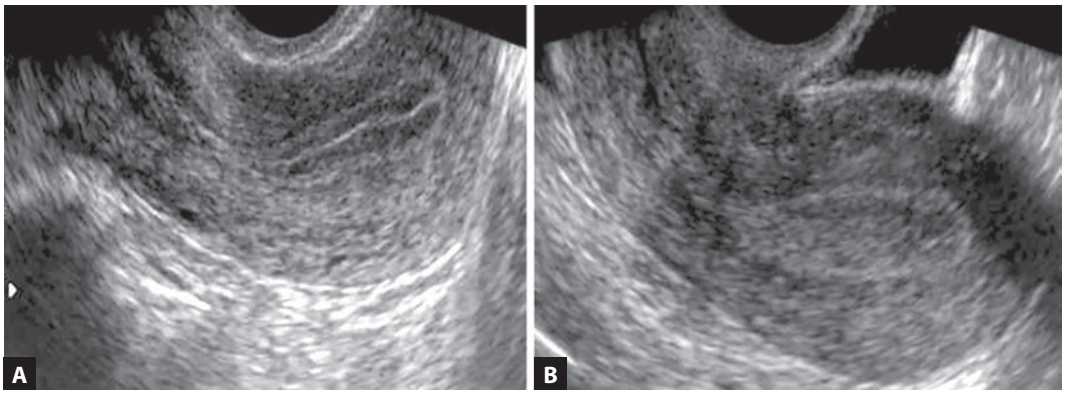
Phase	*Thickness*	*Pattern*
Menstrual (days 1–5)	<5 mm	Thin
Early follicular (days 6–10)	7–9 mm	Distinct "triple line" hypoechogenic endometrium
Late follicular (day 11 to ovulation)	9–12 mm	Isoechogenic (similar to myometrium)
Luteal (postovulation)	10–14 mm	Bright, fluffy. Absence of triple line

In the late follicular phase, on trigger day, grade B pattern is associated with higher pregnancy rates.[34]

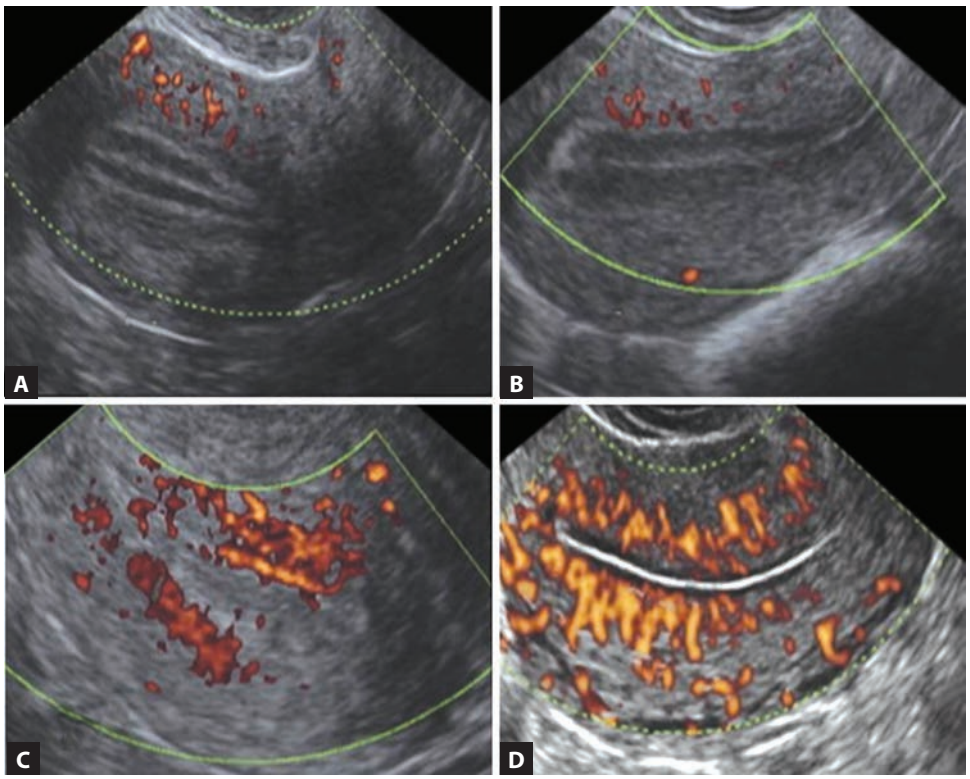
Nowadays, the endometrium pattern is classified into only two groups as multilayered and nonmultilayered **(Figs. 10A and B)**. Serafini et al.[35] have shown that a multilayered pattern is more predictive of implantation than any other parameter measured.

Estrogen produces a vasodilatory effect on the uterine arteries. It has been seen that RI and PI of uterine artery drop with increasing estradiol levels. Steer et al.[36] have found that no pregnancy occurred if the PI of uterine was >3 and there was no spiral artery blood flow in the zones of endometrium. Depending on the vascularization of the endometrial layers, the late proliferative triple line endometrium is divided into four zones **(Figs. 11A to D)**:[37]

1. *Zone I:* 2 mm thick area surrounding zone II



Figs. 10A and B: Multilayered and nonmultilayered endometrium.



Figs. 11A to D: Endometrial vascularity zones.

TABLE 6: Applebaum's uterine scoring system for reproduction.

Parameter	*Determination*	*Score*
Endometrial thickness (mm)	<7	0
	7–9	2
	10–14	3
	>14	1
Endometrial layering	No layering	0
	Hazy five-line appearance	1
	Distinct five-line appearance	3
Endometrial motion (no. of myometrial contractions in 2 minutes—real time) **(Table 7)**	<3	0
	≥3	3
Myometrial echogenicity	Course, inhomogenous	1
	Relatively homogenous	2
Uterine artery Doppler flow (pulsatility index)	>3	0
	2.5–2.99	0
	2.2–2.49	1
	<2.19	2
Endometrial blood flow within zone 3	Absent	0
	Present but sparse	2
	Present multifocally	5
Myometrial blood flow (gray scale)	Absent	0
	Present	2

Note: The score of 13 or less was found to have no conception

TABLE 7: Uterine contractions during menstrual cycle.

Time of the menstrual cycle	*Uterine contractions/ min*	*Direction*
Follicular phase	4–5	Retrograde
Luteofollicular transition phase	2–3	Anterograde
Luteal phase	<2.5	

2. *Zone II:* Hyperechoic outer endometrial edge
3. *Zone III:* Hypoechoic inner endometrial area
4. *Zone IV:* Endometrial cavity.

Applebaum's uterine scoring system for reproduction (USSR)–uterine biophysical profile (UBP): It is based on certain sonographic qualities of the uterus that are noted during the normal mid-cycle **(Table 6)**.[37]

Endometrial volume **(Fig. 12)**: 3D measurement of endometrial volume can predict outcomes, especially in intrauterine pathologies such as adhesions, uterine anomalies, and adenomyosis. Most of the pregnancies occur with a volume of 2–13 mL, but pregnancy has been reported at volume as low as 1.59 mL.[38]

Endometrial vascular flow indices **(Fig. 13)**: They are measured by the 3D power Doppler histogram analysis. For the calculations, VOCAL imaging program is used.

- *Vascularization index* represents the presence of blood vessels (vascularity) in the endometrium. It is measured as the ratio of the number of color voxels to the total number of voxels and is expressed as a percentage (%) of the endometrial volume.
5. *Flow index* is the mean power Doppler signal intensity inside the endometrium and represents the average intensity of flow.
   - VFI is a combination of vascularity and flow intensity.
   - *Flow vessel quotient (FVQ)* is FI divided by VI.

The endometrial and subendometrial blood flow was found to be significantly higher in women with pregnancies resulted in live birth than those with a miscarriage in the study by Ng et al.[39] Wu et al.[40] found that subendometrial VFI may be useful in predicting implantation and pregnancy rates in IVF.

- No pregnancy if VI is <1, FI is <31, and VFI is <0.25.
- In cases of low-volume endometrium, the flow indices are less. Such changes are not seen in cases with thin endometrium.[41]
- Flow indices are lower in stimulated cycles as compared to cycles without stimulation.[42]
- Use of clomiphene but not letrozole negatively affects endometrial vascularity.
- In IVF cycles, higher the estradiol (E2) levels, lower the flow indices.[43]

Timing of trigger: hCG is usually administered when there is a minimum of one follicle measuring 16–18 mm in diameter (usually three in IVF cycles), endometrial thickness around 8 mm, and serum E2 levels of 200–300 pg/mL per dominant follicle.

ABNORMAL RESPONSES IN OVARIAN STIMULATION

- *Poor response:* Less than two or three follicles on D7 of stimulation.
- *Hyperresponse:* It can be predicted by numerous small- and intermediate-sized follicles. The secondary follicles (<16 mm) constitute a heterogeneous group with variable endocrine function. Small follicles continue to grow after hCG administration, thus increasing estrogen secretion and contributing to the cascade of hyperstimulation syndrome. In cases of severe OHSS, ultrasound is useful in the treatment [ultrasonography (USG)-guided taping of ascetic and pleural fluid].
- *Premature luteinization:* Follicle with <15 mm with internal echoes in association with high progesterone levels.

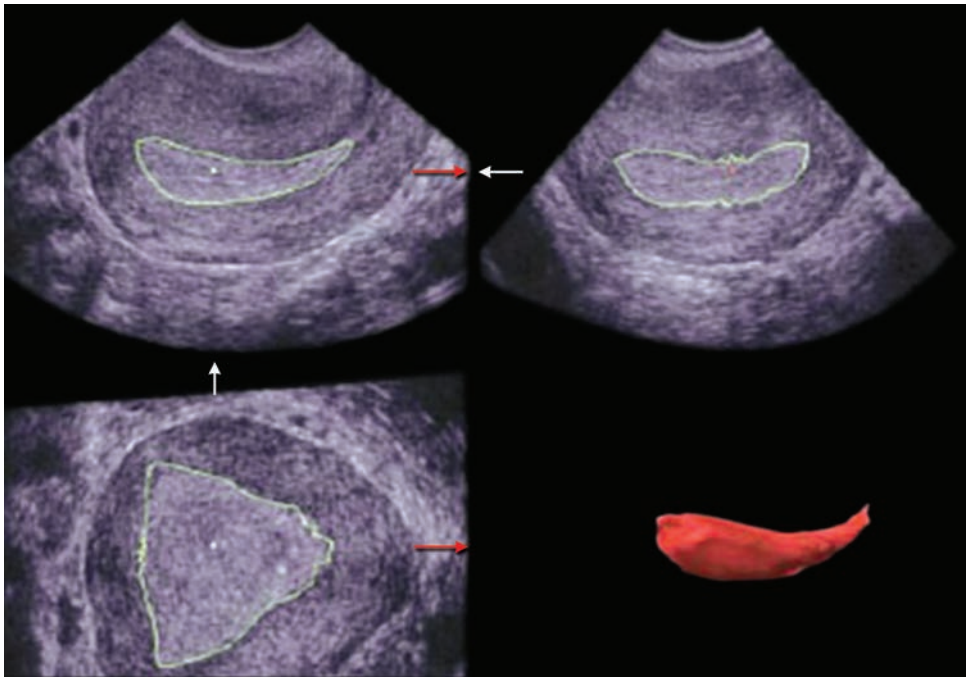


Fig. 12: Endometrial volume.

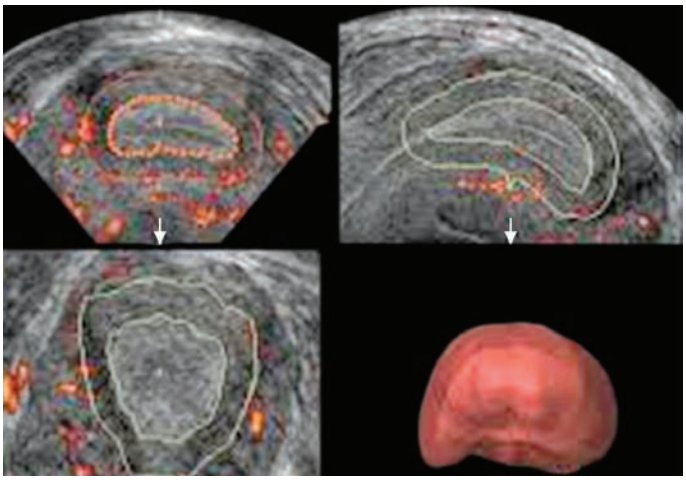

Fig. 13: Endometrial flow indices.

Fig. 14: Self-operated endovaginal telemonitoring (SOET) system.

- *LUF:* 34–36 mm thick-walled follicle with internal echoes persistent even after 48 hours of trigger, thick echogenic endometrium with no fluid in pouch of Douglas.
- *Endogenous LH surge:* Premature rupture of follicle at <16 mm diameter.
- *Functional cyst:* It is an anechoic structure with sharp edges. Present at baseline scan prestimulation as a result of initial high FSH levels. It requires either cycle cancellation or aspiration before starting stimulation.
- *Persistent or retention cyst:* Noticed at baseline scan. It can be a persistent corpus luteum or a cyst from previous cycle.

Self-operated endovaginal telemonitoring (SOET): It is the sonography performed by the patient and her partner at home. It is with the help of server-based communication and imaging software. Some studies showed that SOET reduced economic, logistic, emotional, and potential environmental costs and improved patient's participation and confidence without compromising conception and ongoing pregnancy rates as compared to routine ultrasound **(Fig. 14)**.[44]

HORMONAL MONITORING OF OVARIAN STIMULATION

The hypothalamus–pituitary–ovarian axis controls the ovarian and uterine cycles.[45] Hormones produced by each gland have various local and systemic effects. Bioassays of these various hormones are useful to assess ovarian reserve as well as response of ovary to stimulation.

In 1926, Zondek and Aschheim[46] described their ideas on the function of the human ovary and confirmed the involvement of hormones in the normal functioning of the ovary. Loewe and Lange[47] described the female sex hormone in the urine of menstruating women and the changes in their concentration with the phase of the menstrual cycle.

Hormonal tests for predicting ovarian reserve help to choose the treatment protocol and add prognostic information to the counseling. They are basal FSH, basal estradiol, AMH, and inhibin B.

- *Basal FSH:* Measured on day 2–4. It is less reliable as FSH assays show inter- and intracycle variability.[48,49] As per WHO Second International Standards, FSH assays with the cut point above 10 IU/L are associated with less than two to three follicles or four and less retrieved eggs. This cut point shows high specificity of 83–100% and low sensitivity of 10–80% to predict such poor response.[50] But it cannot predict total failure to conceive. Consistently, elevated FSH predicts poor response but, isolated single high FSH reading with age <40 years of age may not predict poor response.[51] It is suggested that women with fluctuating FSH levels should not wait for "ideal-normal FSH" cycles to initiate IVF cycle.[52]
- *Basal estradiol:* Measured on days 2–4. "Normal" basal FSH levels are correctly interpreted along with basal estradiol. Basal elevated estradiol >60–80 pg/mL with "normal" basal FSH indicates poor response, cycle cancellation, and poor pregnancy rate.[53-55] It has poor inter- and intracycle reliability.
- *Anti-Müllerian hormone:* It is produced by granulosa cells of preantral and early antral follicles. Serum AMH level is gonadotropin-independent, thus no intra- or intercycle variability.[56-59] Low AMH level has been associated with poor response to stimulation, poor egg, and embryo quality, and thus less pregnancy rates in IVF but it does not necessarily predict the same.[60] AMH predicts ovarian reserve more specifically and is thus considered as a more reliable ovarian reserve test. There is a strong positive correlation between serum AMH level and AFC. The use of AMH combined with AFC may improve ovarian reserve evaluation.[61] Low AMH cut points [0.2–0.7 ng/mL DSL enzyme-linked immunosorbent assay (ELISA)] have been found to have sensitivities from 40 to 97% and specificities from 78 to 92% for poor reserve and response (<3 follicles or ≤2–4 oocytes retrieved).[62-64]
- *Inhibin B:* It has high inter- and intracycle variability as the levels increase with stimulation. The levels are lower in poor responders (<45 pg/mL).[64]

Monitoring before stimulation helps to optimize IVF success rates by achieving individualized controlled ovarian stimulation (iCOS) where starting stimulation doses are adjusted considering different parameters as follows:

- *PIVET algorithm* based on age, AFC, AMH, body mass index, day-2 FSH, and smoking[65]
- *Ovarian response prediction index (ORPI)* based on AMH, AFC, and age[66]
- Only AMH.[67]

Hormonal monitoring during stimulation frequently involves assessment of levels of estradiol, LH, and progesterone.

Serum Estradiol

Serum estradiol is used to monitor ovarian activity. In unstimulated cycles, a linear response is observed between estrogen levels and growth of the dominant follicle. This correlation is disturbed with the development of multiple follicles during gonadotropin stimulation. Gonadotropin dose is adjusted every 3 days so that estradiol levels increase by 50% per day.[68] The total serum E2 is a function of the state of maturity of all follicles present at a given time. An equation to determine the expected serum E2 levels depending on the number and size of follicles in both ovaries is:[69]

$$E2 \text{ on trigger day} = 291 \text{ pg/mL} + 180\,(x) + 64\,(y) + 18.7\,(z)$$

where

x: Follicles measuring ≥17 mm

y: Follicles measuring 15–16 mm

z: Follicles measuring ≤14 mm

Estradiol level at the time of hCG administration is more critical than the rate of rise. Trigger is usually given when estradiol levels reach 200–300 pg/mL per large follicle.

Estradiol levels predict the IVF cycle prognosis:

- *Low E2 after first few days of stimulation:* Higher cycle cancellation rate and poor outcome[70-72]
- Higher pregnancy rate in cycles with a higher E2/oocyte ratio in the late follicular phase[73]
- *Optimum estradiol window:* 1,000–1,500 pg/mL[74]
- *Estradiol levels >3,000 pg/mL:* Significant risk of hyperstimulation[75-77]
- Very high E2 levels (>5,000 pg/mL) may diminish endometrial receptivity.[78]

The rate of E2 rise remains the same in natural and stimulated cycles as well as in the cycles which result in multiple pregnancies.[79]

Serum Luteinizing Hormone

Serum luteinizing hormone is monitored to detect the spontaneous premature LH surge and premature luteinization. Several literatures have demonstrated less pregnancy rates in the presence of premature LH surge during ovarian stimulation due to its effect on egg and embryo quality.[80] The incidence of premature LH surge in GnRH agonist cycles is negligible, but 1–2.5% in GnRH antagonist cycles.

Premature LH surge is nothing but an LH level of ≥10 mIU/mL and a progesterone level of ≥1.0 ng/mL demonstrated for at least 2 consecutive days before trigger.[81,82]

There are three types of premature LH rise:

1. *Sustained type:* LH release started during the stimulation and present till hCG administration.
2. *Transient type:* LH release started during the stimulation but normalized before hCG administration.
3. *Onset type:* LH was released only on the day of hCG administration.

Serum Progesterone

High serum progesterone on day 2 of the cycle predicts poor pregnancy outcomes.[83] It has been observed that 5–35% of GnRH agonist cycles and 20–38% of GnRH antagonist cycles will have subtle increases in serum progesterone levels at the end of the follicular phase.[84,85] This progesterone rise is not with LH rise; rather it reflects the granulosa cell response to high FSH stimulation.[85] Ongoing pregnancy rates are low when trigger day serum progesterone levels of 1.5 ng/mL or high irrespective of the GnRH analog are used for pituitary downregulation.[86] Elevated preovulatory progesterone mainly affects endometrial development, not the oocyte or embryo quality.[87] Embryo cryopreservation has been shown to be an effective means of circumventing disruptions caused by COS, including embryo–endometrium asynchrony.[88]

Criteria for Adequate Pituitary Suppression

- *Ultrasound markers:* No follicle ≥10 mm; endometrial thickness ≤5 mm, and absence of ovarian cyst
- *Hormonal markers:* LH <2 IU/L; E2 <50 pg/mL, and serum progesterone (P4) <1.2 ng/mL.

Protocol for the Monitoring of Ovarian Stimulation

- *Monitoring of ovarian stimulation in TI and IUI cycles:* In TI and IUI cycles, ovarian stimulation aims at unifollicular or maximum two or three follicle development. So usually, ultrasound monitoring alone would suffice to prevent complications. Sometimes, the LH kit method (urinary LH levels) is used to detect LH surge and thus to TI or IUI procedure accordingly. Serum monitoring of estradiol and LH levels is rarely required when there is hyperresponse, especially with gonadotropin use. As the follicular growth and endometrial thickness show a good correlation with serum estradiol levels in these cycles, serial transvaginal ultrasound examination alone is the most efficient and cost-effective way of monitoring.[89]
- *Monitoring of ovarian stimulation in IVF or intracytoplasmic sperm injection (ICSI) cycles:* Previously, combined use of USG and serum estradiol measurement was considered as optimum for monitoring of stimulation. Later in different studies, it was shown that E2 levels correlate well with the size of the dominant follicle, endometrial thickness, and uterine dimensions all of which can be easily measured by ultrasound. These USG parameters can be considered as "biological assays" of estrogen activity.[89] Thus, ultrasound can assess both morphology and function of the ovary. Currently, several trials are evaluating whether only ultrasound without hormonal assessment can be used for monitoring in IVF cycles.[90-93] As the incidence of premature luteinization is reduced with GnRH analogs use, merely USG without hormone monitoring is adequate in these cycles.

Cochrane review in 2014 by Kwan et al.[94] has found:

- No evidence from randomized trials to suggest that combined monitoring by transvaginal ultrasound and serum estradiol is more efficacious than monitoring by transvaginal ultrasound alone with regard to clinical pregnancy rates and the incidence of OHSS.
- The number of oocytes retrieved appeared similar for both monitoring protocols.
- The data suggest that both these monitoring methods are safe and reliable.
- A combined monitoring protocol including both transvaginal ultrasound and serum estradiol may need to be retained as precautionary good clinical practice and as a confirmatory test in a subset of women to identify those at high risk of OHSS.

With the increasing trend toward simplification of IVF and reduction of the costs involved, many centers now use ultrasound alone or in combination with minimal hormonal assays for the monitoring of COS.

CONCLUSION

- Some anatomical structures (such as internal iliac artery and vein cross section, cross section of blood vessels around the uterus and ovary, bowel, hydrosalpinx) will look similar to growing follicle, but they will change shape from circular to oblong when the probe is moved from transverse to longitudinal section.
- At the start of stimulation, 2D transvaginal ultrasound is the most commonly used clinical tool.
- AFC is the most commonly used ultrasound marker for ovarian reserve, which shows good correlation with AMH values and thus helps in determining gonadotropin dosages for iCOS.
- Endometrial thickness is measured by transvaginal ultrasound along the longitudinal axis of the uterus. It is the maximum distance between the echogenic interfaces of the myometrium and the endometrium.
- At the start of stimulation (day 2 of period), these readings indicate adequate pituitary suppression and give green signal to start gonadotropins:

  - No follicle ≥10 mm, endometrial thickness ≤5 mm, and absence of ovarian cyst on USG
  - LH: <2 IU/L, E2: <50 pg/mL, and P4: <1.2 ng/mL
- E2 levels are generally repeated on stimulation day 4, day 6, and trigger day with or without LH levels.
- E2 levels >250–300, along with one of the follicles >14 mm on scan is generally an indicator to start GnRH antagonist in the flexible antagonist protocol.
- Serum progesterone levels are generally done at the start of stimulation and on trigger day.
- Serum progesterone ≥1.5 ng/mL on trigger day is an indicator of cryopreservation of all the embryos and cancellation of fresh embryo transfer (ET).

KEY POINTS

- AFC shows a good correlation with age, ovarian reserve, and response to stimulation.
- AFC predicts the ovarian response and decreases the chances of cycle cancellation.[7]
- AFC has good intercycle and interobserver reliability in experienced centers.[9]
- There is a good correlation between the volume aspirated during oocyte retrieval and the SonoAVC calculated follicular volumes.[13]
- SonoAVC has more accuracy than traditional 2D measurements.[14]
- Follicles having >75% of surface perfusion, ovarian stromal PSV >10 cm/s, and RI <0.4–0.48 usually contain good-quality oocytes which develop into good embryos.[22]
- In TI and IUI cycles, serial transvaginal ultrasound examination alone is most efficient and cost-effective way of monitoring.[89]
- In IVF cycles, combined monitoring protocol, including both transvaginal ultrasound and serum estradiol, may need to be retained as precautionary good clinical practice.[94]

CHAPTER 51

Ovulation Trigger

Vyshnavi A Rao, K Aruna Saradha

INTRODUCTION

Ovulation triggers are of many types. They are responsible for triggering the process of ovulation and also help in final maturation of the oocyte.

Couples are in tremendous psychological pressure while they attempt intercourse as their clinicians counsel them in detail about the most fertile period and the maximum chance of pregnancy would occur in this period.

Human chorionic gonadotropin (hCG) is responsible for producing progesterone which maintains the corpus luteum, which helps in maintaining pregnancy in the initial stages. It is also called a "trigger shot" **(Fig. 1)**.

Human chorionic gonadotropin was the most ideal ovulation trigger for the purpose of final oocyte maturation in assisted reproductive technology (ART) cycles. hCG has higher affinity for luteinizing hormone (LH) receptors and has a long half-life, being more prone for ovarian hyperstimulation syndrome (OHSS). With the advent of antagonist protocol, option of using gonadotropin-releasing hormone agonist (GnRHa) trigger for triggering the final oocyte maturation was instrumental in eliminating the risk of OHSS. Recombinant luteinizing hormone (r-LH) has also been used with some limitations. Kisspeptins (KPs) and combining small dose of hCG with GnRHa (dual trigger) in some patients have also been investigated. This chapter deals with the various agents available for triggering final oocyte maturation in ART cycles.

In a natural cycle, there is early rise in follicle-stimulating hormone (FSH) level which results in follicular growth thereby causing a rise in the level of serum estrogen **(Fig. 2)**. This initial increase in estrogen level initiates a negative feedback on the production of FSH from the hypothalamo-pituitary-ovarian (HPO) axis. The FSH level remains high which causes unifollicular development—"FSH window effect". Estrogen rises subsequently causing midcycle LH surge which begins oocyte maturation and release.

Ovulation occurs approximately 10–12 hours after LH peak and 24–36 hours after peak serum estradiol levels.

Onset of LH surge appears to be the most reliable indicator of ovulation occurring 34–36 hours prior to

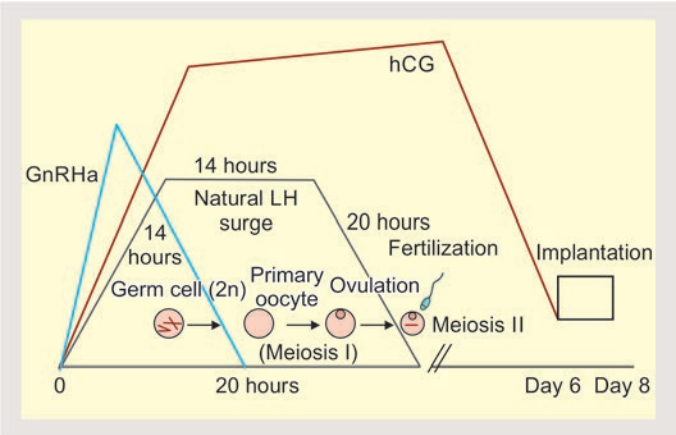

Fig. 1: The response shown by human chorionic gonadotropin (hCG) and gonadotropin-releasing hormone agonist (GnRHa) in final follicle maturation as surrogates for midcycle luteinizing hormone (LH) surge.

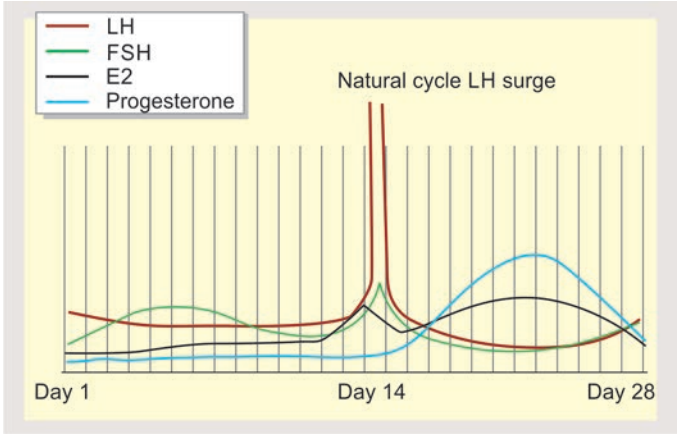

Fig. 2: Natural cycle luteinizing hormone (LH) surge. (E2: estradiol; FSH: follicle-stimulating hormone)

follicular rupture. The LH surge lasts for about 48–50 hours and comprises of three phases:

1. Ascending phase—14 hours
2. Plateau phase—14 hours
3. Descending phase—20 hours.

The midcycle LH surge is accompanied by a midcycle FSH surge, the influence of which is proven to be unclear, but plays a role in oocyte maturation, resumption of meiosis, and functioning of corpus luteum.

This gonadotropins surge initiates series of cascade of events which result eventually in ovulation, the physical release of oocyte, and its cumulus mass of granulosa cells.

OVULATION TRIGGER

Definition

A bioactive preparation which will trigger a cascade of events resulting in the maturation and release of developmentally competent oocyte from a preovulatory Graafian follicle. In a natural cycle, the physiological trigger is the midcycle surge of gonadotropins (LH and FSH surge) from the pituitary gland.

Physiology of Oocyte Maturation and Release

Luteinizing Hormone Surge

In an ovulatory cycle, LH surge is caused by estrogen released from preovulatory follicles, which causes luteinization of granulosa cells.[1]

Oocyte maturation and release occur as a result of positive feedback by high levels of estrogen (>300 pg/mL for >48 hours) which leads to LH surge from pituitary.[2]

Luteinizing hormone surge is characterized by three phases:

1. Ascending phase of 14 hours
2. Plateau phase of 14 hours
3. Descending phase of 20 hours.[3]

Luteinizing hormone surge is responsible for following events:

- Germinal vesicle breakdown
- Resumption of meiosis in oocyte
- Luteinization of granulosa cells and secretion of progesterone
- Expansion of cumulus and loss of gap junctions between cumulus cells and oocyte
- Secretion of prostaglandin and other eicosanoids essential for follicular rupture
- With LH surge, levels of progesterone in follicle rise up until the time of ovulation.
- Progesterone increases distensibility of follicular wall and causes preovulatory FSH surge by positive feedback mechanism from pituitary.

Follicle-stimulating hormone surge is known to help in cumulus expansion, promotion of nuclear maturation, and induction of LH receptors on granulosa and cumulus cells.[4,5]

Follicle-stimulating hormone, LH, and progesterone also stimulate the activity of proteolytic enzymes thereby causing digestion of collagen in follicular wall and increasing its distensibility, nuclear maturation (resumption of meiosis), cytoplasmic maturation, and release of the developmentally competent oocyte from follicle.

- Oocyte arrest in prophase 1 of meiosis is maintained by elevated levels of cyclic adenosine monophosphate (cAMP) in the oocyte which is transported inside oocyte from cumulus or somatic cells through gap junctions.[6]
- LH and FSH surge results in cumulus expansion and disruption of these gap junctions, resulting in low concentrations in cAMP in the oocyte. This results in the germinal vessel breakdown and resumption of meiosis **(Fig. 3)**.

Follicular Rupture

The process of follicular rupture consists of various events like:

- Changes in the cumulus and matrix
- Increase in plasminogen activator mediated by FSH and LH in granulosa cells to activate plasminogen to plasmin, which in turn activates collagenase to disrupt follicular wall
- Proteolytic digestion of tunica and basement membrane
- Follicular vascular and membrane remodeling
- Appearance of more inflammatory cells such as neutrophils in the follicular wall
- Prostaglandin being E2 and F2 α synthesized by cumulus cells, which causes cumulus expansion, resumption of oocyte meiosis, and extrusion of oocyte-cumulus complex from ruptured follicle by contraction of smooth muscle cells.

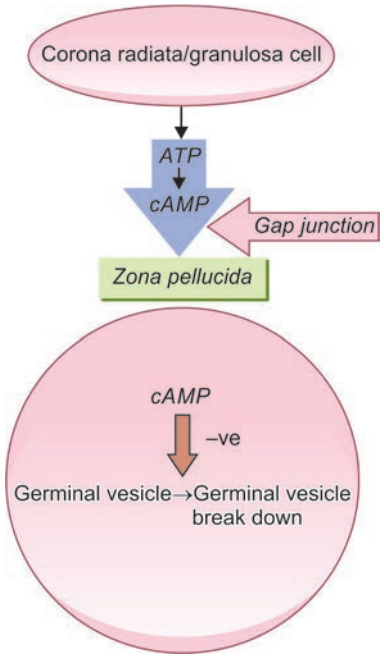

Fig. 3: Resumption of meiosis.

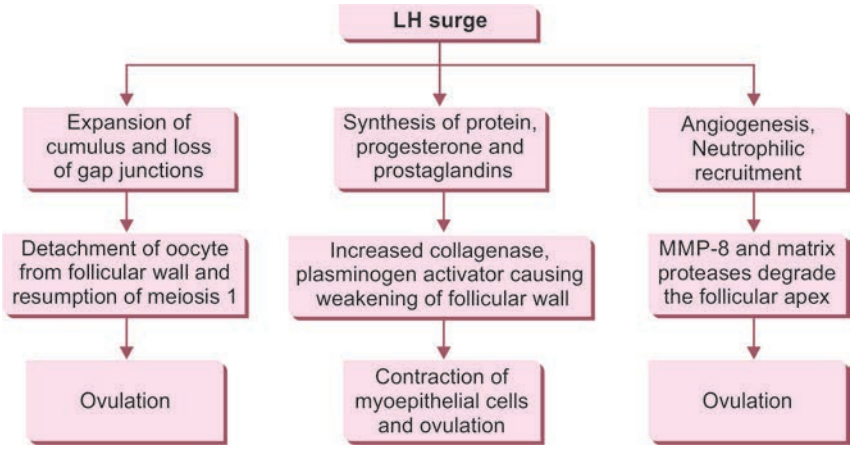
Flowchart 1: Complex inter-related events in ovulation.



(LH: luteinizing hormone; MMP-8: matrix metalloproteinase-8)

- Apoptosis of the epithelial cells over the apex or stigma mediated by matrix metalloproteinases enzymes which are activated in response to LH
- Rise in intrafollicular pressure and contractions of the myoepithelial cells will result in the rupture of the follicle with extrusion of the mature oocyte[7] **(Flowchart 1)**.

Role of Ovulatory Triggers in Intrauterine Insemination and In Vitro Fertilization Cycles

In in vitro fertilization (IVF) cycles, mature oocytes are retrieved artificially around 34–36 hours after administration of ovulation trigger.

Since ovulation occurs 36 hours after ovulatory trigger, it enables correct timing of intrauterine insemination (IUI) and intercourse.

In natural cycle, midcycle LH surge induces follicular rupture and ovulation. In stimulated ART cycles, LH surge is deliberately suppressed by gonadotropin-releasing hormone (GnRH) analogs to prevent follicle rupture before oocyte retrieval. Hence, administration of trigger for final oocyte maturation is essential.

Various Pharmacological Options for Ovulation Trigger

- Urinary human chorionic gonadotropin (u-hCG)
- Recombinant human chorionic gonadotropin (r-hCG)
- Recombinant luteinizing hormone (r-LH)
- Gonadotropin-releasing hormone agonists (GnRH agonist)
- Dual trigger (hCG + GnRH Agonist)
- KPs.

Human Chorionic Gonadotropin

Chorionic gonadotropin (CG) is a heterodimeric glycoprotein comprising of α and β subunits. LH, thyroid-stimulating hormone (TSH), and FSH share a common 92-amino acid α subunit with CG.[8] The differences arise due to unique functions and receptor-binding capacity of all these hormones among the β subunits.

Human chorionic gonadotropin acts as surrogate for LH because of homology between these two hormones. Both are glycoproteins with molecular weight of 30 kDa and both have almost identical α subunits and high cysteine content. hCG is used for granulosa cells luteinization, resumption of meiosis, and final oocyte maturation of follicle 36 hours later and is proven to yield better clinical pregnancy rates compared to other ovulation triggering agents.

- As a result of structural differences and posttranslational modifications, hCG is more stable, has a longer half-life, and has greater receptor affinity than LH, thus making it more biologically active.[9]
- After subcutaneous administration, hCG has significantly longer half-life in comparison to LH.[10]
- Due to abovementioned pharmacokinetic properties and because of sustained luteotrophic effect, development of multiple corpus luteum, and supraphysiological levels of estradiol and progesterone synthesis, hCG is notorious in producing OHSS.
- Although hCG has LH-like activity, it does not reconstitute midcycle FSH surge.
- Minimal effective doses of u-hCG used to trigger oocyte maturation were studied as 2,000 IU, 5,000 IU, and 10,000 IU.
- In a randomized controlled trial (RCT) study involving 80 polycystic ovary syndrome (PCOS) patients stimulated with rFSH and antagonist being added on day 6 of stimulation, no significant difference was noted in terms of ongoing pregnancy rates, severe OHSS, or number of oocytes retrieved in 2,000 IU, 5,000 IU, and 10,000 IU groups.[11]
- Recombinant preparations are associated with higher serum progesterone and serum hCG levels postadministration and lower incidence of local adverse reactions.

- Urinary products still remain the first choice as they are cheap and easily available. A recent meta-analysis has found no difference in terms of follicular maturation, risk of OHSS, and pregnancy outcomes between two preparations.[12]
- 250 µg r-hCG = 5,000 IU u-hCG.[13]
- One RCT including 180 women comparing urinary hCG with recombinant hCG for triggering final oocyte maturation in long GnRH agonist protocol showed no difference in number of oocytes retrieved, occurrence of OHSS, and clinical pregnancy rates between two groups. However, 500 µg of r-hCG seemed to be more beneficial than 250 µg of r-hCG in this indication.[14]
- European Society of Human Reproduction and Embryology (ESHRE) guideline 2019 for ovarian stimulation for IVF/intracytoplasmic sperm injection (ICSI): Use of recombinant and urinary hCG is equally recommended for triggering final oocyte maturation during ovarian stimulation protocols.
- The use of other ovulatory triggers in anovulatory women treated with other ovulatory agents has not been properly evaluated.[15]

Recombinant Luteinizing Hormone

Recombinant luteinizing hormone has a shorter half-life and is very physiological **(Table 1)**. The European Recombinant LH Study Group, in a prospective multicenter dose finding study, found a single dose of r-LH of at least 15,000 IU (750 mg r-LH) or 30,000 IU (1,500 mg r-LH) equivalent to that of 5,000 IU u-hCG with safety superior to that of u-hCG, particularly with respect to the incidence of OHSS. However, in this dose finding study, it was also found that 30,000 IU LH yielded more metaphase 1 (M1) and germinal vesicle (GV) oocytes compared to u-hCG.

The research for using LH as trigger in literature is limited. Currently, recombinant luteinizing hormone (r-LH) is not routinely used as ovulation trigger. Hence, recombinant LH is not commercially available for ovulation triggering.[13]

The Cochrane meta-analysis reported no difference in live birth rate, moderate OHSS, and number of oocytes retrieved between r-LH and u-hCG when used for triggering final oocyte maturation.[12]

Another RCT done including 49 women with poor ovarian reserve to compare r-LH and u-hCG showed that there is no statistically significant difference in cycle cancellation rates, number of oocytes retrieved per cycle, fertilization rates, the number of embryos obtained per cycle, implantation, clinical pregnancy, and live birth rates.[16]

ESHRE guideline 2019 for ovarian stimulation for IVF/ICSI strongly recommends against administering r-LH for triggering final oocyte maturation as the available evidence to draw solid conclusions is lacking.

TABLE 1: Advantages and disadvantages of recombinant luteinizing hormone (r-LH).

Advantages	*Disadvantages*
• More physiological • Risk of ovarian hyperstimulation syndrome is almost nil	• Very high doses of r-LH is required to induce ovulation (15,000–30,000 IU) • Not cost-effective • Limited literature to support its use

Recombinant Human Chorionic Gonadotropin (Table 2)

The onset of spontaneous LH surge is usually sudden, the concentrations of which double within 2 hours between 100 IU/L and 200 IU/L, being elevated for 12–14 hours over a mean duration of 50 hours.[3]

The midcycle surge in addition to follicular rupture[17] aids in several periovulatory events which comprise the following events:

- Disruption of oocyte-cumulus oophorus cell contact and induction of resumption of meiosis[18]
- Cumulus oophorus mucification
- Luteinization of follicular granulosa cells[19]
- Secretion of progesterone.

Farrag et al. conducted a prospective randomized study in order to investigate the effect of r-hCG on oocyte nuclear and cytoplasm maturity compared to u-hCG, for inducing ovulation in women treated with ICSI for male factor infertility. Their results showed that r-hCG increases the rate of metaphase II (MII) oocytes with mature cytoplasm compared to u-hCG.[20]

However, many RCTs have shown that r-hCG and u-hCG are equally effective.[13]

Gonadotropin-releasing Hormone Agonist

Gonadotropin-releasing hormone agonist is an analog which activates GnRH receptors causing increase in the levels of FSH and LH. It mimics a natural midcycle FSH and LH surge following its administration. This is called "flare effect". This effect is used to obtain oocyte maturation.

TABLE 2: Luteinizing hormone (LH) and human chorionic gonadotropin (hCG) are not identical.

	LH	*hCG*
No. of AA beta subunit	121	145
Receptor-binding affinity	Low	High
Initial half-life (h)	0.6–1.3	3.9–5.5
Bioequivalency	6–8 IU	1 IU
Terminal half-life (h)	9–12	23–31
No. glycosylation sites	1	6

TABLE 3: Gonadotropin-releasing hormone (GnRH) agonists.

Decapeptides	*Nanopeptides*
Native GnRH	Leuprolide
Nafarelin	Buserelin
Triptorelin	Goserelin
+	Histrelin

The capability of GnRH agonist to induce ovulation was first described by Nakano et al. in 1973.[21] The antagonist protocol has gained a lot of importance in recent years. Antagonist protocol not only is associated with low risk of OHSS but also allows clinicians to use an agonist trigger thereby reducing the risk of OHSS to be very minimal.

In antagonist protocol, antagonist blocks pituitary GnRH receptors by competitive inhibition. This prevents endogenous LH surge. GnRH agonist displaces antagonist from receptors and activates them to release gonadotropins from anterior pituitary.

- GnRH agonist is derived from native GnRH by substitution of amino acids at 6th and 10th positions.
- These modifications result in alteration of enzymatic cleavage and potency of the molecule.
- Native GnRH is a decapeptide **(Table 3)**.
- Dose of agonists as trigger: Triptorelin 0.2 mg, leuprolide 1–1.5 mg, and buserelin 0.5 mg.[22,23]
- Dose of leuprolide has been reported in literature for trigger as 0.5–4 mg.
- ESHRE guideline 2019 recommends choosing dosage of triptorelin ranging from 0.1 to 0.4 mg.
- Some studies have used higher dose (4 mg) and others two doses 12 hours apart.
- A single dose of 1 mg of leuprolide yields optimal mature oocyte yield.[24]
- The surge induced by a GnRH agonist is short-lasting and consists of two phases:
  1. A short ascending limb (4 hours)
  2. Long descending limb (20 hours), in total of 24–36 hours as compared to 48 hours in a natural cycle **(Fig. 4)**.[25]
- GnRHa trigger is as effective as hCG in inducing final follicular maturation and also has an additional theoretical advantage of inducing FSH surge which along with LH might help in bringing up better follicular maturation.
- There is no difference in oocyte and embryo quality when compared to hCG with almost elimination of OHSS.[25]
- But reduction in clinical pregnancy rates with GnRH agonist and conventional luteal support as compared to hCG in normal responders was noted in meta-analysis comparing 10,000 IU urinary hCG and 0.2 mg triptorelin.[26]
- The drawback of a GnRHa trigger is early corpus luteolysis and inadequate steroidogenesis due to lack of sustained endogenous LH in luteal phase which may result in decreased pregnancy rates and increased miscarriage rates.[27]
- ESHRE guideline 2019 strongly recommends against use of GnRH agonist for final oocyte maturation with conventional luteal phase support and fresh transfer in general IVF/ICSI population.

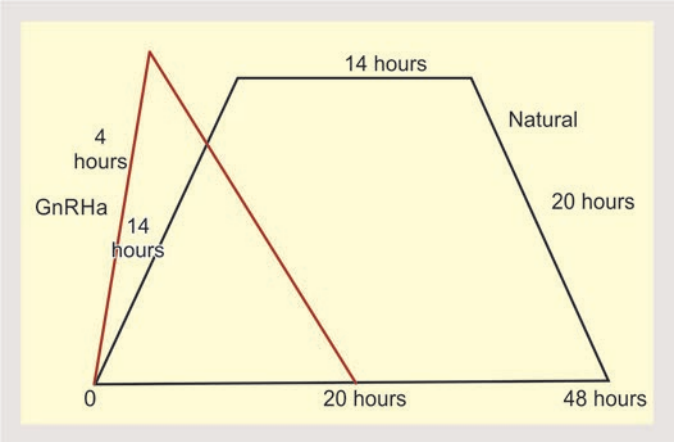

Fig. 4: Comparison of gonadotropin-releasing hormone (GnRH)-induced luteinizing hormone (LH) surge versus human chorionic gonadotropin (hCG)-induced LH surge.
(GnRHa: gonadotropin-releasing hormone agonist)

Intensive and optimal luteal support after GnRH agonist for fresh embryo transfers will improve pregnancy outcomes.

Indications for Gonadotropin-releasing Hormone Agonist Trigger

Any woman who is not planned for fresh embryo transfer can be triggered with GnRH agonist 28–30 like:

- Oocyte donors
- Fertility preservation
- Risk of OHSS
- Preimplantation genetic diagnosis
- Prematurely elevated progesterone prior to trigger.

Gonadotropin-releasing hormone agonist trigger is not preferred in patients with hypothalamic dysfunction and those with long-term hypothalamus and pituitary suppression as with oral contraceptive (OC) pill due to inability to mount sufficient surge of pituitary gonadotropins.[31]

Follicular Fluid and Granulosa/Luteal Cell Changes after Gonadotropin-releasing Hormone Trigger

- Combined higher levels of both FSH and LH than those after hCG trigger[32]
- Progesterone levels reduced by 25% due to lack of LH stimulus on luteal cells.[32,33]
- Levels of amphiregulin and members of epidermal growth factor like family are much lower in follicular fluid than hCG trigger.

- Reduced levels of vascular endothelial growth factor (VEGF) and angiopoietin-2, key factors in OHSS, help in preventing OHSS.[34]
- Higher levels of pigment epithelium derived factor (PEDF) and antiangiogenic factor help in preventing OHSS.
- The concerns of GnRH agonist trigger to be associated with empty follicle syndrome (EFS) have been abolished by recent studies.[35]

How to Predict Gonadotropin-releasing Hormone Agonist Trigger Failure?

- Failed oocyte maturation after GnRH trigger often detected with low serum LH on the day after trigger[36]
- GnRH agonist trigger needs to be avoided in patients with preexisting hypothalamus-pituitary axis dysfunction and also with a pretrigger LH <0.5 IU/L.
- Predicting probability of EFS after GnRH trigger is important as to decide whether to proceed with retrieval or whether rescue dose of hCG is needed.

Meyer et al.[31] aimed to identify risk factors in GnRHa trigger in IVF cycles who are known to be suboptimal responders. The main factors identified were: The prolonged use of contraception, very low levels of LH concentrations on the day of trigger, low serum levels of FSH and LH at the start of the cycle, and irregular menses at the baseline.

Using a Dual Trigger (GnRH Agonist with hCG)

- Shapiro et al.[37] retrospectively evaluated the administration of low-dose hCG (1,000–2,500 IU) in combination of GnRHa in order to induce final oocyte maturation in patients prone for OHSS, this combination was called "dual trigger".

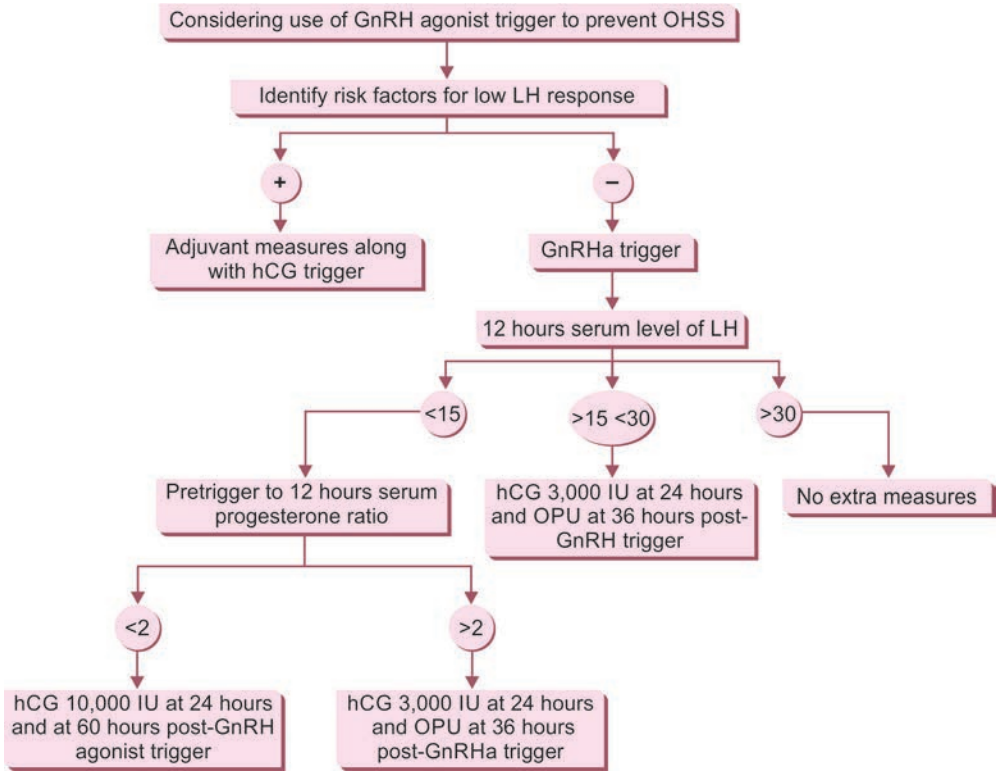
The goal of dual trigger aided in oocyte maturation also provided sustained support for the corpus luteum, higher clinical pregnancy rates along with absence of OHSS, thereby concluding safety of this type of trigger in patients prone for OHSS **(Flowchart 2)**.

Kummer et al.[24] showed that there is no post-trigger progesterone cut-off that can be used to reliably predict the number of oocytes retrieved, but all patients with EFS after GnRH agonist trigger had low-serum LH and progesterone levels (<3.5 ng/mL).

Studies have shown that post-trigger LH and progesterone after GnRH agonist trigger strongly correlated with total oocytes and mature oocytes obtained.

- Serum LH and progesterone levels measured 12 hours after trigger can indicate failed endogenous response to trigger injection and need for intervention.
- If no LH surge and/or progesterone rise noted after GnRH trigger, repeat trigger with hCG and oocyte retrieval after 35 hours later is indicated.[24]

Flowchart 2: Algorithm to use gonadotropin-releasing hormone (GnRH) trigger to prevent ovarian hyperstimulation syndrome (OHSS).



(GnRHa: gonadotropin-releasing hormone agonist; hCG: human chorionic gonadotropin; LH: luteinizing hormone; OPU: oocyte pick up)

- If suboptimal LH rise with value <15 IU/L is noted, repeat trigger with hCG as soon as possible and oocyte retrieval as planned or cancellation of cycle is indicated.
- Also, unilateral follicle aspiration and if no oocytes are obtained, hCG trigger and oocyte retrieval after 34 hours can be done.[36]

Luteal Phase Support after Gonadotropin-releasing Hormone Agonist Trigger

Luteinizing hormone acts as luteotropic hormone. It supports growth and function of corpus luteum and steroidogenesis after ovulation.

Gonadotropin-releasing hormone trigger luteal phase is shortened due to early luteolysis, partial downregulation of pituitary inhibiting LH secretion, and supraphysiological levels of estrogen and progesterone from ovarian stimulation suppressing LH secretion.

Average duration of luteal phase after GnRH agonist trigger may be as short as 9 days compared to 13 days after hCG trigger.[38]

Luteal Support with Progesterone and Estrogen

Serum levels of progesterone and estrogen throughout the luteal phase are significantly lower with GnRH agonist trigger than after hCG trigger.

Intense luteal phase support with estradiol and progesterone or low-dose hCG after GnRHa trigger have shown reasonable pregnancy rates after fresh transfer, in patients at risk of OHSS.

American approach is to supplement high dose of steroids in the luteal phase in the form of intramuscular progesterone 50 mg daily and transdermal estrogen patches three doses 0.3 mg alternate days. Engmann et al. described this approach.[22] Serum E2 and progesterone levels were evaluated on days 3 and 7 after oocyte retrieval and weekly thereafter and continuing intramuscular (IM) progesterone and transdermal estrogen till 10 weeks of gestation. Based on serum levels, doses of IM progesterone can be increased to maximum of 75 mg daily with addition of micronized vaginal progesterone daily as needed to maintain serum progesterone above 20 ng/mL. Similarly, estrogen patches can be increased to four 0.1 mg patches alternate days and adding oral micronized E2 (2–8 mg) daily if required to maintain serum E2 above 200 pg/mL.[39]

In this study, 53% ongoing pregnancy rate was reported after GnRH agonist with intensive luteal support compared to 48.3% in the hCG group with standard luteal phase support.

European approach relies on supplementing two small doses of hCG in the luteal phase which will rescue the corpus luteal function without increasing the incidence of OHSS. 1,500 IU hCG is given on the day of oocyte retrieval and 5 days after retrieval.[39]

Shapiro et al. in his study reported ongoing pregnancy rate of 50% in GnRH agonist trigger patients who received intensive luteal support compared to 25.3% ongoing pregnancy rate with standard luteal support.[40]

Intramuscular progesterone over vaginal progesterone in luteal support after GnRH agonist trigger improves pregnancy outcomes.[41]

Recombinant Luteinizing Hormone for Luteal Support

Luteinizing hormone supplementation in the luteal phase after agonist trigger can also be used to rescue luteal phase with good pregnancy rates[42] with less risk of OHSS due to shorter half-life.

Luteal Support with Human Chorionic Gonadotropin at the Time of Oocyte Retrieval

Human chorionic gonadotropin administration on the day of oocyte retrieval within 1 hour in addition to standard luteal support has been suggested in some studies after GnRH agonist trigger to support corpus luteal function.[43]

Radesic and Tremellen reported one case of severe OHSS among 71 women at risk of OHSS receiving 1,500 IU hCG within 1 hour of oocyte retrieval.[44]

Seyhan et al. evaluated 23 women at high risk of OHSS who had E2-4891 pg/mL on the day of trigger and received GnRH agonist trigger and hCG 1,500 IU administered within 1 hour of oocyte retrieval. OHSS rate reported in this study was 26%.[45]

Very Low-dose hCG for Luteal Support

This supports corpus luteum function. Additional progesterone or E2 support in luteal phase is not required.

Recombinant hCG 125 IU given daily starting from either the day 2 or 6 of stimulation and continued throughout luteal phase.[46,47]

This approach showed high luteal progesterone levels but pregnancy rates were similar.

This approach of luteal support is not currently used routinely and additional studies are needed.

LUTEAL COASTING

Kol et al. in a study of 21 patients at risk of OHSS no luteal phase supplementation was provided and serum progesterone levels were monitored and one bolus of 1,500 IU hCG was given if values dropped below significantly.[48]

By this method, luteal phase support was individualized and risk of OHSS was minimized.

FREEZING OF EMBRYOS

To avoid suboptimal luteal phase after GnRH agonist, trigger freezing of all embryos and transfer in subsequent cycles.

Garcia-Velasco study showed pregnancy rates of 50% who underwent freezing and transfer in subsequent natural cycles when compared to patients who had pregnancy rates of 29.5% who had coasting and fresh embryo transfer.[49]

PREDICTORS OF SUCCESS AFTER GONADOTROPIN-RELEASING HORMONE AGONIST TRIGGER

One study revealed that peak E2 >4,000 pg/mL and raised levels of LH on the day of trigger improved pregnancy rates after GnRH agonist trigger. Pregnancy rate in this group was 53.6% compared to 38.1% in the group that had E2 <4,000 pg/mL.[50]

In the group with E <4,000 pg/mL, dual trigger with GnRH agonist trigger and low-dose hCG 1,000 IU had higher pregnancy rates than GnRH agonist trigger alone.[51]

In all those with E >4,000 pg/mL, supplementation with E2 and progesterone alone is sufficient in luteal phase or freeze all embryos can be done. But in those with E <4,000 pg/mL, adjuvant low-dose hCG in luteal phase improves pregnancy rates.[51]

Number of follicles on the day of trigger will also determine if 1,500 IU of hCG has to be given on the day of oocyte retrieval after agonist trigger.[52]

Seyhan et al. suggested that all women with 10–14 mm follicles of >18 in number should not be given hCG bolus as the risk of OHSS is 26% and embryos should be cryopreserved.[45] Few other studies also suggested that women with >25 follicles of greater than 11 mm in diameter should not be given hCG bolus and cryopreservation of embryos should be done.[53]

OVARIAN HYPERSTIMULATION SYNDROME IN GONADOTROPIN-RELEASING HORMONE AGONIST TRIGGER

Because of short duration of LH surge and early corpus luteolysis, risk of OHSS is negligible after GnRH agonist trigger which has been shown in various studies.[54]

ESHRE guideline 2019 strongly recommends triggering with GnRH agonist for final oocyte maturation to reduce risk of early onset OHSS in patients at risk of OHSS.

Few cases of OHSS with use of GnRH agonist trigger have been reported which is thought to be due to low dose of hCG (dual trigger).

Very few cases of OHSS with use of GnRH agonist alone have been reported which has been attributed to activating mutations in GnRH or FSH receptor.[55]

Dual Trigger

Dual trigger which includes triggering of the final oocyte maturation by a combination of a GnRHa together with a low-dose hCG (1,000–2,500 IU) was first described by Shapiro.[37]

Dual trigger enables clinicians to lengthen time between ovulation triggering and oocyte pick up and also simultaneously adding a FSH component causing a FSH surge which can help overcome any impairment in granulosa cell function, oocyte meiotic maturation, or cumulus expansion.[56]

- Increase in the level of LH was found in the dual trigger soon after trigger along with a surge in FSH compared with hCG trigger. There was no major difference in the number of MII oocytes, or the number of two pronuclei oocytes.[57]
- The risk of OHSS was almost eliminated by using GnRHa trigger and proper luteal function was also modified by the added hCG when dual trigger was used.
- The combined surge of FSH and LH in dual trigger is particularly useful in patients with immature oocytes and EFS in the previous IVF cycles.[56]
- Dual trigger may aid in implantation, clinical pregnancy, and live birth rates when used in normal responder patients in an antagonist cycle.[56]

Haas et al. did a prospective control double-blinded RCT which inferred that the dual trigger helps in increasing the oocyte yield, mature oocytes, and the number of zygotes compared to triggering with hCG alone in patients who are normal responders. The increase in the number of mature oocytes may potentially benefit the outcome of the IVF cycle.[58]

Kisspeptins

Kisspeptins are recently discovered peptides which act on kisspeptin neurons located in the anteroventral periventricular nucleus, anterodorsal preoptic nucleus, and prearcuate nucleus in hypothalamus and are thought to play an important role of GnRH pulse generator in mammals. KP is an important regulator of onset of puberty, secretion of gonadotropins, and fertility. They bind to their specific receptor and result in release of GnRH from hypothalamus which in turn acts on pituitary to release LH and FSH. Many forms of endogenous KPs have been described which differ in length of amino acid chain. KP-10 and KP-54 are most studied for their potential applications.

After encouraging results from animal studies, now human studies are accumulating.

- Exogenously administering of KPs has been found to result in release of gonadotropins particularly in cases of hypothalamic amenorrhea.[59]
- When given in the periovulatory phase, exogenous KP has been shown to induce a 3–4-fold increase in LH secretion.[60]
- In women undergoing ART, KPs were capable of eliciting an effective LH surge that resulted in successful oocyte maturation and live birth.[61-63]
- KPs, therefore, may offer a completely different, "natural" concept for ovulation induction in ART without the risk of OHSS.

Ovulation Trigger Preferred in Oocyte Donors

Mourad et al.[64] did a study intervention for prevention of OHSS in ART cycles, that proved GnRHa trigger was better in donor oocyte or "freeze-all" programs. It included a total of 27 reviews in this Cochrane study, a study by Youssef et al.[27] included 17 RCTs which concluded that GnRH agonist trigger in donor recipient cycles would be the preferred trigger.

Several studies have showed that there is no difference in the number of oocytes retrieved, implantation, pregnancy, and live birth rates in donor cycles on comparison of GnRH agonist trigger with hCG trigger.[65,66] However, use of GnRH

TABLE 4: Differences between GnRH agonist trigger versus hCG trigger.[67]

Parameters	*GnRH agonist trigger*	*hCG trigger*
Basis of the Trigger	GnRH agonists induce LH endogenous surge by their flare up effect which is useful in ovulation triggering	A bolus dose of hCG induces ovulation in 24–36 hours. Longer half-life of more than 24 hours versus 60 minutes for endogenous surge of LH, is linked with prolonged stimulation of follicles and corpus luteum as well as increased serum estradiol levels
Half-life	Shorter half-life	Longer half-life
Risk of OHSS	Used for prevention of OHSS	Prolonged luteotrophic effect and increased VEGF expression with hCG is associated with higher risk of OHSS
Luteal phase support	Intensive luteal phase support is mandatory post GnRHa trigger as luteal phase is defective	Luteal phase support required modified according to individualized cases
Freeze all strategy	Usually employed	May or may not be employed

(GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone; hCG: human chorionic gonadotropin; OHSS: ovarian hyperstimulation syndrome; VEGF: vascular endothelial growth factor)

TABLE 5: Advantages and disadvantages of various triggers.

Ovulation triggers	*Advantages*	*Disadvantages*
GnRH agonist	• GnRH agonist is an analog which activates GnRH receptors causing increase in the levels of FSH and LH. It mimics a natural midcycle FSH and LH surge following its administration. This is called "flare effect". This effect is used to obtain oocyte maturation • Significant reduction of OHSS using this type of trigger	The drawback of a GnRH agonist trigger is early corpus luteolysis and inadequate steroidogenesis due to lack of sustained endogenous LH in luteal phase which may result in decreased pregnancy rates and miscarriage rates. Intense luteal phase support with estradiol and progesterone or low-dose hCG after GnRH agonist trigger have shown reasonable pregnancy rates after fresh transfer, in patients at risk of OHSS
hCG trigger	• hCG acts as a surrogate LH. Used as an ovulation trigger for final maturation of oocyte 35 hours prior to oocyte pick up, yields better clinical pregnancy rate • More stability, longer half-life, greater affinity for LH receptors makes hCG biologically more active	In hyper responders, hCG is more prone for OHSS
Dual trigger	• Dual trigger which includes triggering of the final oocyte maturation by a combination of a GnRHa together with a low-dose hCG (1,000–2,500 IU) • Enables clinicians to lengthen time between ovulation triggering and oocyte pick up and also simultaneously adding a FSH component causing an FSH surge which can help overcome any impairments in granulosa cell function, oocyte meiotic maturation, or cumulus expansion[58] • Dual trigger is particularly useful in patients with immature oocytes and empty follicle syndrome in the previous IVF cycles • Dual trigger may aid in implantation, clinical pregnancy, and live-birth rates when used in normal responder patients in an antagonist cycle	The risk of OHSS was almost eliminated by using GnRHa trigger and proper luteal function was also modified by the added hCG when dual trigger was used
r-LH trigger	Shorter half-life and is physiological	Expensive; the research for using LH as trigger in literature is limited. Currently, r-LH is not routinely used as ovulation trigger
Kisspeptins	When given in the periovulatory phase, exogenous KP has been shown to induce a 3–4-fold increase in LH secretion	Not used as ovulation trigger in routine practice

(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; GnRHa: gonadotropin-releasing hormone agonist; hCG: human chorionic gonadotropin; IVF: in vitro fertilization; KP: kisspeptin; LH: luteinizing hormone; OHSS: ovarian hyperstimulation syndrome; r-LH: recombinant luteinizing hormone)

agonist trigger in donor cycles is associated with less risk of OHSS as shown in various studies. The differences between hCG trigger and GnRHa trigger are as shown in **Table 4**.

Advantages and disadvantages of each ovulation triggers are as shown in **Table 5**.

OVULATORY TRIGGER IN BREAST CANCER PATIENTS

In breast cancer patients, stimulation with aromatase inhibitor and gonadotropins helps in minimal estrogen exposure and use of GnRH agonist trigger is associated with less risk of OHSS and faster recovery.[29]

KEY NOTES

- In order to significantly reduce the risk of OHSS in ART cycles, using a GnRH agonist trigger in an antagonist protocol may be useful in most patients.
- Clinical pregnancy rates in fresh transfer after GnRH agonist trigger found to be less than with hCG trigger.
- Few clinicians may fear the use of GnRH agonist as a trigger due to its effects on the luteal phase which may be corrected by the use of hCG as a luteal phase support or with intensive luteal phase support.
- Adding 1,500 IU of hCG on the day of oocyte pick up has been useful in rescuing the luteal phase. Other alternatives such as increasing the progesterone and E2 are of vital importance.
- The possibility of performing a fresh embryo transfer following GnRH agonist trigger is high when the luteal phase support is modified accordingly.
- Vitrification of embryos thus obtained following a stimulated IVF cycle and subsequent transfer of the vitrified embryos in the next menstrual cycle has been found to be more effective.
- GnRH agonist trigger to be avoided in patients with hypothalamic dysfunction and those with low LH on the day of trigger (<0.5 IU/L).
- No difference in oocyte and embryo quality on comparison of GnRH agonist trigger with hCG trigger.
- Dual trigger is useful in patients with immature oocytes and empty follicle syndrome in previous cycles.
- No differences in oocyte maturation, quality, risk of OHSS and pregnancy, and live birth outcomes on comparison of r-hCG with u-hCG.
- No differences in clinical pregnancy rates, OHSS rates, and number of oocytes obtained in 2,000 IU, 5,000 IU, and 10,000 IU u-hCG dosages.
- GnRH agonist trigger preferred in donors due to reduced incidence of OHSS.

CHAPTER 52

Individualized Controlled Ovarian Stimulation

Richa Sharma, Anindita Thakker

INTRODUCTION

Infertility can be due to various factors or can be multifactorial and can vary as per race, ethnicity, place, surrounding factors, etc., in different demographic areas. Childlessness has serious psychological, social, and health implications, and it affects not only an individual but also the whole family. The first successful in vitro fertilization (IVF) baby was born in 1978. Since then, science has undergone rapid advancement significantly,[1] so it was the beginning and not the end of medical evolution. Since that day, Louise Brown made a history; rather it was a stepping stone to an unraveled world of IVF. IVF technology has grown in leaps and bounds. Success rates have improved drastically. Besides, innovations in assisted reproductive technology (ART) laboratory supplemented with an individualized patient-directed approach have been a boon.

In vitro fertilization is an ever-evolving technology. There has been a sea change in technique in both the clinic and the laboratory and an improvement in drug quality and mode of administration. Despite these changes, there is still an immense physical and emotional burden attached to the treatment. The treatment involves daily injections, frequent ultrasounds and blood tests, and general or local anesthesia for oocyte retrieval. Among the complications, the most terrifying one is ovarian hyperstimulation syndrome (OHSS) which can be life-threatening.

Mild stimulation protocols resulted from a desire to make the procedure more safe and simple. The fact that there has been an immense improvement in the IVF laboratory gave courage to the physician to aim for fewer eggs reducing the dose of gonadotropins required and consequently the cost and complications. Unfortunately, the change was not universally accepted because the per-cycle pregnancy rates are lower, and the cumulative pregnancy rate (CPR), though projected to be similar, takes many more cycles of stimulation since there are less embryos available for cryopreservation. The cost too, though low per cycle, ultimately levels out.

The social scenario is also changing with an advanced age group of couples getting enrolled for IVF, especially due to more career orientation, delaying marriages with change in the patriarchal trend of society with more women empowerment enabling them to control their life, body, and future fertility. Increasing awareness and opting out of unmarried females for oocyte cryopreservation is one such example.

BASICS

Let us talk about the basics first. Treatment offered to a couple in ART can be:

- Timed intercourse with ovulation induction (fertile window utilization)
- Intrauterine insemination (IUI)
- IVF
- Intracytoplasmic sperm injection (ICSI)
- Third-party reproduction (gamete donation/surrogacy).

Irrespective of the kind of treatment, controlled ovarian stimulation (COS) protocols have been refined, focusing on multiple follicular development so as to extract the optimal number of mature (M2) oocytes per treatment cycle and to increase pregnancy rates.[2] Here comes the latest concept of individualized COS.[3-8]

How to Individualize Treatment and What are the Advantages?

- Individualized treatment optimizes success rate and improves the safety of IVF.
- Biomarkers help to individualize the treatment such that each couple will have a different treatment as per the clinical profile.
- Use of most reliable markers of ovarian reserve assessment
- Individualize expectations of oocyte yield
- Clinical workup supported by investigations—history, physical examination, and investigations have roles to

play in individualizing IVF treatment; the mainstay is individualized COS.
- Antral follicle count (AFC) and anti-Müllerian hormone (AMH) are the most specific of all prognostic factors.
- Categorization as per parameters—normal responders, high responders, and poor responders

PROGNOSTIC FACTORS FOR OVARIAN RESPONSE AND PROTOCOL RECOMMENDED

How to decide which protocol is for which patient? Definitely, that is a very routine common clinical query we face but practically it is very difficult to set fixed protocols [standard operating procedures (SOPs)] due to various confounding factors in ovarian stimulation, some of which are unpredictable/unexpected.

Grossly speaking, these factors can be:
- Genetic
- Nongenetic
- Demographic characteristics of patients
- Age of the female partner
- Presence of associated pathologies/factors such as endometriosis, polycystic ovaries, and a high body mass index (BMI)—all these can also affect the response of ovaries and the outcome.
- Physician experience, and SOPs and protocols of a fertility clinic play an important role. But definitely, at the end of the day, it is the success of an individual couple rather than of a clinic which depends a lot on their clinical profile besides the role of drugs and laboratory parameters.

It has been observed that in spite of similar parameters in two different patients, genetic differences may predispose some individuals to respond better as compared to other patients, though protocols may be the same. Tailoring of protocols is done based on all the above-mentioned factors.[9-15]

A study by Shahine et al. had compared Asian and Caucasian women and showed that even on transferring the highest quality embryos in both, Caucasian women had significantly higher implantation, clinical pregnancy, and live birth rates than Asian women.[16] Variable responses have been attributed to follicle-stimulating hormone (FSH) receptor gene polymorphisms in a study such that good responders more often carry the Asn/Ser allelic variant, which has a higher FSH sensitivity as compared to those with Ser/Ser allelic variant, which falls into the category of ovarian dysfunction.[14] To understand the utility of FSH receptor gene polymorphisms, more studies are needed.[17]

ROLE OF LUTEINIZING HORMONE AND RECEPTOR POLYMORPHISM

The need to add luteinizing hormone (LH) in some patients undertaking ovarian stimulation can vary due to the presence of common LH receptor polymorphisms, which is significantly higher in them. Such patients may also need high doses of recombinant FSH (r-FSH) for COS.[18-20] So we need to identify such patients for better results by following an individualized approach. Individualization can be based on AMH and AFC as depicted in **Figures 1 and 2**.

Clinical history with previous treatment records, more so if a patient had a previous IVF cycle, can be of help in

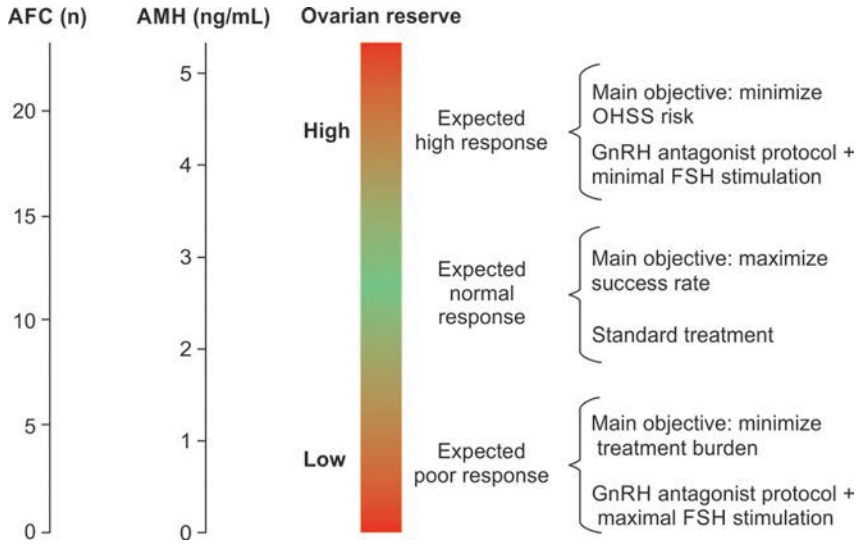

Fig. 1: Ovarian reserve testing before the first in vitro fertilization (IVF) cycle would permit categorizing patients as expected poor, normal, or hyper-responders. Since there is no evidence of superiority of one approach over another in the treatment of poor responders, the protocol associated with reduced discomfort and treatment burden should be preferred. In hyper-responder patients, one of the most important objectives of medical counseling is to prevent ovarian hyperstimulation syndrome (OHSS). Hence, the first-line protocol would be based on administration of low doses of follicle-stimulating hormone (FSH) in a GnRH antagonist-based scheme.[20]
(AFC: antral follicle count; AMH: anti-Müllerian hormone; GnRH: gonadotropin-releasing hormone)

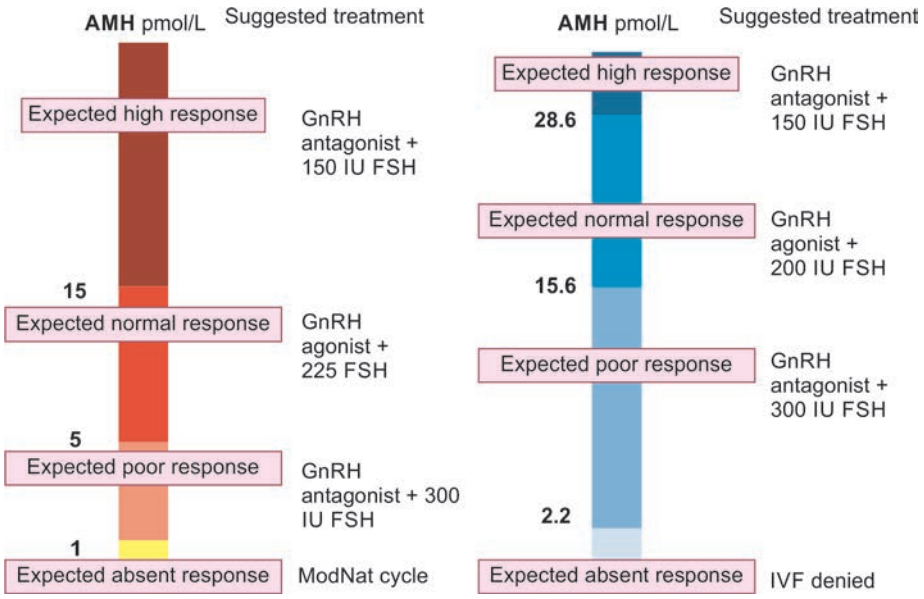

Fig. 2: Strategic (multiple models) modeling of controlled ovarian stimulation (COS) on the basis of ovarian reserve markers. The introduction of individualized anti-Müllerian hormone (AMH)-tailored COS utilizing agonist and antagonist protocols has been reported as associated with improved in vitro fertilization (IVF) cycle, i.e., increased pregnancy rate.[21]
(FSH: follicle-stimulating hormone, GnRH: gonadotropin-releasing hormone)

predicting response in the next cycle. For that, we need to extract the following information:

- Type of protocol used
- Type and dosage of stimulation drug
- Number of days on COS
- Number of oocytes retrieved
- Type of treatment (IVF/ICSI)
- Number of eggs retrieved and fertilized
- Day of embryo transfer and number of embryos transferred
- Any embryo freezing done
- Any history of cancellation of the cycle
- Any history of freezing all embryos with OHSS leading to ovarian suppression
- Luteal phase support—injectables/vaginal suppositories/gel form
- Outcome of IVF cycle.

Normal Responders

Favorable factors are:

- Age <35 years (younger age group)
- Normal BMI
- Adequate ovarian reserve [day 2/3 FSH <10 mIU/mL, estradiol (E2) <75 pg/mL]
- AFC between 6 and 10
- Short duration of infertility
- Previous live birth (secondary subfertility)
- Previous successful IVF
- Male factor as a predominant cause
- Tubal factor as a cause of infertility.

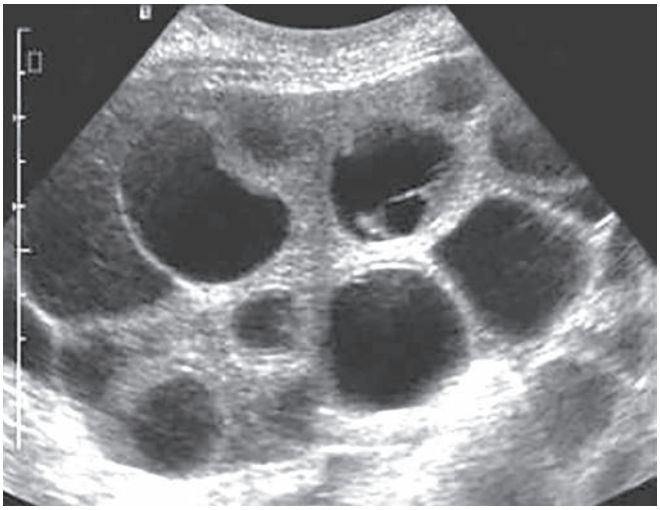

Fig. 3: Stimulated ovary in ovarian hyperstimulation syndrome (OHSS).

Protocols:

- Gonadotropin-releasing hormone (GnRH) agonist short or long protocols
- GnRH antagonist protocols.

High Responders

The greatest risk is OHSS, so we need to take precautions accordingly as depicted in **Figure 3**.

Factors that increase the risk of OHSS:

- Young age
- Polycystic ovaries on ultrasound
- Previous history of OHSS
- Lean polycystic ovary syndrome (PCOS)

- High dose of gonadotropins
- E2 levels >3,000 pg/mL on the day of ovulation trigger
- Rapidly rising E2 levels.

Why is individualized COS needed?

Each patient is different as etiology varies. The response of the body to medicines can also vary as per BMI or previous ovarian response.

Target on the number of oocytes in IVF is based on a study by Ben-Haroush et al. and Majumder et al. Appropriate ovarian reserve with a maximum of 8–12 mature oocytes is considered enough to achieve the highest CPRs. The quality of oocytes has more role than the number alone for a higher chance for a patient to become pregnant,[22,23] and a change in protocol may not always work.

ROLE OF AMH, AFC, AND OTHER BIOMARKERS IN INDIVIDUALIZED COS

- Various parameters, which include endocrine/paracrine biomarkers such as FSH, AMH, or inhibin B hormone levels, as well as sonological parameters such as AFC.[23]
- Day 3 FSH/LH, E2, and inhibin B—indicators of ovarian reserve.

Inhibin B: Inhibin levels are highest during the earliest and mid-stages of a menstrual cycle, and it is basically a protein produced by the granulosa cells of pre- and early antral follicles.[23]

Follicle-stimulating hormone and E2: They are more valid if done in the first 3–5 days of menstrual periods and their levels can vary from cycle to cycle besides being affected by factors such as presence of cysts and ovarian reserve. A patient with high levels of FSH in one cycle and having normal in another would behave differently on ovarian stimulation.[24,25]

Anti-Müllerian hormone: It can be used as an indicator of the quantity and quality of oocytes over a period of time. It is a member of the transforming growth factor beta family. It is the most specific of all parameters and is not affected by the day of the menstrual cycle but it definitely shows a decline with advancing age. Very rarely, especially in younger age groups, it may not correlate and in that case the final judgment is definitely by the clinical response of the patient after subjecting ovaries to stimulation by gonadotropins.[26,27]

Anti-Müllerian hormone plays an important role and is the most specific prognostic factor in predicting ovarian response, which can vary as per female age besides the inherent tendency to respond.[28]

It is likely that AMH cannot predict pregnancy, but it can predict probability, also predicting who will be poor responders and who will be prospective hyper-responders.

In a study by Nelson et al.,[29] they investigated the relationship between AMH levels and the success of different IVF treatment protocols and classified them as given in the following text.

High Responders

- Women with AMH levels >15 pmol/L
- Need a low starting dose of FSH in a GnRH antagonist protocol (to eliminate the need for complete cryo-preservation of embryos due to excess response)
- These women have a higher fresh cycle clinical pregnancy rate.

Normal Responders

- Women with AMH levels of 5–15 pmol/L
- Generally treated with a traditional GnRH agonist long protocol
- Have a low incidence of excess response and poor response.

Poor Responders

- Women with low AMH of 1–5 pmol/L
- Also called reduced responders
- Generally show suboptimal response to COS and low pregnancy rates irrespective of the treatment protocol used.

INDIVIDUALIZED CONTROLLED OVARIAN STIMULATION AND DIFFERENT STIMULATION PROTOCOLS

Different ovarian stimulation protocols show variable success, and one single blanket treatment protocol would not work for all patients, which is why the concept of individualized COS exists **(Fig. 4)**. Individualized COS functions based on parameters such as AMH and AFC. The pregnancy rate depends on the quality and quantity of oocytes and embryos being produced per stimulated patient,

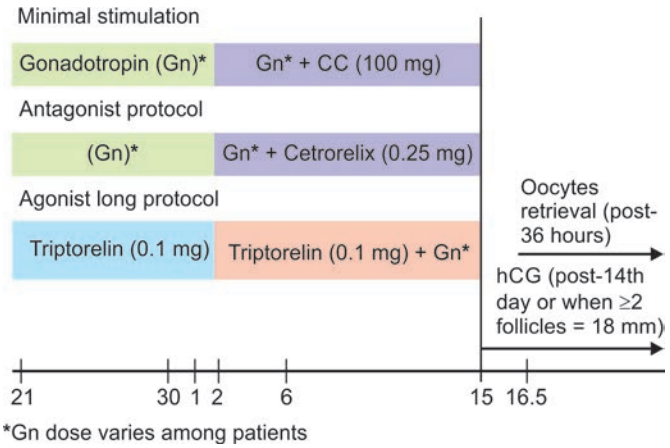

Fig. 4: Pictorial representation and comparison of different stimulation protocols.
(CC: clomiphene citrate, hCG: human chorionic gonadotropin)

TABLE 1: Summary of available conventional protocols for ovarian stimulation.

Protocol	*Agent*
Long, short, and microflare protocols	GnRH agonists and recombinant FSH, hMG, recombinant FSH plus recombinant LH, and other adjunctive agents
Standard, mild, and modified natural cycle protocols	GnRH antagonists and FSH, hMG, FSH plus LH, and other agents such as clomiphene citrate
Minimal and natural cycle protocols	No GnRH analogs and FSH, hMG, and FSH plus LH

(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; hMG: human menopausal gonadotropin; LH: luteinizing hormone)

while the CPR is based on outcomes from fresh and frozen embryos from the same cycle of stimulation.

Various protocols are as follows:
Long protocol: It is the most common of all protocols and aims at complete pituitary suppression.

Short and ultrashort protocols: The initial "flare-up" of gonadotropins is used for ovarian stimulation.

- Conventional—step up/step down **(Table 1)**
- GnRH analogs—antagonist/short/microflare/flare/long protocols
- Mild/minimal/natural IVF cycles/modified natural protocols—what we call as patient-friendly protocols
- Accumulation and vitrification of embryos (ACCUVIT). Choices for COS according to possible combinations of GnRH agonist/antagonist and stimulation drugs:
  - GnRH agonist/antagonist protocol—standard, mild, modified natural, mini, natural
  - GnRH agonist—long, short, microflare, stop
- Agents used in stimulation can be:
  - Gonadotropins—FSH, human menopausal gonadotropin (hMG), FSH + LH
  - Others—clomiphene, letrozole, testosterone, estrogens.

Standard Long Protocol

A significant milestone in the development of COS was the implementation of GnRH agonists for pituitary suppression from the mid-luteal phase of the prior cycle until the completion of the COS process (long protocol). This approach allows IVF centers to manage patients more easily, thereby reducing cycle cancellation rates (as high as 35% before the introduction of GnRH agonists),[21,30] resulting in greater number of oocytes retrieved and producing better quality embryos and higher pregnancy rates than older protocols.[31]

Sub-variations of GnRH agonist protocols are:

- Short
- Ultrashort
- Microflare
- Stop

Basics

These protocols involve adjusting the timing and dose of GnRH agonist administration so that the patient benefits from the initial flareup of endogenous FSH and LH that may stimulate the follicles, in addition to the action of exogenous gonadotropins.

Disadvantages of Long Protocol

The protocol is time-consuming and involves complex regimens (at least 3 weeks of daily injections) that cause considerable patient discomfort and has important short-term complications, including OHSS and a high incidence of multiple pregnancies.

These negative aspects lead to a high rate of dropouts and increased costs.

Alternative Controlled Ovarian Stimulation Approaches: Mild and Minimal Ovarian Stimulation, Antagonist Protocol

Aim

The aim is to optimize the likelihood of achieving a healthy birth at a reasonable cost, while ensuring patient comfort and reducing the incidence of complications.

Principle of Action

It is based on two principles:

1. Use of GnRH antagonists, which cause immediate and dose-dependent gonadotropin suppression which may involve the use of clomiphene citrate.
2. Impact of r-FSH on follicular recruitment depends on the length of exposure above a threshold rather than the degree of FSH elevation.[32-34]

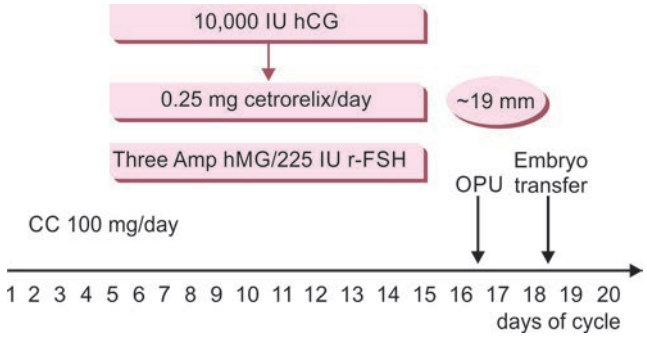
Advantages

- Less complex
- Less time-consuming
- Less expensive
- Lower dropout rates
- Have improved oocyte quality and endometrial receptivity with a higher proportion of chromosomally normal embryos.

Natural and Modified Natural Cycles

Natural cycles involve monitoring a patient's spontaneous cycle and retrieving a single oocyte prior to the LH peak, but it leads to a significantly lower pregnancy rate than is achieved with stimulated cycles. In modified natural cycles, a cumulative ongoing pregnancy rate of 30% after six

Flowchart 1: Soft protocol (mild stimulation).



(CC: clomiphene citrate; hCG: human chorionic gonadotropin; hMG: human menopausal gonadotropin; OPU: oocyte pickup; r-FSH: recombinant follicle-stimulating hormone)

cycles has been reported and can be used before opting for conventional IVF.[5,35]

Soft Protocols (Flowchart 1)

Clomiphene citrate (100 mg) is administered orally from cycle days 2 to 8. From cycle day 6 onward, three ampoules of hMG or 225 IU r-FSH are administered, overlapping with clomiphene citrate for 3 days. Cetrorelix, in its minimal effective dose of 0.25 mg/day, is given from cycle day 6 onward until ovulation induction by 10,000 IU human chorionic gonadotropin (hCG) occurs.

Dosage Pattern

The dosage pattern of gonadotropins used also varies as per the criteria of the selection of patients. A list with starting dose of gonadotropins is given in **Table 2**.[36,37]

Treatment protocols in different situations will vary—individualized COS—mention individual protocols for each patient [as per the cause—PCOS/endometriosis/tubal factor/poor ovarian reserve/male factor/unexplained/frozen embryo transfer (FET)/donor embryo/donor egg/donor sperm/surrogacy/recurrent implantation failure (RIF)/recurrent pregnancy loss (RPL), etc.].

TABLE 2: Dosage of gonadotropins in different categories and age groups of patients.

Group of patients	*Starting dose of gonadotropins (IU)*
PCOS	100–112.5
First cycle <37 years	150
First cycle 37–39 years	225
First cycle >40 years	300
Previous normal response	150
Previous OHSS	75
Previous poor response	450
BMI > 30 kg/m^2	Increase by 75 IU (except in PCOS)
Severe endometriosis	Increase by 75 IU

(BMI: body mass index; OHSS: ovarian hyperstimulation syndrome; PCOS: polycystic ovary syndrome)

TABLE 3: Low prognosis groups—POSEIDON (Patient-Oriented Strategy Encompassing Individualize D Oocyte Number) classification.

Young	*Older*	*Ovarian reserve*
Group 1 Age <35 years AFC ≥5 AMH ≥1.2 ng/mL Subgroup 1a <4 oocytes Subgroup 1b 4–9 oocytes (in previous OS cycle)	Group 2 Age ≥35 years AFC ≥5 AMH ≥1.2 ng/mL Subgroup 1a <4 oocytes Subgroup 1b 4–9 oocytes (in previous OS cycle)	Adequate
Group 3 Age <35 years AFC <5 AMH <1.2 ng/mL	Group 4 Age ≥35 years AFC <5 AMH <1.2 ng/mL	Poor

(AFC: antral follicle count; AMH: anti-Müllerian hormone; OS: ovarian stimulation)

LOW PROGNOSIS GROUPS—POSEIDON (PATIENT-ORIENTED STRATEGY ENCOMPASSING INDIVIDUALIZED OOCYTE NUMBER) CLASSIFICATION

Low prognosis groups—POSEIDON (Patient-Oriented Strategy Encompassing IndividualizeD Oocyte Number) classification is shown in **Table 3**.

Management

- *Group 1 (good reserve, good quality)*
  - *Possible reasons:*
    - Asynchronous cohort
    - Starting dose of gonadotropin lower than required
    - Trigger issue
    - Polymorphism of FSH or LH receptors
  - *Suggestions:*
    - GnRH antagonist COS with E2/oral contraceptive pill (OCP)/progestin
    - r-FSH in preference to urinary FSH (uFSH)/hMG
    - Higher FSH dose + LH supplementation
  - *Measure of success:*
    - Minimum of five mature oocytes for one euploid embryo
- *Group 2 (good reserve, poor quality)*
  - *Possible reasons:*
    - Asynchronous cohort
    - Starting dose of gonadotropin lower than required
    - Trigger issue
    - Polymorphism of FSH or LH receptors

- *Suggestions:*
  - GnRH antagonist COS with E2/OCP/progestin priming
  - r-FSH in preference to uFSH/hMG
  - Higher FSH dose + LH supplementation
  - DuoStim
  - Dual/hCG trigger if not contraindicated
- *Measure of success:*
  - 10–12 mature oocytes for one euploid embryo

- *Group 3 (poor reserve, good quality)*
  - *Possible reasons:*
    - Poor ovarian reserve
    - Asynchronous cohort
    - Polymorphism of FSH or LH receptors
  - *Suggestions*:
    - Long GnRH agonist
    - GnRH antagonist with E2/OCP priming
    - Progestin-primed ovarian stimulation (PPOS) protocol[39]
    - Start r-FSH 300 units
  - *Measure of success:*
    - Four to seven mature oocytes for one euploid embryo
- *Group 4 (poor reserve, poor quality)*
  - *Possible reasons:*
    - Poor ovarian reserve
    - Asynchronous cohort
    - Polymorphism of FSH or LH receptors
  - *Suggestions:*
    - Long GnRH agonist
    - GnRH antagonist with E2/OCP priming
    - Start r-FSH 300 units
    - Add recombinant LH (rLH), androgens
    - DuoStim
    - PPOS protocol
  - *Measure of success:*
    - >12 mature oocytes for one euploid embryo.

ROLE OF LUTEINIZING HORMONE

Basics

The two-cell, two-gonadotropin model is a fundamental concept in ovarian physiology that establishes a role for both LH and FSH in hormone production. Androgen production and release during folliculogenesis are dependent on the stimulation of the theca cells by LH.

Follicle-stimulating hormone plays a crucial part in recruitment, selection, and dominance, while LH contributes to dominance, final maturation, and ovulation.

The amount of LH activity actually necessary for normal follicle and oocyte development, however, is not known but is likely to be very low since <1% of follicular LH receptors need to be occupied in order to elicit a maximal steroidogenic response and, accordingly, resting levels of LH (1–10 IU/L) should be sufficient to provide maximal stimulation to theca cells.[38-42]

Indications of the Use of Luteinizing Hormone in Ovulation Induction

Indications of the use of LH in ovulation induction include the following:

- Poor responders
- Poor ovarian reserve
- Advanced age of female
- Slow growth of the follicles
- Resistant response to FSH alone
- Low LH levels in blood
- Low E2 levels on ovarian stimulation.

INDIVIDUALIZATION FOR TIME CONSTRAINT

For fertility preservation before radiotherapy/chemotherapy, it is now accepted that ovarian stimulation can be done during both follicular and luteal phases of the same cycle, provided all embryos are frozen and no fresh transfer has been done, taking advantage of multiple waves of follicular recruitment in the same cycle.

- Protocols:
  - Duplex/DuoStim protocol
  - Random start protocol

Total oocyte yields of these protocols were found to be much more than only early follicular stimulations.

INDIVIDUALIZATION FOR NECESSITY OF LOW ESTROGEN

- Possible reasons:
  - Thrombosis-prone cases for COS [deep vein thrombosis (DVT) or another thrombotic event in the past]
  - Estrogen-sensitive malignancies such as estrogen receptor (ER)-positive breast and endometrial cancers
- Suggestions:
  - Serum E2 level is maintained at a level preferably lower than 200 pg/mL

Addition of letrozole up to maximum 10 mg/day with conventional doses of gonadotropins from the start of stimulation till the trigger day

CONCLUSION

- Individualized COS is the new modality to treat different patient groups as COS regimens are complex and cannot be optimal for all patients, so to get improved outcomes, we need to broaden our approach.
- Going to the basics and resorting to alternatives to standard COS protocols such as natural and mild cycles have shown some success. Also, we cannot negate

the negative effects of COS such as OHSS, multiple pregnancies, and ectopic pregnancy.

- Further development of objective biomarkers of response will be an important first step toward implementing personalized medicine in reproductive science.

CHAPTER 53

In Vitro Fertilization Lite

Adrija Kumar Datta, Stuart Campbell, Geeta Nargund, Anuradha Kumari

WHAT IS "IN VITRO FERTILIZATION LITE"?

In vitro fertilization (IVF) protocols, which involve reduced gonadotropin (Gn) stimulation, are various; called "IVF lite", "mild stimulation IVF", "minimal IVF", "mini IVF", or "gentle IVF". Essentially, all these terms mean the same thing. In this chapter, we will use the term mild stimulation IVF (MS-IVF) as defined by the International Society of Mild Approaches to Assisted Reproduction (ISMAAR) **(Table 1)**.[1]

Mild stimulation IVF entails the use of Gn or oral agents—clomiphene citrate (CC) or aromatase inhibitors (AI) either alone or in combination in an antagonist cycle with the intention of retrieving 2–7 oocytes. The standard dose of Gn is 150 IU from day 2 of the menstrual cycle, but this can rise to a maximum of 225 IU according to the woman's past history or body mass index (BMI). It is important to stress that MS-IVF is designed to elicit a mild response, which is in contrast with conventional controlled ovarian hyperstimulation (COH) that requires the maximum possible dose of Gn. MS-IVF should not be confused with natural IVF (N-IVF) or modified natural IVF (MN-IVF) which have distinct protocols and indications **(Tables 1 and 2)** and are not discussed in this chapter.

Mild stimulation IVF is being practiced by an enthusiastic but growing minority of IVF specialists and the reasons for this will be explored in this chapter.

TABLE 1: Definitions of in vitro fertilization (IVF) protocols.

Types	*Definitions*
Natural cycle IVF	IVF is carried out with oocytes collected from a woman's ovary or ovaries in a spontaneous menstrual cycle without administration of any medication at any time during the cycle
Modified natural IVF with hCG	The use of hCG to induce final oocyte maturation in a natural cycle
Modified natural IVF with addition of GnRH-antagonist	The administration of GnRH-antagonist to block the spontaneous LH surge with or without FSH or hMG as add-back therapy
Mild stimulation IVF	A method when follicle FSH or hMG is administered at a lower dose and or for a shorter duration in GnRH-antagonist cotreated cycle, or when oral compounds: Antiestrogen or aromatase inhibitors are used either alone or in combination with gonadotropins with an aim to collect a fewer number of oocytes

(FSH: follicle-stimulating hormone; hCG: human chorionic gonadotropins; hMG: human menopausal gonadotropin; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone).
Source: Adapted from ISMAAR consensus statement.[1]

EVOLUTION OF OVARIAN STIMULATION—RESURGENCE OF NATURAL OR MILD IVF

Mild approach to ovarian stimulation is not a new concept. We may recall that the first IVF baby was born from an oocyte collected in a natural cycle. Low dose of Gn with or without oral antiestrogen (mostly CC) were used in the early days of IVF, aiming to achieve multi follicular growth.[2] In course of time, as pituitary down regulation (desensitization) by gonadotropin-releasing hormone (GnRH)-agonist was introduced to prevent premature luteinizing hormone (LH) surge, COH with higher dose of Gn prevailed in the IVF world. The so-called "long down regulation" subsequently became the predominant protocol in "conventional" IVF (C-IVF) treatment. The intention of C-IVF is to collect as many eggs as possible, to allow selection of one or more embryos for transfer and cryopreservation of the remaining ones, from a decent cohort of embryos. The long down regulation protocol usually requires administration of Gn at a higher dose and or for a long duration, to develop follicles from completely shutdown ovaries.[3,4] However, side effects and risks of intense ovarian stimulation and multiple embryo transfer (ET) have now been well appreciated. The two major complications of IVF programs—ovarian hyperstimulation syndrome (OHSS) and multiple pregnancy are more commonly linked with C-IVF.[3-5] Considering these risks, in addition to physical discomfort, increasing emotional and

TABLE 2: In vitro fertilization (IVF) protocols.

Types	*Protocols*
Natural cycle IVF	The cycle is monitored from cycle day 4–6, by serial ultrasound scans ± serum LH and E2. Urine LH test is commenced once the dominant follicle reaches ≥12 mm in diameter. Optimal timing of oocyte retrieval is determined by hormone levels and follicular diameter. Indomethacin is usually added if there is a risk of premature ovulation. Luteal support is not necessary
Modified natural IVF with hCG	Elective "trigger" of final oocyte maturation by hCG, once the dominant follicle reaches ≥15 mm average diameter with satisfactory serum E2 levels. OR is scheduled 35–36 hours later. Triggering before endogenous LH surge reduces the incidence of premature ovulation. Luteal support is optional
Modified natural IVF with addition of GnRH-antagonist	The cycle starts with natural selection of the dominant follicle. Add-back FSH or hMG at 150 IU/day is started along with cetrorelix (antagonist), once the leading follicle is 13–14 mm size and serum E2 is >500 pmol/L. The hCG trigger is planned when the follicle reaches >16 mm in average diameter with a satisfactory serum E2 level and OR follows 35–36 hours later. The luteal phase support is required
Mild stimulation IVF	• *Low-dose Gn:* A fixed low dose of Gn (usually 150 IU of FSH), titrated with body mass index (BMI), is started in the early follicular phase (either on 2nd day or day 5 of a natural menstrual cycle). GnRH antagonist (e.g., cetrorelix) is commenced when the leading follicle is around 14 mm in diameter or if indicated by serum E2 level (usually >800 pmol/L). Ovulation is triggered when three follicles reach a diameter of 17 mm or greater. Oocyte retrieval is performed 35–36 hours after the ovulation trigger • Oral antiestrogen—selective estrogen receptor modulator (SERMs) or AIs with or without Gn top up: The SERM, commonly used is either CC (usually 100 mg/day) or rarely tamoxifen (40 mg/day). Letrozole (2.5 mg/day) is the most commonly administered AI. There are two different regimens for antiestrogen: – Antiestrogen are administered for 5 days—starting from 2nd or 3rd day of a natural menstrual cycle and low-dose (usually 150 IU) of FSH (± LH) is added from 5th day on either daily or alternate day, depending on the initial ovarian response. GnRH antagonist is commenced when the follicles are around 14 mm or as indicated by serum estradiol and LH levels – CC or tamoxifen is commenced from the 2nd or 3rd day of the cycle and continued until the day of ovulation trigger. FSH at a 150 IU daily dose may be added from 3rd–5th day and continued on alternate days or on a daily basis. SERMs, when administered in this way, effectively blocks the positive feedback action of E2 on the initiation of LH surge; therefore, no antagonist is usually required to suppress the surge

(AI: aromatase inhibitor; CC: clomiphene citrate; E2: estradiol; FSH: follicle-stimulating hormone; Gn: gonadotropin; GnRH: gonadotropin-releasing hormone; hCG: human chorionic gonadotropin; hMG: human menopausal gonadotropin; LH: luteinizing hormone; OR: oocyte retrieval)
Source: Adapted from ISMAAR consensus statement.[1]

financial burden associated with prolonged treatment cycles with aggressive hormonal manipulation, a safer and more "patient friendly" ovarian stimulation protocol was called for.[6] Recently, MS-IVF has been suggested as the way forward to make IVF more accessible and affordable globally.[7]

WHY ADOPT A MILDER APPROACH?

Several systematic reviews with meta-analysis have now demonstrated that mild ovarian stimulation significantly reduces the risk of OHSS.[3,4,8] MS-IVF allows administration of lower dose hCG for final oocyte maturation, which also lessens the risk of OHSS.[9] GnRH-agonist for ovulation trigger has recently been shown to be extremely effective in prevention of OHSS. Not a single patient developed OHSS in a very large cohort study (44,468 IVF cycles), by using a protocol comprising of CC plus Gn followed by a GnRH-agonist trigger.[10] A more recent study showed that, after a certain number of retrieved oocytes, the risk of OHSS rises in parallel with the number of oocytes, with no further increase in pregnancy rate (PR) or live birth rate (LBR).[11]

Elective single embryo transfer (SET) is the most effective way of reducing the chance of multiple births within an IVF program. A large randomized controlled trial (RCT) found significantly lower incidence of twin with similar cumulative LBRs when an MS-IVF with SET was compared with C-IVF and double embryo transfer (DET).[5] By applying strict SET policy in both MN-IVF and C-IVF cycles, a retrospective analysis of large database reported better cumulative LBRs (24% vs. 17.5%) with significantly fewer occurrence of OHSS and multiple pregnancy.[12] The aforementioned large Japanese study found the incidences of ectopic pregnancy (0.36%) and twin (0.9%) to be lower than those in general population by transferring single blastocyst following MS-IVF cycles.[10] High ovarian stimulation also increases the risk of venous thromboembolism (VTE) during the course of treatment, as well as in subsequent pregnancy.[13,14] To date, there is no published study that compares this particular risk between MS-IVF and C-IVF; however, by reducing the incidence of OHSS, the risk of VTE is also expected to be lowered.

Studies that assessed the psychological aspect of IVF treatment, often found the conventional down regulated

protocol to be associated with treatment-related stress,[15] depression,[16] and anxiety[17] compared to those with MS-IVF. A systematic review identified physical and psychological stress to be the most common reason to discontinue IVF treatment.[18] Women undergoing MS-IVF are more likely to accept further treatment following a failed cycle and are less likely to drop out.[17,19] Getting the treatment "fitted" into a woman's natural cycles, the course of treatment tends to be shorter, with fewer clinic visits and less disruption to her working life. Thus, administration of lower dose of Gn for a short duration and its flexibility makes MS-IVF more tolerable and acceptable to the patients.[15,20] ISMAAR has taken a role in advocating the concept of "patient-centered" IVF worldwide.[21]

Apart from clinical safety and better tolerance, the mild approach is a way to make IVF treatment more affordable, by reducing the cost of medications. All the RCTs that compared the treatment cost found MS-IVF to be significantly less expensive than that of C-IVF, among normal responders,[12,22] as well as low responders.[23]

Despite the collection of fewer oocytes, comparable clinical outcomes may be achieved through a treatment cycle, which is less intense, less costly, safer, and more "patient friendly".[24] A recent study revealed that the dose of Gn actually inversely correlated with the LBRs, irrespective of women's age and other prognostic factors.[25] LBRs have been regarded as the benchmark of success in assisted reproduction. Currently, there is a trend of considering "a healthy singleton baby born at term" to be the yardstick of success with more emphasis on perinatal outcomes.[26] A study showed higher mean birth weight of the babies born out of MS-IVF.[27] An analysis of a large dataset of 63,686 singleton births has demonstrated an association between high number of recovered oocytes and higher incidence of perinatal complications, including preterm birth and low-birth weight babies.[28]

Is MS-IVF Clinically Effective?

There has been an ongoing skepticism on the clinical effectiveness of MS-IVF. The controversy has been fueled by publication of two meta-analyses that found the LBRs or ongoing pregnancy rates (OPRs) were lower with MS-IVF as compared to those with C-IVF.[4,29] However, a careful scrutiny of the meta-analyses revealed that predominant contribution to the pooled data came from a large RCT that undertook a policy of DET after conventional COH, while SET following mild stimulation.[5] Higher LBRs in this trial could be attributed to this differential ET policy. Several large adequately powered RCTs (which were not included in the above two meta-analyses) found no difference in the CPRs or LBRs between C-IVF and MS-IVF, whether in normal responders,[30,31] or poor responders.[23,32,33]

Cumulative LBRs of MS-IVF in normal responders have also shown to be comparable with C-IVF.[5,20]

A recent meta-analysis has shown that cumulative live birth rates were similar in poor, normal and hyper-responders following use of MS-IVF versus C-IVF. Risk of OHSS was significantly less with MS-IVF in both normal and hyper responders as compared to C-IVF.[34] A milder ovarian stimulation thus achieves a success, which is at least as good as that of C-IVF through a less intense process, making the approach more tolerable and affordable.

A milder ovarian stimulation thus achieves a success, which is at least as good as that of C-IVF through a less intense process, making the approach more tolerable and affordable.

How Does Mild IVF Hold Good Treatment Success?

High Proportion of Good Quality Oocytes or Embryos

Studies using C-IVF have found that an optimum of 13–15 oocytes needed to be retrieved to maximize the LBR.[35,36] However, these figures are not applicable for MS-IVF; it has been demonstrated that retrieval of only six oocytes optimize the LBR following MS-IVF cycles.[29] An RCT reported that six out of 10 women conceived when four or less oocytes were retrieved by MS-IVF, compared to none, when the similar numbers of oocytes were retrieved with long down regulation protocol.[37] A more recent RCT on good prognosis patients showed 46.7% top-grade embryos from mild IVF, compared to 42.1% from long protocol; however, the difference was not statistically significant.[20] A higher yield of oocytes in poor responders has been associated with higher proportion of morphologically as well as chromosomal abnormal embryos.[38] Indeed, one of the landmark RCTs found equal number of euploid embryos, whether mild or conventional IVF was undertaken, despite twice the number of embryos created in the latter.[39] In a more recent RCT, the doses of recombinant FSH was found to be strongly correlating with the number of recovered oocytes, but not with the number of blastocyst created.[40] The blastocyst–oocyte ratio and fertilization rate (FR) actually declined with the increasing dose of exogenous FSH in this study. This goes in the line with the aforementioned study by Baker et al. that identified a decline in LBRs with increasing Gn dose.[25] The emerging concept is that, low grade of stimulation encourages development of only healthier follicles with more competent eggs, strong ovarian stimulation may just force the growth of less competent follicles.[29]

Improved Endometrial Receptivity

There is increasing evidence that very high, supra-physiological serum estrogen levels may adversely affect implantation. A basic science study demonstrated

progressively less adhesiveness of mouse embryos with human endometrium from fertile oocyte donors, as they were exposed to increasing high concentrations estrogen.[41] Endometrial gene expression has been found to be altered in COH cycles with high circulating estrogen as well as progesterone levels, when compared with those in natural cycles or treatment cycles with low-progesterone levels.[42,43] In practice, the implantation rates as well as PRs have been shown to be significantly lowered by high estradiol (E2) levels in normal or high responders.[44] Also, it has been shown that a "step-down" regimen with decreasing stimulation improved implantation.[29,45]

WHEN DO WE CONSIDER USING A MILD OVARIAN STIMULATION PROTOCOL?

Broadly speaking, there is hardly any clinical situation when MS-IVF should not be considered. Its effectiveness in treating the population in general has been demonstrated in large RCTs.[20,30,31] However, natural or mild stimulation is particularly advantageous in the following conditions:

- *Suspected or previous poor responders:* Treating women with poor ovarian reserve (POR) has always been a challenge; many strategies have been tried with no clear advantage. Until date, all the RCTs where one of MS-IVF protocols was judged against C-IVF, in women with POR found comparable to LBRs, OPRs, or PRs,[23,32,33] while the former was associated with significantly less use of medication and, hence the treatment cost.[23] Subsequently, two systematic reviews confirmed the advantages of MS-IVF in this clinical scenario.[8,46] Indeed, an RCT showed no difference in PRs among poor responders (according to Bologna criteria) whether 150, 300, or 450 IU daily dose of FSH was administered.[47] Natural IVF cycles, when compared with one of C-IVF protocols in women with POR, have also been reported to yield equivalent treatment outcomes.[48] Significant physical, emotional, and financial stress associated with high, often prolonged course of ovarian stimulation in C-IVF has made mild approach a preferred choice in this group of patients.
- *Older women undergoing IVF:* The changing socio-economic condition in the modern world has led women to delay in starting a family; therefore, increasingly more women in their late 30s or 40s are now seeking IVF to achieve a pregnancy. Data are limited on evaluation of mild IVF in older women. A study found no difference in PRs whether women were younger than or >35 years of age (26.6% vs. 35.0% per ET), when ovarian reserve was satisfactory.[49] The PR however was 6.2% among older women with POR in this study.

  An emerging option in treating poor responders or older women with POR is accumulation of oocytes and embryos through repeated cycles before embarking on ET. A retrospective study has demonstrated the benefit of this approach in poor responders.[50] Higher probability of obtaining good quality or euploid embryos from a larger pool of embryos, more likelihood of multiple embryos being available per ET or likelihood of more than one ET may raise the cumulative PR. Further studies are required to prove this unique concept.
- *Conditions where high doses of ovarian stimulation should be avoided:* A high serum estrogen level is not desirable while treating women with estrogen-sensitive breast cancer or early endometrial cancer. Some medical conditions, e.g., acute intermittent porphyria could be exacerbated by excess estrogen stimulation. The antiestrogen, tamoxifen, by virtue of its protective effect on the breast tissue and AI (e.g., letrozole), in conjunction with low gonadotropins may be considered for fertility preservation or treatment of women with breast cancer.[51,52] MS-IVF with AIs could be safer option for women with treated endometrial cancer[53] or porphyria. Other approaches for these clinical scenarios include conducting IVF through a purely natural cycle or in vitro maturation (IVM) of oocytes with little FSH priming.
- *Risk of OHSS:* Recently, the use of GnRH agonist as ovulation trigger, with or without freezing all embryos has been shown to almost eliminate the risk of OHSS in an IVF cycle. However, cases of primary OHSS have sporadically been reported.[54] Women with an extremely high risk of developing OHSS may choose to undergo an MS-IVF with oral agent or a delayed (day 5) start of Gn. Both these strategies tend to recruit fewer follicles. An IVM could also be an option for these women.[55]
- *Low-cost IVF:* Cost is an important consideration for IVF treatment, whether it is self or public funded, regardless of the economic status of the society. There is a drive to make IVF treatment more affordable and accessible to wider section of people by reducing the cost as much as possible.[7,21,26] As described earlier, all the studies that investigated the financial aspect of fertility treatment, found MS-IVF to be less expensive, with no compromise in its success. An MS-IVF protocol comprising of administration of CC or tamoxifen until ovulation trigger has been shown to be particularly inexpensive by avoiding relatively costly GnRH-antagonist injections.[56] There is an ongoing research on a "simplified culture media" that has the potential to reduce the laboratory expenses in IVF treatment. Preliminary results are encouraging.[57]

WHAT ARE THE LIMITING FACTORS IN MS-IVF?

Potential cycle cancellation: A treatment cycle is usually canceled either as a consequence of inadequate response or premature ovulation. The meta-analysis of three RCTs by Matsaseng et al. found an increased incidence of cycle

cancellation before oocytes retrieval in MS-IVF, as compared to conventional IVF (16% vs. 9%; odds ratio 2.55, confidence interval 1.62–4.02).[4] The RCT by Revelli et al. on poor responders reported higher cycle cancellation with CC + Gn cycles, as compared to down regulated cycles (13% vs. 2.7%).[32]

In contrast, several other reports, including RCTs, failed to find an increased risk of cycle cancellation by mild approach, both in normal responders[20,58,59] and poor responders.[33,47] No cycle was canceled due to premature ovulation in the RCT by Lin et al.;[59] while a prospective study with CC + Gn protocol in normal responders reported a lower chance of cycle cancellation (4.7% vs. 34.0%).[60] Cancellation rates due to premature ovulation were between 2.1 and 2.8% by administration of CC up till ovulation trigger.[10] Interestingly, the Cochrane review by Gibreel et al., which compared COH with CC + Gn regimen, found an overall increased incidence of cycle cancellation with the latter, but there was no difference in the subgroup where a GnRH-antagonist was used.[3] Also, the majority of the studies, including RCTs adopted a criterion of canceling cycles if there are less than three dominant follicles for both C-IVF and MS-IVF; while the development of less than three dominant follicles is deemed a poor response for C-IVF, it could be actually a normal response for MS-IVF. Current evidence suggests that the risk of cycle cancellation rate with MS-IVF is low and comparable to that of C-IVF with appropriate use of GnRH-antagonist and close cycle monitoring.

Fewer embryos for cryopreservation: Sensibly, there is a concern that MS-IVF tends to generate fewer oocytes or embryos for transfer or cryopreservation.[61] In reality, the evidence is very conflicting—some RCTs showed the number of available oocytes or embryos not significantly different comparing cycles using C-IVF from those of MS-IVF[20,47,62] while others found fewer oocytes or embryos with MS-IVF.[33,63] However, a number of RCTs reported that the probability of obtaining good quality embryos or blastocyst was similar to,[33,40,63] if not higher with MS-IVF.[37,39,64] This finding may explain why the cumulative success (OPRs/LBRs) with MS-IVF has generally been found to be satisfactory and comparable with that of C-IVF, despite the disadvantage of obtaining fewer embryos for cryopreservation with the mild approach.[5,19,20]

Less flexible scheduling for the clinic and need for a high quality laboratory: Closer cycle monitoring and a high standard of embryology laboratory are the two essential prerequisites for MS-IVF. A successful vitrification program is vital for the success of cumulative outcomes. However, judicious administration of GnRH-antagonist or timely use of indomethacin to prevent ovulation, monitoring perifollicular blood flow, and serial measurement of serum E2 and LH levels may help flexibly scheduling treatment cycles avoiding weekend work.

Since the last 25 years, various literatures have been published suggesting a mild ovarian stimulation approach for all poor responders. Based on current evidence all poor responders are not same and should be managed on individualized basis rather than "one fits all" mild stimulation protocol.[65]

Mild approach is being practiced in different parts of the globe, and India is no exception. Does it fit the need, expectation, and financial situation of Indian couples? Studies from all over the world found MS-IVF overall to be as successful as C-IVF, with N/NM-IVF being a better option for poor responders. There is no reason why it will be different in an Indian population. The published evidence so far indicates an acceptable and comparable treatment outcome.[55,64] More importantly, a low-cost IVF may make this treatment more affordable to the vast section of people in the Indian subcontinent, where fertility treatment is predominantly self-funded. One of the few studies in the world literature, that did economic evaluation of a low-cost MS-IVF protocol (continuing CC until trigger day to avoid the use of more expensive GnRH antagonist) was conducted in Vellore, India.[55] Like Western society, more and more Indian women approaching 40 years or older are now seeking IVF to achieve a pregnancy. The use of MS-IVF in treating older women has become a burning topic among the specialists in India.[66,67] Conducting repeated mild cycles before transferring the embryos in poor responders has become increasingly adopted.[66] Patients' acceptance of undergoing repeated MS-IVF cycles and its cost implications are being investigated in Indian context— it would be interesting to follow future work in this regard.

FUTURE PROSPECTS

Today, the major deterrents to widespread practice of mild approach IVF are—lack of robust RCT data on its success rates, the clinicians' attitude of adhering to more convenient cycle scheduling, satisfaction in retrieving as many oocytes as possible, and variation in the standard of embryology laboratories and the public funding policies in some parts of the world.[68] Several adequately powered RCTs have been published in recent years; almost all the trials found MS-IVF to yield comparable treatment success, both in normal and poor responders. An updated meta-analysis and systematic review is now required to prove its effectiveness. Future research needs to look into its efficacy, especially among poor responders, in terms of LBR per cycle and cumulative success. Flexible cycle scheduling is possible by judicious cycle monitoring with ultrasound scans in combination with measurement of serum E2/LH, timely use of GnRH-antagonist. An effective vitrification technique, which is required for an MS-IVF, is an important goal for any successful IVF laboratory anyway.[68] Future research focusing on MS-IVF would help building up more robust protocols,

taking patient's characteristics (age, BMI, etc.) into account. Further promotion of MS-IVF may be possible through education, training, and research.[69] Communication between the investigators and publishing research data on treatment success as well as patients' attitude and cost, would increase clinicians' acceptance of MS-IVF. Progress in this field may raise the hope that mild and natural IVF could replace C-IVF in all clinical circumstances.

KEY POINTS

- Mild stimulation IVF involves the use of gonadotropin (Gn) or oral agents—clomiphene citrate (CC) or aromatase inhibitors (AI) either alone or in combination in an antagonist cycle with the intention of retrieving 2–7 oocytes ISMAAR consensus.
- Mild stimulation protocols have been safer, less uncomfortable for patients, and at reduced costs when all the expenses are taken into account.

  However, concerns remain about the reduction in the per-cycle chance of pregnancy. Success rates should be evaluated with regard to safety, comfort, direct and indirect costs involved in treatment and management of OHSS.
- An individualized approach to controlled ovarian stimulation based on anti-Müllerian hormone and antral follicle count should be practiced to match patients with the most appropriate protocol.
- In women considered to be poor responders, there is fair evidence that clinical pregnancy rates after IVF are not substantially different when comparing mild ovarian stimulation protocols using low-dose gonadotropins (150 IU/d) to conventional-gonadotropins protocols [American Society for Reproductive Medicine (ASRM) 2018].
- Among poor responders, there is fair evidence to support the recommendation that mild ovarian stimulation is cost-effective, though live-birth rates are extremely low in both groups (ASRM 2018).

CHAPTER 54

Role of Luteinizing Hormone in Ovarian Stimulation

Nivedita Shetty, Shraddha Pol

INTRODUCTION

Normal follicular growth requires the complementary action of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH). During controlled ovarian stimulation, exogenous FSH alone is usually adequate for optimal follicular growth, *if the endogenous LH activity is optimum*. However, in certain groups with inadequate or suppressed LH activity, the addition of LH may be necessary. This chapter attempts to understand the rationale behind LH supplementation during controlled ovarian stimulation, the specific groups that require LH and the various options available for adding LH activity.

PHYSIOLOGY OF THE ROLE OF LH IN FOLLICULOGENESIS

Two-cell–Two-gonadotropin Theory

Luteinizing hormone has a really important function in steroidogenesis. It has different roles during the early and the late folliculogenesis.[1,2]

Follicle-stimulating hormone receptors are present in the granulosa cells and the LH receptors are present in the theca cells in the *early follicular phase*. LH stimulates the theca cells to produce androgens, i.e., testosterone and androstenedione, from cholesterol. The androgens enter into the granulosa cells and are aromatized into estrogens.[3]

In the *late follicular phase*, when the follicular size is around 8–12 mm, LH receptors also appear in the granulosa cells. FSH and LH bring about the local production of inhibin B and insulin-like growth factor (IGF)-1 and -2, which have a role in promoting follicular maturation.[4] The final oocyte maturation, resumption of meiosis, and ovulation occur with the midcycle LH surge.

It can be concluded that both FSH and LH addition appear to be very pertinent for optimal follicular development.

Concept of LH Ceiling and Window

The ovarian follicle needs a certain minimum level of LH for optimal steroidogenesis, considered as the *LH threshold*. This concept is clearly reflected in hypogonadotropic hypogonadism patients, who require minimum LH supplementation during ovarian stimulation with FSH, for adequate steroidogenesis.[5]

However, excess amounts of LH also have been known to be linked with lower fertilization, lower implantation, and poorer pregnancy rates. The higher levels of LH may subdue aromatase activity and suppress cell growth. This is the concept of the LH ceiling.

The *LH window* is the range of LH level, between the LH threshold and LH ceiling, which is when optimal follicular growth occurs. The optimal range, i.e., the LH window, is considered to be between *1.2 and 5 IU/L*.

The LH ceiling may be higher in larger follicles and lower in smaller ones. An increasing LH level would result in growth of the leading follicle (being below its ceiling) and regression of the secondary follicles (by exceeding their ceiling).

Rationale of LH Supplementation during Controlled Ovarian Stimulation

The role of FSH, without any doubt, is very important to obtain adequate number of follicles, in controlled ovarian stimulation. The addition of LH during ovarian stimulation, however, is a controversy and there is no clarity as to which group would benefit and at what dose.

Most normogonadotropic women do not need exogenous supplementation with LH during controlled ovarian stimulation as the endogenous LH is usually sufficient to support multiple follicular growth. For adequate ovarian steroidogenesis, merely 1% of LH receptors need to be taken up. There is also the complex paracrine mechanism comprising inhibin B and IGF-1 and -2, which gets activated and contributes to the follicular growth.[4]

On the other hand, a meta-analysis by Lehert et al. found that in the group where ovarian stimulation was done with recombinant-FSH (rFSH) and recombinant-LH (rLH), the clinical pregnancy rate was slightly higher (estimate of 9%) as compared to the group treated with only recombinant human FSH (r-hFSH).[6]

Then the *MERIT* trial by Andersen et al. compared the clinical outcome following controlled ovarian stimulation with highly purified human menopausal gonadotropin (HP-hMG) or recombinant FSH, after downregulation with *long gonadotropin-releasing hormone (GnRH) agonist protocol*. They concluded that a higher number of oocytes were retrieved after rFSH stimulation (11.8) compared to HP-hMG (10.0). More importantly, a larger proportion of oocytes developed into top-quality embryos with HP-hMG (11.3%) than with rFSH (9.0%). The ongoing pregnancy rate per cycle was 27% with HP-hMG and 22% with rFSH [odds ratio (95% confidence interval): 1.25 (0.89–1.75)].[7]

In one study, the incidence of apoptosis was found to be higher in granulosa cells of follicles aspirated from patients who were not pregnant after IVF as compared to granulosa cells aspirated from patients who were pregnant.[8] Using the apoptosis rate in cumulus cells as an indicator of oocyte quality, a study investigated "low responder" patients undergoing ovarian stimulation with rFSH and recombinant LH versus rFSH alone. In the control group, controlled ovarian stimulation with rFSH from cycle day 3 was done for 42 patients. In the study group, from day 8 of stimulation, 150 IU of rLH was added to the rFSH. The cumulus cells in the control group had a higher rate of apoptosis than in the rLH group which could suggest that addition of rLH improves the chromatin quality of cumulus cells involved in the control of oocyte maturation.[9]

Another advantage with the addition of LH is the lesser risk of premature progesterone rise. FSH promotes the cholesterol conversion into progesterone while LH promotes the conversion of progesterone into androgens which get aromatized to estrogens. If the LH levels are inadequate, the progesterone that gets accumulated is secreted into the circulation. This can result in an endometrium that is advanced and hence resulting in asynchrony in embryo and endometrial development.[10,11]

Specific Groups that Require Luteinizing Hormone

- Hypogonadotropic hypogonadism to support FSH in development of follicles (levels of LH <1.2 IU/L; WHO group I anovulation)
- Deeply suppressed LH due to GnRH analogs
- In GnRH antagonists cycle
- In advanced reproductive age
- Women with low prognosis—Poseidon classification
- In women with a hypo response to exogenous FSH monotherapy.
- In prevention of ovarian hyperstimulation syndrome.

Hypogonadotropic Hypogonadism

The efficacy of recombinant human LH (r-hLH) was analyzed by the European Recombinant Human LH Study Group.[12] All patients were administered 150 IU of r-hFSH daily. They were then randomized to receive either nil or 25 IU or 75 IU or 225 IU/day of r-hLH. In the only FSH group, only 12.5% of patients developed follicles while 42.8% of patients who received 25 IU of recombinant LH developed follicles. However, in the group that received 75 IU of rFSH, 77.8% of patients and in patients who received 225 IU of rFSH, 80% developed follicles.

In conclusion, exogenous LH activity supplementation of at least 75 IU is necessary for follicles to develop in women with hypogonadotropic hypogonadism.

Deeply Suppressed LH Levels

Normogonadotropic women who undergo GnRH agonist downregulation and controlled ovarian stimulation, may demonstrate suppression of LH concentrations below the threshold needed for optimum steroidogenesis.

In a GnRH agonist downregulated cycle with FSH only ovarian stimulation, if the mid-follicular (day 7/8) serum LH levels are low (between 0.5 and 0.7 IU/L), the ovarian follicular response, oocyte yield, and outcome of the IVF cycle are also lower.

The number of patients having deeply suppressed mid-follicular LH suppression varied with the choice of GnRH analog. In one study, the pregnancy rate was similar in the low and normal LH groups (30% vs. 34% per started cycle, respectively). In the low LH group, however, a fivefold higher risk of early pregnancy loss was observed.[13]

However, few other studies have shown that low LH levels did not affect the follicular response, oocyte yield, and pregnancy outcome.

In GnRH Antagonist Cycles

The evidence concerning the clinical use of r-hLH in GnRH antagonist cycles is limited to women 35–39 years of age. In these women, a dosage of 75 IU r-hLH started on the first day of OS significantly improved the implantation rate. No effect was detected in studies that included women >40 years of age. Of note, although r-hLH did not exert a beneficial effect in infertile women <35 years of age undergoing IVF/ICSI, it improved the implantation rate and embryo quality in donor cycles from young good-prognosis women without infertility history.

In Advanced Reproductive Age Group

The available evidence suggests that r-hLH exerts a beneficial effect in terms of implantation rate in women aged 36–39 years, regardless of the pituitary suppression protocol. Nonetheless, no effect in terms of pregnancy rate was observed. No significant effect was observed in studies in which women aged ≥40 years were included in the groups receiving an agonist or an antagonist regimen.

Low Prognosis Women

The Poseidon group proposed a change, from the definition of *poor ovarian reserve* based on Bologna criteria,[14] to a concept of *low prognosis.*[15]

- *Group 1:* Patients below 35 years with good ovarian reserve parameters [antral follicle count (AFC) >5 and anti-Müllerian hormone (AMH) >1.2 ng/mL] and with an unexpected poor or suboptimal ovarian response—hyporesponders.
- *Group 2:* Patients >35 years with good ovarian reserve parameters (AFC >5 and AMH >1.2 ng/mL) and with an unexpected poor or suboptimal ovarian response.
- *Group 3:* Patients below 35 years with poor ovarian reserve (AFC <5 and AMH <1.2 ng/mL).
- *Group 4:* Patients above 35 years with poor ovarian reserve (AFC <5 and AMH <1.2 ng/mL).

Group 1—Hyporesponders: In 15% of normogonadotropic women, with normal AMH and AFC, an initial poor response to standard FSH doses is observed. This could be due to hyposensitivity to standard FSH doses resulting in "hyporesponse" identified by the absence of follicles over 10 mm on day 8 of stimulation with r-hFSH. It is also associated with low serum estradiol levels (below 180 pg/mL) and at least 6 follicles ranging between 6 mm and 10 mm.

Hyporesponders usually have a normal ovarian reserve and are young (<39 years). In spite of FSH requirement of hypo responders being higher (>2,500 IU total dose), the response is unexpectedly poor (i.e., <3 eggs retrieved) and IVF outcome is also poorer.

If hyporesponse is identified early (i.e., day 5–8 of COS), either r-hLH or increase in FSH dose are effective in rescuing and forming adequate numbers of follicles and good embryos. At least two genetic variations, one a polymorphic allele of the LH beta subunit gene (v-beta LH) and the other the FSH receptor (FSHR) *Ala/307 and Ser/680 variant, have been implicated in the resistance to* exogenous FSH.[16,17]

The FSHR gene can be used as a marker to predict ovarian response. The gene contains two important single-nucleotide polymorphisms (SNPs) in exon 10, wherein two amino acids at positions 307 and 680 can change. These women with 307 Ala and 680 Ser SNPs have been associated with a poorer ovarian response.

About 282 SNPs have been found to exist on the LH receptor gene. In 1991, Pettersson and Söderholm identified a common genetic LH beta variant or v-beta. Patients requiring LH addition, during ovarian stimulation, could be identified, if its role is confirmed, with further research.

De Placido et al. conducted a multicentric randomized control trial (RCT) of 117 in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) cycles[17] analyzing the role of LH addition in high responders. These patients underwent downregulation and ovarian stimulation with r-hFSH of 225 IU for 8 days and were identified to be hyporesponders. They were randomized to either undergo the step-up protocol, wherein the daily dose of rFSH was increased by 150 IU and an equal number of patients were randomized to receive 150 IU/day of r-hLH addition ($n = 65$). "Normal responders" were selected as a control group ($n = 130$).

Significantly more oocytes were obtained in the rLH supplementation group (9.0 ± 4.3) compared with the group with increased dose of r-hFSH (6.1 ± 2.6; $p < 0.01$) while the highest number of oocytes were retrieved in the control group (10.49 ± 3.7; $p < 0.05$). The control group and the rLH supplemented group had similar implantation and ongoing pregnancy rates (14.2% and 32.5% vs. 18.1% and 40.2%, respectively), however, the group treated with the increase in FSH had the least pregnancy rates.[18]

Group 2—older women more than 35 years: Hill et al. analyzed seven trials comprising 902 assisted reproductive technology cycles in older women. They concluded that, in women more than 35 years old, it was beneficial to add LH as the clinical pregnancy rate was significantly higher.[19] A significant observation was that addition of LH did not increase the oocyte or M2 yield. This decrease is probably due to the fact that there was a decline in smaller developing follicles. The larger developing follicles may be yielding better quality oocytes and hence the better clinical pregnancy rate.

Also, a study which demonstrated lesser cumulus cell apoptosis in rLH supplemented cycles, suggested better oocyte quality.[9] The lower serum progesterone, on addition of LH, may also have a role to play in the better implantation rate.[10,11]

In older women the LH receptors become less sensitive and the serum androgen levels decline. The administration of LH enhances androgen levels and hence estrogen production is also increased.[20]

Current available evidence recommends that LH supplementation when started from day 1 of controlled ovarian stimulation has a better IVF outcome in women older than 35 years of age.

Groups 3 and 4—poor responders with poor ovarian reserve: A meta-analysis assessing the outcomes of r-hLH supplementation as compared to r-hFSH alone involved a total of 40 RCTs comprising of 6,443 women of which 14 studies (1,129 patients), specifically analyzed poor responders.

Significantly higher numbers of oocytes were retrieved and also significantly higher clinical pregnancy rates were observed with r-hFSH plus r-hLH, in the poor responders group as well.[6]

In women with hyporesponse to FSH monotherapy: It is important to know the distinction between hyporesponders and poor responders and analyze these groups separately. They defined hyporesponders as women with normal

ovarian reserve tests (i.e., anti-Mullerian hormone and antral follicle count) and an adequate number of recruited oocytes, however they required higher doses of gonadotropins. In contrast, poor responders may have abnormal ovarian reserve tests but the number of oocytes retrieved is low irrespective of the amount of gonadotropin administered.

With the definition of hyporesponse in mind, current evidence indicates that in high responders: (1) r-hLH supplementation starting from day 7–10 of OS can rescue the ongoing cycle, thereby compensating for an initial slow response (stagnation); (2) administration of r-hLH is more efficient than increasing the dosage of r-hFSH; and (3) when a hyporesponse is retrospectively identified (i.e., history of excessive consumption of FSH, r-hLH supplementation from day 7 or 8 of stimulation seems to improve the outcome of IVF. Furthermore, it seems that 150 IU r-hLH results in more oocytes retrieved and a higher percentage of mature oocytes than does 75 IU r-hLH in a long GnRH agonist protocol. All of these findings were obtained with the use of a GnRH agonist long protocol. In contrast, the effect of r-hLH supplementation in high responders undergoing OS with the use of GnRH antagonists remains to be established. The mechanism by which r-hLH exerts its beneficial effect in hyporesponders is not fully understood. It is plausible that an excessively profound suppression of endogenous LH after downregulation with the use of GnRH analogs may create the need for exogenous LH supplementation.

In prevention of ovarian hyperstimulation syndrome: Caserta et al. investigated 999 infertile women ≤40 years of age with basal FSH levels ≤12 mIU/mL and no history of OHSS or polycystic ovary syndrome. The women were randomized to receive r-hFSH alone (n = 501) or r-hFSH þ r-hLH (n = 498). A daily dose of 150 IU r-hFSH was administered in both groups; r-hLH supplementation was given at a dose of 75 IU/d from stimulation day 7 onward. No differences in age or mean number of embryos transferred were observed between groups. Although the number of eggs retrieved was lower in the supplemented group than in the r-hFSH–alone group (6.1 ± 3 vs. 6.6 ± 3.8; $p < .05$), the clinical pregnancy rate was higher in the supplemented group than in the r-FSH–alone group (16.8% vs. 11.9%; $p < .05$). The proportion of canceled cycles owing to OHSS risk (8.3% vs. 2.4%; $p < .000001$) and the proportion of patients who developed clinical OHSS (1.6% vs. 0.2%; $p < .05$) were significantly higher in the r-hFSH–alone group than in the r-hFSH and r-hLH group.

Types of Luteinizing Hormone Activity

Luteinizing hormone activity containing gonadotropin preparations:

- Urinary hMG contains human chorionic gonadotropin (hCG) which has LH-like activity
- Recombinant LH
- Urinary and recombinant hCG, which have LH-like activity
- A combination of recombinant FSH and LH in a fixed ratio of 2:1.

Human Menopausal Gonadotropins

It is obtained from the urine of postmenopausal women and contains equal quantity of FSH and LH bioactivity (approximately 75 IU of each).

Disadvantages of hMG

- Local allergic reactions which may be due to protein contamination
- Batch-to-batch variations
- Difficulty in sourcing large quantities of urine of postmenopausal women
- Contamination with prion proteins which may be associated with transmissible spongiform encephalopathies.

In HP-hMG, it is hCG supplementation that provides 95% of LH bioactivity.[21] Urinary hMG undergoes a purification process but as the purity of an hMG preparation is increased, LH molecules get reduced[21] and in order to maintain the required FSH:LH ratio of 1:1 of the original hMG, more exogenous hCG needs to be added. This means that the longer terminal half-life of hCG being 32–34 hours leads to the possibility of drug accumulation. Patients treated with 50 IU/day of hCG showed increasing levels of hCG over the course of a treatment cycle to 16.2 ± 3.2 IU/L of hCG, which is equivalent to 113.4 IU/L of LH activity.[22] This is of importance since a threshold level of 1.2 IU/L of LH is required for optimal follicular development and there is a "ceiling" LH level (5 IU/L) above which granulosa cell proliferation is suppressed and atresia (of the nondominant follicles) and premature luteinization (of the preovulatory follicle) occur.

Noninferiority of hMG was established with the MERIT trial which compared the clinical outcome with HP-hMG and recombinant FSH following a long GnRH agonist protocol. The conclusion was that, although more oocytes were retrieved following ovarian stimulation with rFSH (11.8 oocytes vs. 10 oocytes, $p < 0.001$), the proportion of top quality embryos obtained with HP-hMG was higher (11.3% vs. 9%, $p = 0.044$). Lower levels of estradiol and higher levels of progesterone were noted on the day of hCG with rFSH. The ongoing pregnancy rates per cycle was 22% with rFSH and 27% with hMG [odds ratio (95% confidence interval): 1.25 (0.89–1.75)].[7]

The *Megaset* trial, by Paul Devroey et al., is a randomized trial including 749 women, wherein HP-hMG was compared with recombinant FSH in a *GnRH antagonist* cycle with compulsory single blastocyst transfer. They concluded that the ongoing pregnancy rate after a fresh cycle was 30% with HP-hMG versus 27% with rFSH for the per-protocol (PP) population and 29% versus 27% for the intention-to-treat

(ITT) population. When frozen cycles were considered, *the cumulative live birth rate was 40% and 38% for patients treated with HP-hMG and rFSH*, respectively. The results proved that HP-hMG is at least as efficient as rFSH in GnRH antagonist cycles.[23]

Recombinant Luteinizing Hormone[24-26]

A better safety profile and batch-to-batch consistency as compared to urinary gonadotropins is assured with rLH. Its shorter half-life allows for more precise dosing during controlled ovarian stimulation. On subcutaneous administration, the terminal half-life of recombinant LH is 21–24 hours. Hence, even if 150 IU of r-hLH is administered subcutaneously daily, it results in only a low level of 1.6 IU/L of LH.[27]

A meta-analysis of 40 RCTs[6] comparing the outcome of only rFSH as compared to r-hFSH supplemented with r-hLH demonstrated a minor increase (estimate of 9%) in clinical pregnancy rates with LH supplementation, although the number of oocytes obtained, were similar in both groups.

In the poor responders group, comprising 14 RCTs, significantly more oocytes were retrieved and significantly higher difference in clinical pregnancy rates was noted in the rLH supplemented group.

A meta-analysis by Oliveira et al. concluded that in *GnRH agonist* downregulated cycles, rLH supplementation with rFSH, resulted in shorter duration of stimulation ($p < 0.0001$), a lesser amount of rFSH used ($p < 0.0001$) and a greater serum E2 level on the day of hCG administration ($p < 0.0001$). However, the total number of oocytes retrieved, number of mature oocytes obtained, and the clinical pregnancy rate and miscarriage rates were similar.[28]

Another meta-analysis by Baruffi et al. concluded that with LH addition in *GnRH antagonist* cycles, the serum E2 level on the day of hCG was higher and also more oocytes were retrieved. However, there was no difference in the amount of rFSH used, duration of stimulation, total number of oocytes retrieved, the clinical pregnancy rate, and the miscarriage rate.[24,25]

Urinary and Recombinant hCG, Which have LH-like Activity

Human chorionic gonadotropin can be added during two different times of the follicular phase:

1. *Early follicular phase:* For ovarian priming.
2. *Late follicular phase:* When the LH receptors appear.

Early follicular phase: Between 200 and 1,250 IU hCG was used, for ovarian priming. It acts on the theca cells in preantral and small antral follicles and induces the formation of the androgens which are needed as a substrate for estradiol which in turn helps in follicular differentiation.

Late follicular phase: In both the GnRH agonist and antagonist cycles, hCG was administered at doses of 200 IU/day, when follicles reached 12–14 mm in diameter, i.e., in the late follicular phase. Even under physiological conditions, LH plays an important role in folliculogenesis in the late follicular phase as the FSH levels start decreasing. During ovarian stimulation, low-dose hCG may promote the growth of intermediate-sized follicles which have LH/hCG receptors and may be effective in ovarian stimulation until the final stages in the absence of FSH.

A meta-analysis by Checa et al. concluded that the use of hCG in the early and late follicular phase in controlled ovarian stimulation has the advantage of decreasing the consumption of FSH. The total dose of FSH required was decreased by over 800 IU, in patients in whom hCG was added. However, there was a slight decrease in the number of metaphase II (MII) oocytes retrieved.

Timing and Dosing of LH Supplementation

Exogenous LH activity supplementation of *at least 75 IU* is necessary for follicles to develop in women with hypogonadotropic hypogonadism.

In women >35 years of age, current available evidence recommends that LH supplementation gives a better IVF outcome, especially when *started from day 1* of controlled ovarian stimulation in GnRH antagonist protocol and on stimulation day 6 in a GnRH agonist protocol.

Controlled ovarian stimulation with an LH-to-FSH ratio of 0.30–0.60 resulted in the least risk of progesterone increase. Most risk of progesterone elevation >1.5 ng/mL was seen in patients where no LH was added during stimulation. This pattern of lowest risk in the 0.30–0.60 range held true for low, normal, and high response cycles. Hence, FSH and LH in a *ratio of 2:1* is recommended for ovarian stimulation.

The beneficial effect on implantation rate was for women between 36 and 39 years, but no effect was detected in women above 40 years.[29]

KEY POINTS

- Both FSH and LH appear to be important for optimal follicular development and pregnancy.
- The *LH window* is the range of LH level, between the LH threshold and LH ceiling which is when optimal follicular growth occurs. The optimal range, i.e., the LH window, is considered to be between *1.2 and 5 IU/L*.
- During controlled ovarian stimulation with FSH only, the endogenous LH is usually adequate to support multiple follicular growth. However, in certain groups, the addition of LH improves the IVF outcome.
- Addition of LH activity is recommended in *hypogonadotropic hypogonadism, poor responders, older women, and hyporesponders.*

- The LH activity can be added using gonadotropin preparations such as *urinary hMG, recombinant LH, and urinary and recombinant hCG.*

CHAPTER 55

Anesthesia in Assisted Reproductive Techniques

Dorothy Dessa, Ravi Kumar IR

INTRODUCTION

In vitro fertilization (IVF), started first in the late 1970s, is now a common procedure—the answer to infertility due to both maternal and paternal disorders.[1,2] The 1980s witnessed a drastic change from follicle aspiration laparoscopically under general anesthesia to transvaginal ultrasound-guided oocyte retrieval.[3-6] Today, worldwide, almost all IVF techniques are performed under ultrasound guidance, transvaginally. IVF techniques include:

- Ovarian stimulation and monitoring
- Follicle aspiration or oocyte retrieval
- Fertilization in the embryology laboratory and transfer of the embryos into the uterus.

ANESTHETIC CONSIDERATIONS

Infertile couples, especially the female partner, are often anxious and in fear.[7-9] Although transvaginal oocyte retrieval (TVOR) is considered less invasive, it is one of the most painful and stressful components of the assisted reproductive treatment cycle. Pain during oocyte retrieval is due to the traction on the vaginal wall, ovarian capsule, and ligaments and also due to the puncture on the vaginal wall and the ovarian capsule by the aspiration needle.[10] Multiple attempts are usually needed according to the condition of the ovary and the follicles. Although oocyte retrieval can be done without anesthesia, adequate pain relief possesses more benefits during the procedure for both the patient and the surgeon.

In this 21st century, IVF procedures are performed as "day care procedures" based on the principle of "ambulatory or office-based anesthesia."[11]

IDEAL FEATURES OF THE ANESTHETIC TECHNIQUE FOR THE PROCEDURE OF IN VITRO FERTILIZATION[12]

The ideal features are as follows:

- Able to provide safe, effective, and adequate analgesia
- Rapid onset and recovery with minimum side effects and no effects on the oocytes
- Quick recovery time from anesthesia
- No changes in the follicular fluid and pH
- No effect on fertilization, early embryo development, and pregnancy rate.

GENERAL CONSIDERATIONS

Couples need to be evaluated for existing medical or surgical illnesses. In India, where tuberculosis is rampant and consists of a big chunk of infertile patients, it is important to know the drug interactions, especially antitubercular drugs with anesthetic drugs.

The hormonal manipulation during controlled ovarian stimulation causes variation in the serum estrogen level from baseline to supraphysiological level during oocyte pickup. The albumin and α-1 acid glycoprotein synthesis is affected by estrogen, which reduces drug binding and results in increased free fraction of the highly protein-bound drugs in the circulation. So, the selection of the drugs and appropriate dose is extremely important.

To prevent a hypercoagulable state due to prolonged gonadotropins use, some patients may be started on anti-coagulants (aspirin or heparin). Aspirin should be stopped 3 days prior to oocyte retrieval. If the patient is on heparin, it is wise to know the activated partial thromboplastin time (aPTT).

Infertility has a major psychological impact. Some of these patients may be on antidepressant drugs, antipsychotics, or antiepileptics. It is important to elicit this history during the preanesthetic evaluation. It is advised to take these drugs into consideration and anesthetic agents to be adjusted accordingly based on the expected interactions.[13,14]

Thyroid disorders, a common finding in the infertile population, also interfere with the anesthetic protocol. Therefore, appropriate anesthetic precautions should be taken. Special considerations are given for anesthesia in morbid obesity and severe pulmonary/cardiac or

renal disease patients. A study conducted to evaluate the intravenous (IV) anesthesia for IVF in obese and normal body mass index (BMI) patients concluded that the visualization of the ovary during the procedure becomes difficult, leading to longer duration of the procedure and thus requiring additional dosage of anesthetic agent resulting in higher drug consumption and even frequent use of muscle relaxant (succinylcholine).[15]

Fertility preservation is an issue in patients undergoing chemotherapy or radiotherapy along with anesthetic implications of the basic malignancy. So, in cancer patients, oocyte retrieval is done prior to starting chemotherapy or radiotherapy.

Patients presenting to the IVF clinics are generally under psychological and social stress. This immense pressure, accompanied by hormonal manipulation during ovarian stimulation, makes them more susceptible to psychosomatic disorders. It is a challenge to the anesthetists to allay their anxiety and provide them with a conducive environment so as to extract complete medical and pharmacological history.

ANESTHESIA TECHNIQUES—OPTIONS AVAILABLE TO THE ANESTHETIST

- Conscious sedation or monitored anesthesia care (MAC)
- General anesthesia
- Regional anesthesia—spinal anesthesia and epidural anesthesia
- Local anesthesia—paracervical block and preovarian block
- Total intravenous anesthesia
- Patient-controlled anesthesia
- Acupuncture.

The most common procedure performed during an IVF cycle that requires anesthesia is oocyte retrieval. Occasionally, embryo transfer may be performed under anesthesia. Dilatation and curettage (D and C) is seldom encountered in an IVF unit. Very rarely, the urologist may incorporate percutaneous epididymal sperm aspiration (PESA) or testicular sperm aspiration (TESA) in the IVF anesthesia schedule.

According to Cochrane review 2013, no one method of anesthesia or technique is better over another during oocyte retrieval. However, conscious sedation is the most widely practiced method of anesthesia in IVF clinics.[16]

CONSCIOUS SEDATION

Conscious sedation ("twilight sleep") is a specific anesthesia technique for a diagnostic or therapeutic procedure done under local anesthesia along with sedation and analgesia. It is a drug-induced depression of consciousness where the patient remains calm while she is awake and responds to verbal commands or tactile stimulation. This is the most commonly used anesthesia technique in an IVF setting.[17]

Advantages

- No intervention is required for maintaining normal respiration and cardiovascular function
- Acts as a good anxiolytic, sedation, and analgesia effect
- The recovery post anesthesia is fast due to the quick metabolism—patients can be discharged fully awake because the post-anesthesia recovery is fast and also pain-free.
- Easily administered
- Well tolerated
- Minimal side effects.

Disadvantages

- Lack of airway control
- Risk of airway obstruction and aspiration.

Complications

- Due to the use of sedatives—cerebral hypoperfusion, hypoxia, and hypercarbia
- Due to local anesthesia toxicity:
  - Localized reactions—rash and urticaria
  - Systemic reactions—anaphylaxis, breathlessness, dysrhythmias, hypotension, and cardiac arrest

The commonly used drugs in conscious sedation are midazolam, fentanyl, propofol, ketamine, and dexmedetomidine.[18]

- *Midazolam:* It is a water-soluble benzodiazepine which is potent with a rapid onset and short duration of action. There is a low level of venous irritation after IV injection of midazolam. Midazolam causes anterograde amnesia. Dosage of 0.2 mg/kg is used for induction and 1 μg/kg/min for maintenance of anesthesia. Very low levels of midazolam have been reported in the follicular fluid, which has no detrimental effect on implantation or pregnancy rates.[11] The combination of midazolam with opioids increases the risk of apnea and hypoxemia. The addition of propofol has a synergistic effect causing cardiorespiratory depression.
- *Opioids (fentanyl, remifentanil, alfentanil, and meperidine):* Remifentanil and fentanyl are usually used during conscious sedation and in general anesthesia for oocyte retrieval due to the rapid onset and short duration of action. However, high doses of opioids may cause respiratory depression, muscle rigidity, and bradycardia. Opioids have been found to be safe during oocyte retrieval.[19,20] Fentanyl and alfentanil have the least penetration in the follicular fluid, i.e., 10:1 ratio in the serum and follicular fluid.[21] Among all opioids, remifentanil is the most preferred.[22,23]

- *Propofol:* The pharmacokinetic property of propofol makes it the first-choice drug for anesthesia. It is a lipophilic anesthetic agent. It rapidly distributes into the central nervous system (CNS) and is associated with reduced nausea and vomiting postoperatively. The administration of propofol causes a local burning sensation, which can be avoided by prior administration of IV lidocaine (10 mg). It is given in 2 mg/kg bolus dose or 150 µg/kg/min in titrated dose as an infusion. Monitoring is an important part while using this drug as it causes respiratory and myocardial depression.[24] There are controversial reports regarding propofol anesthesia on embryo quality, implantation, and pregnancy rates.[25-27] Propofol accumulates in the follicular fluid, which shows a rise in the concentration only with the increased duration of exposure.[28] Hence, propofol should be used with caution during oocyte retrieval by limiting the maximum dose administered to <4 mg/kg.
- *Ketamine:* It causes "dissociative anesthesia" (cataleptic state with eyes open and a slow nystagmic gaze). It belongs to the phencyclidine family. It is not a popular drug due to its postoperative psychological adverse effects like fear, vivid dreams, excitement, and illusions. A study showed reduced fertilization rate with ketamine as compared to propofol ($p = 0.013$) and in the combination group of propofol with ketamine ($p = 0.008$). An increased anesthesia duration (>30 minutes) was found to be associated with lower implantation and pregnancy rate.[29] Therefore, ketamine alone is not one of the good choices for assisted reproductive technology (ART), though there are reports of satisfactory outcomes when it is mixed with propofol or midazolam. Good analgesia is achieved with a bolus dose of 2 mg/kg.
- *Dexmedetomidine:* It is a centrally acting α-2 adrenoreceptor agonist.[30] It has both analgesic and sedative properties with a lack of respiratory depression. Hence, it is also known as "cooperative sedation" because it induces a state similar to natural sleep and at the same time, the patient is easily arousable and cooperative.[31,32] It is rapidly absorbed, distributed, and metabolized in the body. Studies have shown that dexmedetomidine is a good alternative to midazolam for conscious sedation due to its better patient satisfaction, less opioid requirements, and minimal respiratory depression.[33-35] It is given in a dose of 1 µg/kg IV. The use of this anesthesia drug may be limited due to the reported increase of bradycardia, hypotension, and limited ability to achieve deep sedation.
- *Drugs to be avoided:* Majority of the studies have shown detrimental effects of halogenated fluorocarbons like nitrous oxide. These agents were found to have a negative effect on embryo quality and increased abortion rates.[36]

BOX 1: Sedation protocol for transvaginal oocyte retrieval (protocol followed by at Milann Infertility services).

- Confirm patient identification
- Preprocedure interview and documentation, informed consent
- Preparation in the procedure room:
  - Secure a peripheral intravenous (IV) line
  - Skin sensitivity test for local anesthesia—lignocaine and antibiotics
  - Pretreatment with antiemetic (Emeset) and ranitidine
- Check the availability of emergency equipment
- Place routine monitors
- Give oxygen via a nasal cannula or a mask
- Position patient in dorsal lithotomy position
- Start sedation with glycopyrrolate 0.2 mg bolus
- Give injection midazolam 0.2 mg/kg IV
- Give injection dexamethasone 8 mg IV—to prevent postoperative nausea and vomiting
- Give injection fentanyl 2–5 µg/kg body weight, injection propofol (1%) 10 mL IV slowly, and then titrate as per requirement
- Keep communicating with the patient
- Give reassurance during the retrieval
- Continuous monitoring of vitals

Monitoring of Conscious Sedation Anesthesia

- *Pulse oximetry*—for oxygen saturation. Other than sedatives, extremes of age, obesity, lithotomy position, respiratory disease, and preexisting upper airway obstruction predispose to hypoxia
- Electrocardiography (ECG), heart rate, respiratory rate, noninvasive blood pressure (NIBP)—ECG lead II should be continuously displayed. NIBP is measured and recorded at least every 5 minutes. Heart rate and respiratory rate should be recorded every 10–15 minutes.
- Temperature—external and core body temperature is measured to detect hypothermia or hyperthermia.

Response to communication—important for the titration of the anesthesia drug. Continuous evaluation of the response to tactile stimulation and verbal commands should be carried out **(Box 1)**.

ANESTHESIA IN EMBRYO TRANSFER

Sometimes, when the patient is anxious, uncooperative, or when a difficult embryo transfer is anticipated, conscious sedation may be used.[37] The use of sedation does not alter the outcome of the embryo transfer procedure.[38,39]

ANESTHESIA FOR SURGICAL SPERM RETRIEVAL

Majority of the sperm retrieval procedures can be performed under adequate local anesthesia. When the local anesthetic is performed well, the nonanxious patient will tolerate a TESA, PESA, testicular sperm extraction (TESE), and minimally invasive epididymal sperm aspiration (MIESA) with local

anesthesia alone. Conventional microsurgical epididymal sperm aspiration (MESA) is usually performed under general anesthesia. Depending on patient factors, cost, patient, and surgeon preference, sperm retrieval techniques may require general anesthesia or preferably MAC, also known as conscious sedation or twilight anesthesia.[40]

For adequate local anesthesia during surgical sperm retrieval, a well-performed spermatic cord block must be used in addition to a peri-incisional and superficial pudendal block. A spermatic cord block is performed according to the initial technique described by Wakefield and Elewa.[41] Using a 10 mL syringe and 25-G, 1.5-inch needle, 1:1 mixture of lidocaine 1% and bupivacaine 0.25% is directly infiltrated into the high scrotal spermatic cord below the external inguinal ring. While fixating the cord in between the thumb and index finger, approximately three passes of the needle are made into the cord in a fan-like distribution, followed by subcutaneous infiltration lateral to the cord along the scrotal-inguinal plane to anesthetize the superficial branches of the pudendal nerve. A total of approximately 10 mL of anesthetic is used during the spermatic cord and superficial pudendal nerve block. After the initial cord block, a peri-incisional block along the planned skin incision is anesthetized using the same syringe, needle, and solution of lidocaine and bupivacaine as a subcutaneous skin block.

According to the American Urological Association Best Practice Policy Statement on Urologic Surgery Antimicrobial Prophylaxis, for a clean open case where the urinary tract is not entered, a single dose of a first-generation cephalosporin is recommended.[42] A randomized, double-blind, placebo-controlled trial of 34 patients who underwent open sperm retrieval demonstrated significant improvements in postoperative pain and narcotic use when twice-daily oral celecoxib 200 mg was initiated the day prior to surgery and continued for a total of 1 week versus placebo.[43] Hence for office-based sperm retrieval procedures, oral antibiotics and oral nonsteroidal anti-inflammatory drugs (NSAIDs) should be considered to be started the day prior to the scheduled procedure.

ANALGESIA FOR HYSTEROSALPINGOGRAPHY

Hysterosalpingography (HSG) is a minimally invasive day-care procedure to evaluate the fallopian tubes and uterine cavity. Patient experiences discomfort and lower abdominal pain during and after the procedure due to cervical manipulation, uterine distension, and stimulation of the peritoneum.

For effective pain relief during HSG, in addition to oral NSAID, local application of lidocaine cream to the posterior fornix of the cervix uteri and paracervical lidocaine injection into the cervix uteri appear to be the most effective methods.[44] Intravenous opioids (tramadol) may also provide effective pain relief, but their benefit must be weighed against their side effects and effect on recovery time.[45] However, there is no consensus concerning optimal analgesics or the timing of its administration. Immersive virtual reality (VR) is an emerging nonpharmacologic and noninvasive analgesic technique, being evaluated as an alternate option for analgesia during HSG.[46]

GENERAL ANESTHESIA

Occasionally, general anesthesia is used in an IVF clinic. It can be performed by the use of intravenous (fentanyl and propofol) or inhalational (nitrous oxide, isoflurane, and sevoflurane) agents with coadministration of sedatives and analgesic drugs. These drugs mainly act on the gamma-aminobutyric acid type A ($GABA_A$) receptors and *N*-methyl-D-aspartate glutamate receptors.[47] It is the technique of choice during laparoscopic follicular aspiration, transabdominal oocyte retrieval, laparoscopic gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT), and also has been used for TVOR in the past.[5,48,49] Invariably, all anesthetic agents have been detected in the follicular fluid and this raises concerns regarding their use.[28] However, fentanyl and propofol have been reported safe and effective.[50] The advantage with using general anesthesia is that the uterus becomes more relaxed, and therefore it is easier for the clinician to aspirate more number of follicles, unlike under sedation, where a contracted myometrium may interfere with the oocyte aspiration. With the proper relaxation of the walls, aspiration of even smaller ovarian follicles becomes simpler. However, it is important that the duration of general anesthetics should be kept to a minimum to avoid the negative effects of these drugs on the oocytes.[51,52]

REGIONAL ANESTHESIA

Regional anesthesia constitutes central neuraxial blockade or the peripheral neural block.

Paracervical and Preovarian Block

In the paracervical block, local anesthetic is injected into two to six sites along the vaginal portion of the cervix at a 3–7 mm depth. The principle of this block is that the nerve plexus lies laterally and posterior to the junction of the uterus and the cervix at the base of the broad ligament. It does not cover the ovarian walls, and the sensations from vaginal and ovarian pain fibers are incompletely blocked; thus, it needs to be supplemented with sedation. Lidocaine is the most common local anesthetic used and the drug acts within 5 minutes of injection. The common complications of this technique are broad ligament hematoma, sciatic nerve block, and neuropathy **(Fig. 1)**.

Preovarian block is a comparatively new technique where the drug is infiltrated into the vaginal wall under

ultrasound guidance between the peritoneal surface of the ovary and the vaginal wall. The most commonly used agent is lidocaine at a dose of 50 mg. These techniques, in combination with an inhalational agent, such as remifentanil, are considered effective and safe.[53,54] There is no difference in pain experienced with either paracervical or preovarian blockade.[55] To improve the effectiveness of pain relief, electroacupuncture has also been used along with paracervical block.

Another local anesthetic used for oocyte retrieval is tetracaine. As a local anesthetic, it acts on the peripheral nerves to block nerve impulse transmission. It has been shown to decrease the total dose of propofol required when both of them are used in combination—propofol for sedation and tetracaine as a local anesthetic.[56,57]

Spinal Anesthesia

Drug is given at the L3–L4 level, into the subarachnoid space with a 27-G spinal needle, 0.5% hyperbaric bupivacaine (10–12 mg). The advantages of this technique are that the patient remains awake throughout the procedure and there is an increased comfort level of the gynecologist.[58] However, it is an invasive procedure with a delay in patient discharge from the hospital and urinary retention is common.[59]

Epidural Anesthesia

Epidural anesthesia is an alternative for IVF procedures. However, there is no advantage of this method over other anesthesia techniques.[60,61]

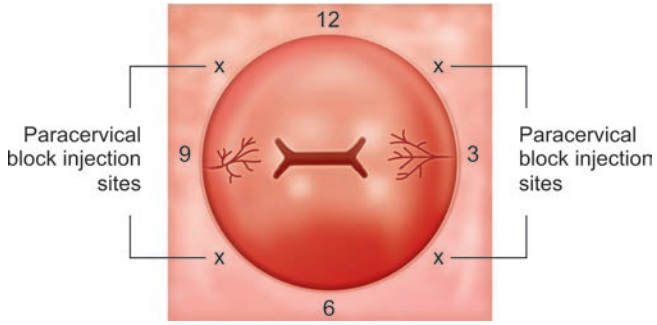

Fig. 1: Paracervical block injection sites—2, 4, 8, 10 o'clock positions. 3 and 9 o'clock positions are avoided due to the presence of blood vessels.

Acupuncture

Acupuncture is a traditional Chinese medicine which involves the insertion of fine needles into certain sites in the body. This method activates the endogenous opioid system by increasing the β-endorphin levels.[62] There is additional antidepressant, anxiolytic, and sympathoinhibitory effect with an increased uterine blood flow. It is usually used along with various conscious sedation regimens or peripheral neural block in order to enhance analgesia.[63,64] One study had reported that acupuncture on the day of embryo transfer had a positive effect on the reproductive outcome.[65] During oocyte retrieval, auricular acupuncture is performed and is believed to act as a pain-relieving method by stimulation of the A-delta fibers and the activation of descending inhibitory pain control systems, as well as psychological aspects.[66]

The electroacupuncture technique can be used along with paracervical block for TVOR, which utilizes the mechanism of neuropeptide release produced by electrical stimulation of different frequencies.[62]

Transcutaneous electrical acupoint stimulation (TEAS) is a user-friendly technique without the use of manual needles and electroacupuncture to reduce invasiveness. It can be used to reduce pain and discomfort during oocyte pickup procedures.[67]

Patient-controlled Analgesia

Patient-controlled analgesia is an alternative technique of analgesia with high levels of patient satisfaction by allowing women to control their drug administration. This method is very patient-compliant and was found to have very low levels of oversedation.[68,69]

Safety of Anesthesia Drugs

Majority of the anesthetic drugs used in the IVF setting have been found to be safe, especially for the gametes. Halogenated agents should be used with caution as they have been found to be associated with reduced reproductive outcomes.[50] The key to anesthesia in IVF is to aim for pharmacological exposure of the shortest duration with minimal penetration into the follicular fluid.

KEY DRUGS, DOSAGE AND SIDE EFFECT

Drug	*Class of drug*	*Dose*	*Significant side effects*
Midazolam	Benzodiazepine	*Induction:* 0.2 mg/kg *Maintenance:* 1 µg/kg/min	
Propofol	2,6-diisopropylphenol	2 mg/kg bolus or 150 µg/kg/min infusion (maximum <4 mg/kg)	Myocardial and respiratory depression
Ketamine (dissociative anesthesia)	Phencyclidine	2 mg/kg	Postoperative psychological adverse effects

Contd…

Contd…

Drug	*Class of drug*	*Dose*	*Significant side effects*
Dexmedetomidine (cooperative sedation)	α-2 adrenoreceptor agonist	1 µg/kg	Bradycardia and hypotension
Lidocaine (used in paracervical and preovarian blocks)		50 mg	
Bupivacaine (used in spinal anesthesia)		10–12 mg	Urinary retention and delay in discharge

KEY POINTS

- In conclusion, studies in different anesthetic techniques fail to give prominence to one specific technique.
- The role of the anesthetist is to provide relief and comfort to the patient to alleviate her fears and anxiety.
- Mild-to-moderate pain experienced during the oocyte retrieval can be relieved by conscious sedation.[70]
- However, the best sedation and anesthetic practice should be tailored to the patient and the provider needs.
- The impact of anesthetic agents on gametes needs to be continuously revisited.
- Majority of the sperm retrieval techniques can be performed under adequate local anesthesia.

CHAPTER 56

Oocyte Retrieval

Sankalp Singh, Nivedita Ananth, Swati Singh, Mohammed Ashraf C

INTRODUCTION

Oocyte retrieval (OCR) can be defined as the process of the aspiration of follicular fluid and the oocytes contained therein, directly from the ovaries of a woman, before them being released spontaneously from the ovarian follicles. It is one of the most important steps of in vitro fertilization (IVF) procedure, since the success of IVF is directly related to the number and the quality of embryos, which in turn are dependent on the number and the quality of oocytes.

HISTORY

Miriam Menken and John Rock were the first to report retrieval of oocytes by laparotomy.[1] The procedure of laparotomy was associated with significant surgical risks to women including hemorrhage, wound infections and injury to abdominopelvic structures, and prolonged convalescence period. This led to the development of alternative surgical approaches for OCR. It took more than three decades from then to have the first birth after an assisted reproductive technology (ART) procedure.[2]

The first successful outcome of IVF was achieved on 25 July 1978 with the birth of Louise Brown in Manchester from a laparoscopic retrieval on the spontaneous cycle of a single ovarian follicle. In the years after that, following on from the excellent results achieved by Steptoe, oocyte pick-up was carried out using the laparoscopic technique, with hospitalization and general anesthesia (GA).[3]

After laparoscopic OCR, the transvesical approach for OCR was promoted by Lenz and Lauritsen in 1982. They showed that ultrasound could be used for operative rather than just a diagnostic tool. Danish gynecologists were the first to experiment with the efficiency of a new ultrasonically guided percutaneous aspiration method in reaching ovarian follicles and carrying out oocyte pick-up. During this procedure, the needle, attached to an abdominal transducer, was inserted percutaneously into the antral follicle, going through the abdominal wall and the urinary bladder. The harvest of oocytes collected was comparable to that of the laparoscopic approach, but with a lower rate of complications and with easier access to the ovaries. The procedure could not be conducted with short-lasting general anesthetic or local anesthetic in an outpatient capacity.[4]

One year later, another group from northern Europe, led by the gynecologists, Hamberger and Wikland, in Gothenburg, Sweden, described for the first time the possibility of using an echographic vaginal probe in OCR.

A needle was guided along the echographic vaginal probe to carry out a precise hole in the follicle and recover the follicular fluid.[5-7]

Once an initial fear relating to the danger of oocyte alteration and ultrasound was overcome, the transvaginal technique, thanks to its simplicity and efficacy, became widespread and now, having been carried out for >30 years, has become the default choice for the retrieval of oocytes for IVF.

VAGINAL PREPARATION BEFORE OOCYTE RETRIEVAL

Vaginal preparation is a common practice before any gynecological procedure. It is done with an aim to prevent infection and also to help improve IVF success rate. Theoretically, inserting a needle through the vaginal wall from essentially an unsterile environment, into the abdomen—a sterile field, increases the risk that intraperitoneal infection may occur. However, pelvic infection after transvaginal oocyte recovery is thankfully rare, irrespective of whether prophylactic antibiotics are used with an incidence of 0.6% as seen in a large series of 2,670 cases.[8]

The two most common agents used are povidone-iodine and normal saline. In a randomized controlled trial (RCT) comparing povidone-iodine (betadine) with a simple normal saline douche in 334 women undergoing OCR, no difference was found in the fertilization rates (45.5 vs. 47.8%) or cleavage rates (49.8 vs. 52.1%). However, the pregnancy rate was significantly lower in the betadine group (17.2 compared to 30.3%), indicating that betadine appeared to

have an adverse impact on the outcome.[9] Likewise, even where betadine is removed by douching with normal saline, there was a higher biochemical pregnancy rate where betadine was employed.[10]

At our center, we do vaginal cleansing with saline a day prior and on the day of OCR.

ROLE OF PROPHYLACTIC ANTIBIOTICS

The benefit of prophylactic antibiotics for OCR is far from proven. The overall incidence of infection after an OCR is estimated to be about 0.4%.[11,12] In most instances, pelvic infections after OCRs have been noted in patients who have endometriosis, likely due to the presence of pelvic adhesions.[13,14]

Additionally, there is no convincing data to suggest improvement in IVF outcome by using antibiotics.

Until further data evaluating live birth is available, its use should be left at the discretion of the clinician and each clinic should have its own policy depending on local needs.

We, at our center, do give the combination of amoxicillin and clavulanic acid for a period of 5 days.

ANESTHESIA AND OOCYTE RETRIEVAL

Oocyte retrieval involves piercing the vaginal mucosa to aspirate the follicles. It is a physically and mentally stressful procedure for women. Women undergoing the procedure should be offered some form of anesthesia. Patient can feel the pain while the needle pierces the vaginal wall or the ovarian cortex. So, anesthesia should be offered to make it pain-free and comfortable for the patient. In cases where the patient is not cooperative during the procedure, there can be unwarranted movement of the patient with needle in situ causing trauma to vital structures or iliac vessels.

The ideal anesthetic modality should be safe for women, have effective pain relief, devoid of harmful effects to the oocytes, and easy to administer and monitor.

Prior to Ovum Pickup

Investigations for medical fitness should be done according to the local guidelines. Preanesthesia evaluation should be done to avoid any intraoperative mishaps. Taking accurate patient history before ovum pickup (OPU) is essential to highlight potential comorbidities and take actions to prevent any possible associated complications. Patients should at least be asked about the use of medications—more specifically the use of blood-thinning agents (aspirin and others), relevant previous surgeries, and any relevant disease or deficit of coagulation factors.

Monitoring

Noninvasive blood pressure and pulse oximetry must be used when drugs have been administered intravenously; electrocardiogram (ECG) and CO_2 monitoring are developmental standards for conscious sedation but are minimal monitoring standards for deep sedation and GA.

Various forms of anesthesia are:

- *Local or paracervical block:* Lidocaine 100 mg (10 mL of 1% lidocaine, xylocaine 10 mg/mL) is injected at two (3 and 9 o'clock) or four points around the cervix. It can be used alone or in conjunction with local sedation. Satisfaction with the procedure was higher when the blocks were used during a GA and postoperative pain was also lower.[15]
- *Conscious sedation:* In conscious sedation, the patient is able to communicate with personnel and be able to follow orders, for example "breathe deeply."

All respiratory and cardiovascular parameters remain intact. Agents such as midazolam, propofol, and ketamine are used for OCR.

Propofol has been shown to be devoid of any harmful effect on various IVF outcomes including live birth rates, thus making it a better anesthetic to use during OCRs. Along with the fact that it is short-acting, safe, and provides good pain relief which makes it an excellent choice for OCR procedures.

- Verbal anesthesia (VA) by the sedationist is a very important part of any OPU that is performed with conscious sedation and/or local anesthetics. VA is a conversational distraction associated with measures to ensure a calming environment, thereby reducing pain, anxiety, and stress.[16]

A Cochrane review which analyzed 21 RCTs performed to compare pain relief modalities during OCR found no difference between different modalities. It showed better pain relief if more than one method were used rather than single.[17]

In our center, 98% of retrievals are performed under conscious sedation with propofol/fentanyl.

The modality of providing anesthesia to a given patient should depend mainly on the patient's cooperation and anticipated difficulty in ovarian access. If the patient is comfortable, conscious sedation is a good option. However, in some cases, like ovaries above the pelvic brim needing abdominal retrieval, regional or GA may be required.

INSTRUMENTS FOR OOCYTE RETRIEVAL

The instruments needed for OCR include:

- Ultrasound machine with a transvaginal probe with a frequency of 5–7.5 mHz **(Fig. 1)**. The transvaginal probe has a groove near the tip where the needle guide could be firmly attached **(Fig. 1)**. Each machine has its corresponding probe which can be used. The ultrasound gel is applied and a nontoxic probe cover is attached over it.

Fig. 1: Ultrasound probe with needle guide.

Fig. 3: Needle with connecting tube and stand.

Fig. 2: Single lumen needle.

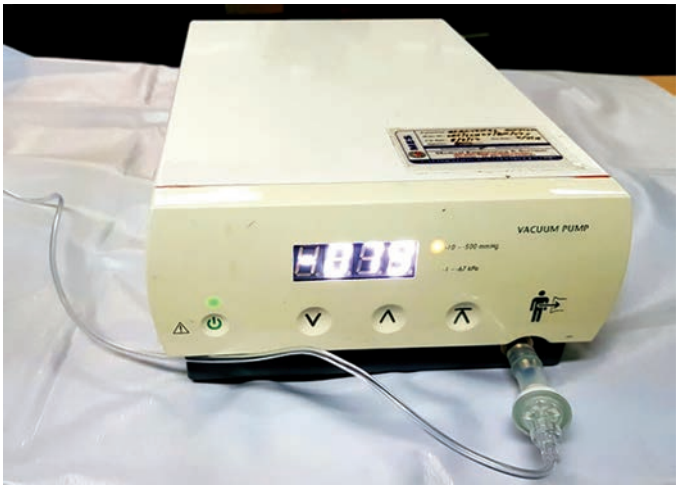

Fig. 4: Suction apparatus.

- *Aspiration needle:* The needle of either 17 or 18 gauge is inserted through the needle guide **(Fig. 2)**. The tip is kept inside the guide till the probe is inserted and the follicle has been brought into the view. The tip of the needle is beveled to facilitate aspiration in an irregular shaped follicle and easy insertion through the vagina and ovarian cortex. The hub or handle of the needle has the proximal portion of the tubing attached to it. The handle of the needle helps in the maneuvering of the needle. The distal end of tubing is fixed to the test tube with the help of a cork and the follicle fluid flows through the tubing into the test tube. Another tubing comes out of the cork and is attached to the suction apparatus tubing to maintain adequate suction pressure during OCR. The aspiration needles could be single lumen or double lumen. Double-lumen needles are usually used in case of follicular flushing or endometriotic cyst aspiration.
- *Test tube warmer stand:* The test tubes are placed in the test tube stand which helps in the maintenance of the temperature at 37°C **(Fig. 3)**.
- *Suction apparatus:* This helps in the formation and maintenance of the negative pressure inside the follicle necessary for aspirating the oocytes **(Fig. 4)**. The foot switch attached to the suction machine is used to apply pressure to suck the follicular fluid out.
- *Operation theater table:* Should have easy maneuverability to adjust the position of the patient **(Fig. 5)**. The patient needs to be in a lithotomy position using the stirrups attached to the table.

ASPIRATION SETUP

The ideal setup for OCR pertaining to the needle type, vacuum pressure, and culture media which can give optimal results is still unknown. Transvaginal ultrasound probe of frequency between 5 and 7.5 MHz is commonly used. The machine should have the option of color Doppler to distinguish the vessels. Also, they should have an option for biopsy line so as to have a marker for the needle entry.

Most commonly, we come across few basic questions:

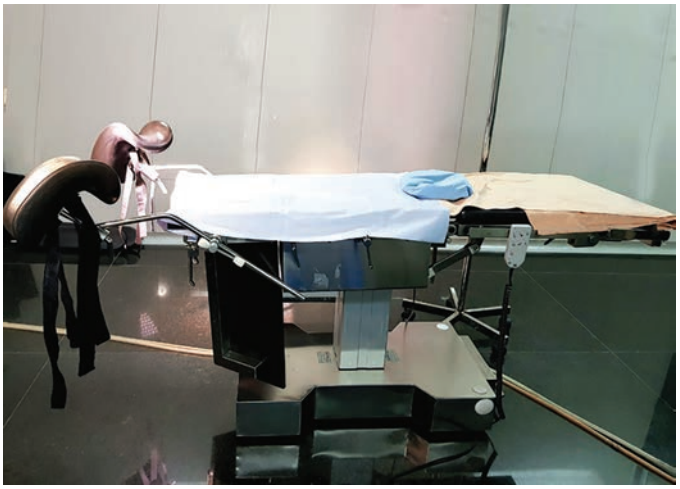

Fig. 5: Operation table.

What Size Needle to be Used for Aspiration

The main aim of OCR is to collect maximum follicles with minimal trauma to the cumulus oocyte complex and adequate temperature control.

Properties to be considered for a needle:

- Should be long enough to pass through the vaginal wall and enter the ovarian stroma
- It should be rigid enough to stay in the course of the tracer present on the screen
- The needle should be sharp and beveled at the tip to ensure easy entry through the ovarian tunica and maintain minimum increase in the follicular pressure on entry.
- Gauge of a needle, which is an estimate of the inner diameter of the lumen of the needle. The diameter of the needle is important as it needs to be great enough such that the inner channel is of a width to allow passage of the cumulus–oocyte complex intact, but small enough to minimize tissue trauma, diminishing the risk of serious bleeding if blood vessels are entered, and reducing pelvic discomfort.[18,19] The thinner the needle, the higher the aspiration pressure required to maintain the same flow rate. The dead space, which represents the volume of the cylinder created by the cross-sectional interior area of the needle and its length,[20,21] needs to be minimized, so collected oocytes pass into the collecting tube and do not remain in the tube.

A study comparing 15-, 17-, and 18-gauge single-lumen needles showed no difference in recovery rates, but a significant reduction in perceived pain when the smaller diameter needle was employed.[18] The needle is attached to a tubing system made of materials that are not toxic to gametes and can retain temperature well.

In our center, we use an 18G single-lumen needle for OCR.

Aspiration Pressure

Prior to the use of electric aspiration pump, hand-held syringes were used for aspiration.

The high pressure caused by a hand-held syringe was found to cause detrimental fracture of the zona pellucida.[22] In view of this, there was a need to find a suction source with a controlled aspiration pressure to drain the follicular without exerting too much pressure.

According to Hagen–Poiseuille's law, an increase in the length of the tube decreases the pressure at the end in proportion to the percentage that the length was increased.

The magnitude of the shear stress that a cumulus oocyte complex (COC) may experience depends on the velocity of the fluid and the diameter of the needle.[23,24] Increasing either the velocity of the fluid (by increasing aspiration pressure) or increasing the diameter of the needle increases the shear forces on the COC. The pressure at the exit of the aspiration device is different from the pressure experienced by the oocyte at the needle tip. Needle gauge, length of needle, connecting tube gauge, length of connecting tube, size of the collection tube, and size of the vacuum reservoir in the pump all play a role in determining the pressure experienced within the needle from the aspiration device.

In clinical practice, suction is applied just before the needle is inserted into the follicle so as to create a seal as to prevent leak of the follicular fluid (between the needle and the punctured follicular wall) and also to maintain the flow rate and avoid turbulence. If the vacuum is stopped too soon before the needle is removed from the follicle, there is risk of back flow, which could leave the oocyte in the follicle.

There was a study done in 537 patients between low aspiration pressure (150 mm Hg) and high pressure (300 mm Hg) for OCR and it was noted that the use of low aspiration pressure resulted in a significantly greater oocyte yield, maturity, and fewer oocytes with an empty zona pellucida compared to high aspiration pressure.

While aspiration pressure did not impact the pregnancy rate per transfer in this cohort, the higher number of usable embryos in the low-pressure group may result in a higher cumulative pregnancy rate.[25]

In our center, with a needle of 18 G, we use suction pressure of 120 mm HG in case of conventional aspiration.

Steps of Oocyte Retrieval (Box 1)

At the outset, the sterile operating room table, vaginal ultrasound probe with attached probe-specific needle guide, collecting tubes containing culture media in a warmer stand, and a working suction apparatus need to be prepared.

The suction apparatus should be checked before each procedure. The tubing should be checked for and the tubes should be tightly corked. After administration of the chosen anesthetic agent or paracervical block, the patient is placed in the dorsal lithotomy position and a sterile speculum is placed inside the vagina. The vagina is cleansed with saline. The vaginal speculum is then removed followed by placement of transvaginal ultrasound probe with already attached

BOX 1: Important steps in oocyte retrieval.

- Patient should be asked to empty the bladder before putting her in the lithotomy position
- Adequate anesthesia should be administered
- Cleansing of the vagina with normal saline
- Elbow support should be given while holding the vaginal probe
- Adequate pressure should be maintained on the probe
- Focus the maximum diameter of follicle after inserting the probe
- Insert the needle into the center of the maximum diameter of the follicle. The needle should be somewhere in the middle of the follicle
- Suction pedal should be switched on just before entry into the follicle
- Follicle collapse should be the focus of the eye rather than the drops in the tube
- Keep the needle surrounded by fluid at all times. If needed, gentle movement of the probe should be utilized
- Follicular curetting at the end of complete follicular collapse
- Anteroposterior movement of probe assisted by lateral movement when needed to focus next follicle
- Once all adequately grown follicles present in both ovaries are aspirated, the pouch of Douglas and both adnexa should be checked to rule out any blood collection

needle guide inserted into the vagina. Elbow support should be given while holding the vaginal probe inside the vagina by placing the elbow on the thigh of the clinician or on the stirrups. This will minimize unnecessary movements of the probe and allow better focusing. Adequate pressure should be maintained on the probe so that there is minimal distance between the vaginal probe and the ovary or follicle. Focus the maximum diameter of the follicle after inserting the probe. The follicle selected should be the one which is nearer to the probe. Warm culture media through the needle (we use 17- or 18-gauge) to stabilize the temperature inside the needle and the tubing. The needle is then passed through the needle guide piercing the vaginal wall and into the center of maximum diameter of follicle under ultrasound guidance. Care should be taken to avoid surrounding structures such as the iliac vessels, bowel, and bladder. The tip of the needle should be in the middle of the follicle, surrounded by fluid all around. The vacuum pump is activated using the footswitch at the entry of needle into the follicle and follicular fluid aspirated into prewarmed tubes placed in a tube warming rack containing culture media taking care to avoid overfilling leading to spillage into the tubing extending toward the suction apparatus. Follicular curetting is performed at the end of complete follicular collapse by gentle rotation of the needle. After completing one follicle, the next follicle should be focused. The movement which helps focus the next follicle better is often the anteroposterior movement of the probe rather than lateral movement. Preferably this follicle should be the one, which is adjacent to or just below the pricked follicle and the above-mentioned steps should be repeated. The tubes are then transferred carefully to the tube warming rack in the adjacent embryology laboratory. The embryologist then places the contents of the tubes into culture plates and the oocytes are identified using a microscope. We advise aspirating all follicles ≥10 mm in a non-in vitro maturation (IVM) OCR.

Postoperative Instructions

Details of following should be documented:

- Number of retrieved follicles, E2 level on the day of trigger, suction pressure, needle size and type used, anesthesia used, confirmed plan for either oocyte freeze or embryo freeze, ease of procedure. In case of any transmyometrial approach, it needs to be mentioned and also signs of premature ovulation should be documented for future reference.
- Any pelvic collection
- Postprocedure antibiotics is given in our center for 5 days.
- OHSS prophylaxis to be documented in specific cases
- In case of a pelvic collection, repeat ultrasonography (USG) after 2 hours to look for the collection.

TROUBLESHOOTING IN OOCYTE RETRIEVAL

ESHRE Guidelines (2019)

What to do when the Needle Tip is Not Visualized?

Withdraw the needle and ensure that the needle director/gauge is in place allowing the needle to move in the same sector as the ultrasound beam.

What to do When Suction Fails?

- Check for any discontinuity in the collection tubing leading to suction failure.
- Check if the needle tubing is properly attached to both the suction apparatus and collecting tube.
- Rotate the needle within the follicle to ensure that it is not blocked by follicular wall tissue.
- If there is still no suction, remove the needle and perform a "retrograde flush" to clear any blockage.
- Before reinserting the needle, recheck by aspirating some culture medium.
- It is always better to have an additional suction apparatus available in the operation theater.
- In case there is no other feasible option, then a manual suction with 20 mL syringe can be used by creating negative pressure.
- If premature ovulation is suspected, peritoneal fluid can be aspirated to recover some oocytes.

Presence of Endometriotic Cyst in Ovaries

Endometriomas should not be aspirated while OPU to prevent contamination of follicular aspirate and reduce risk of intra-abdominal infection. But sometimes they do get

punctured inadvertently, so in such cases, intravenous (IV) antibiotics cover for 48 hours should be provided. Also, the needle should be immediately withdrawn and flushed with media and the collecting tube should be changed. The risk in such cases should be counseled to the patient preoperatively and necessary consent to be taken.[26-28]

ROLE OF FOLLICULAR FLUSHING

- Pregnancy rate is directly correlated to the number of oocytes retrieved.
- The more the number of oocytes, the more the quantity of embryos obtained.[29]
- To maximize the number of oocytes recovered, investigators have suggested follicular aspiration followed by a single 2-mL flush.[30]

There was a Cochrane review updated in 2018 which included 10 studies with total of 928 women to compare the role of follicular flushing and aspiration versus aspiration alone.[31-39]

All included studies reported outcomes per woman randomized.

The conclusion was as below.

- Comparing follicular flushing to aspiration alone revealed probably little or no difference in the live birth rate [odds ratio (OR) 0.95, 95% confidence interval (CI) 0.58–1.56; three randomized controlled trials (RCTs); n = 303; I^2 = 30%; moderate-quality evidence]. This suggests that with a live birth rate of approximately 41% with aspiration alone, the equivalent live birth rate with follicular flushing is likely to lie between 29 and 52%.
- None of the included studies reported on the primary outcome of miscarriage rate.
- Six RCTs showed no difference in the oocyte yield following follicular flushing.[32-37]
- None of the studies showed any difference in the number of embryos or embryo cryopreserved or clinical pregnancy rate.

Mok-Lin et al. conducted an RCT comparing follicular flushing versus aspiration only in 50 extremely poor responders, including women with ≤4 follicles of ≥12 mm on the day of human chorionic gonadotropin (hCG) administration. There were no differences in the number of oocytes retrieved (4 vs. 3, p = 0.41). However, in flushing group, there were significantly fewer embryos for transfer (1.7 vs. 2.5, p = 0.03), lower implantation rate (5.3 vs. 34.2%, p = 0.0006), and lower clinical pregnancy rates (4 vs. 36%, p = 0.01) when compared to the flushing group. These differences remained significant even after adjusting for the number of embryos transferred. This was the first study to demonstrate a negative effect of follicular flushing on IVF outcomes.[37]

One study suggested that aspiration without flushing reduced operative time and decreased the amount of anesthetic required.[38,39]

Possible mechanisms quoted by authors were:

- Increased intrafollicular pressure generated by flushing could impact oocyte quality via mechanistic effects.
- Increased procedure and anesthesia times can be detrimental to oocyte quality.
- The presence of residual flushing fluid in the pelvis could have altered the uterine milieu at the time of implantation.
- Serial flushing could negatively impact granulosa cell number and function, thus impacting the luteal phase.

In our center, we do not advocate follicular flushing for any group of responders.

Temperature Control

The meiotic spindles of the human oocyte consist of microtubules and are extremely sensitive to temperature fluctuation, both up and down.[40,41] The spindle structure can dissemble relatively quickly on cooling, but takes longer to recover on rewarming.

The duration of the drop and the variation in the temperature to which the oocyte has been exposed will determine whether the spindle will recover.

The oocyte can tolerate drop in temperature from 37° to 33° for <10 minutes before rewarming. Further drop or for longer duration can lead to permanent damage to the spindle assembly.[42,43] The meiotic spindles are responsible for the chromosome alignment and separation of the maternal chromosomes during fertilization. Therefore, any disruption to the spindle may lead to abnormal chromosome distribution, leading subsequently to failed fertilization or aneuploidy.[44]

It is advisable to have closed workstations where temperature, oxygen concentration, and pH can be more reliably controlled to reduce these potential stresses.

Working with a closed isolator-based workstation may be technically more challenging but protects against ambient conditions, promoting the development of better-quality blastocysts and higher pregnancy rates.[45]

In Our Set-up

We have all the collecting tubes kept in a tube heater well-maintained at the temperature of 37°C.

The oocyte collecting system is flushed with media which was kept at 37°C before the onset of procedure. Each follicle is aspirated in turn and the collecting tube immediately given to the embryologist to identify the oocyte. There is a small connecting hatch through to the laboratory, where the embryologist is working in a grade A temperature-controlled workstation.

OOCYTE RETRIEVAL IN DIFFICULT CASES

Transvaginal approach is the most commonly used for OCR.

Studies comparing transvaginal, transabdominal, and laparoscopic approaches for OCR have found the transvaginal approach better in terms of safety, efficacy as well as time under anesthesia.

A study on a cohort of 85 infertile women comparing transmyometrial versus conventional approach showed that the transmyometrial retrieval did not significantly affect the pregnancy outcome.[46]

Transabdominal approach is mainly used in cases of women with radical hysterectomies, transposed ovaries, Müllerian agenesis as well as in cases of increased body mass index (BMI) where the poor image quality makes the ovaries unreachable.[47-49]

A study in 2014 was done comparing transabdominal versus transvaginal approach in 204 patients and concluded that in case with difficult transvaginal access due to previous surgery or high BMI, transabdominal approach can be a better alternative for OCR.[50]

Points to be remembered before opting for transabdominal approach:

- Expertise is required for performing the procedure to avoid inadvertent trauma to the vital structures or iliac vessels.
- Maintain stability and coordination of the probe and the operating hand.
- In case the ovaries are adherent to the posterior surface or fundus of the uterus, a transmyometrial approach rather than a transabdominal approach can be done.

COMPLICATIONS OF OOCYTE RETRIEVAL

Transvaginal ultrasound-guided OCR is a safe well-tolerated procedure, with a low risk of serious complications.

The most common problem encountered after USG-guided transvaginal OCR procedure is minor vaginal bleeding, which generally stops spontaneously or can be controlled with local compression. The incidence of vaginal bleeding is reported to be 8.6% of cases in literature.[8]

However, the risks associated with the procedure should not be underestimated because some complications, although rare, may be life-threatening (two deaths were reported in 2010).[51]

Most frequent complications noted are vaginal and peritoneal bleeding.

A retrospective analysis suggested that particularly in patients with ovarian endometriomas, complications, such as tubo-ovarian abscess, can occur even long after the completion of the assisted reproductive technology (ART) cycle, indicating that women with endometriosis are prone to develop infectious complications.[28] Other rarer complications, described as case reports, are ureterovaginal fistulas,[52] pseudoaneurysm of the iliac artery,[53,54] ureteral injury,[55,56] bladder injury with hematuria,[57,58] and ovarian abscess.[59]

Retrospective analysis was done over 10 years in a fertility center in Italy involving 23,827 consecutive transvaginal OCR procedures in 12,615 patients.[60]

A total of 96 complications related to OCR procedures (0.40%; 95% CI 0.33–0.49%) were encountered. A risk factor was present in 28 (29.17%) of the 96 cases experiencing complications. The complication rate for patient was 0.76% with no recurrence of a complication in the same patient. Hospital admission was necessary for 71 of 96 (73.96%) patients suffering complications, representing 0.29% (95% CI 0.23–0.38%) of the total retrievals and the average duration of a hospital stay was 2.77 days. In 54 cases, the complication was peritoneal bleeding (0.23%, 95% CI 0.17–0.30%). A total of 24 patients required surgery (0.1%, 95% CI 0.06–0.15%), of which 19 for peritoneal bleeding; in 18 (33.33%), a laparoscopy could evacuate the hemoperitoneum (volume >1,000 mL), whereas in one patient, an emergent laparotomy was necessary to repair a small laceration of the iliac vein. In one patient, the pelvic bleeding occurred 2 days after the OCR procedure; in another case, 15 days had elapsed between the OCR procedure. In another two cases, a laparoscopy had to be performed for infectious complications and in one patient, a laparotomy was necessary for severe sepsis. Pelvic pain was another retrieval complication and six patients required hospitalization (0.03%, 95% CI 0.009–0.055%). Vaginal lacerations were encountered in only two patients who required sutures (0.008%). Two cases of bladder trauma (0.008%) were noted and diagnosed by hematuria and vesical hematoma, but they did not require intervention.

Concerning anesthetic complications, a total of 14 patients were observed with 12 cases of circulatory shock and nausea. Two serious complications were atrial fibrillation and one case of cardiorespiratory insufficiency, agitation, and confusion.

28 of the 96 patients (29.17%) who suffered complications had pre-existing risk factors: History of endometriosis, history of pelvic surgery for benign reasons, previous pelvic inflammatory disease (PID), or hematologic disease (one was suffering from von Willebrand disease and one had chronic thrombocytopenia).

As some of the complications occur some days following the procedure, underreporting of cases is also possible.

Simple steps which can prevent complications:

- Empty the bladder prior to the procedure.
- Gentle movement of the probe and needle inside the ovary
- Avoid unnecessary lateral movement of the needle inside the ovarian stroma.
- Review any pelvic collection postprocedure to identify any intraperitoneal bleeding early.
- In case of any suspicion, put color Doppler to rule out presence of vessels in the path of the needle marker.

KEY POINTS

- Oocyte retrieval is a generally safe and well-tolerated procedure and is most often accomplished in the patient-friendly outpatient setting with conscious sedation and rarely requires GA.
- It is typically performed using transvaginal ultrasound guidance, but rarely may require transabdominal ultrasound-guided retrieval in case of abnormal anatomy. It is fairly simple to learn and master, if one keeps the basic things in mind.
- In common practice, prophylactic antibiotics are administered prior to the procedure and complications such as clinically significant bleeding or infection are extremely unusual.

CHAPTER 57

Embryo Transfer

Arya Rajendran, Akanksha Gautam Allahbadia, Swati Gautam Allahbadia, Gautam Allahbadia

INTRODUCTION

Embryo transfer (ET) is the final and most critical event in the success of a medically assisted reproduction (MAR) cycle. Very few advances have occurred in the last few decades with regard to this procedure and studies conducted thus far have focused on factors and interventions taking place before, during, and after this procedure. These factors are highly varied and range from methods to improve the psychological state of the patients to methods aimed at reducing uterine contractility and methods aimed at optimizing the precise transfer of the embryo.[1] Several factors preceding and during ET are instrumental in successfully performing an ET, including catheter type, degree of trauma, and ultrasound visualization.

There is good evidence to support an atraumatic transfer, ultrasound guidance,[2-7] the use of soft catheters[8] and echogenic catheters,[9-11] the significance of depth of transfer,[12-14] and the experience of the clinician performing ET,[15-17] in optimizing pregnancy and implantation rates. There has been improvement in different facets of assisted reproductive techniques such as in embryo culture and assessment of viability. With improved pregnancy and live birth rates (LBR), the onus has come on to reducing the complications including multiple gestations, leading to popularization of single ETs.[18-21] Technique of ET demands a detailed insight to optimize the pregnancy outcome. This chapter aims to elucidate clearly the various aspects regarding ET and the evidence to optimize the results.

DEFINITION OF EMBRYO TRANSFER

Embryo transfer is the accurate and atraumatic deposition of embryos by means of an ET catheter, into the uterine cavity at an area with maximum implantation potential.[22]

TYPES OF EMBRYO TRANSFER

Transvaginal Transcervical

- Embryos are passed through the ET catheter, which is inserted transcervically.
- *Advantage:* Most widely used method and also the simplest and least invasive.
- *Disadvantage:* In case of cervical stenosis, this method is not feasible.

Transvaginal Transmyometrial

- *Method:* A transvaginal ultrasound probe is inserted in the vagina and a "Towako" ET catheter (Cook, Queensland, and Australia) is used. The 18-gauge catheter needle with stylet is passed under transvaginal ultrasound guidance, passing through the anterior fornix and anterior myometrial wall, and stopping short of the myoendometrial junction. In case of retroverted (RV) uterus, the needle punctures through posterior fornix and posterior myometrial wall. After removal of stylet, preloaded inner catheter is threaded through the needle and the embryos are released.
- *Advantage:* This is performed in patients with extremely difficult or impossible transcervical ET.
- *Disadvantage:* Increased uterine manipulation triggers greater junctional zone contractions.[23]

Zygote Intrafallopian Transfer

- Involves laparoscopic delivery of embryos into the fallopian tube.
- *Advantages:*
  - Advocated in patients with nontubal infertility with repeated implantation failure (RIF). Since the fallopian tubes provide a more physiological environment for embryos to grow compared to in vitro culture systems.
  - No uterine manipulation, hence lesser myometrial contractions and less chances of embryo expulsion. Of special benefit in patients whose embryos consistently show poor in vitro development.
  - Higher pregnancy rates (PRs) have been documented in patients with RIF (25.5%).

- *Disadvantages:*
  - Surgical as well as anesthetic risks
  - Higher risk of tubal ectopic gestation[24]
  - No longer practiced.

Subendometrial Embryo Delivery

- *Method:* A light flexible tip hysteroscope is used to deliver embryos subendometrially (depth of 1 mm) at a favorable site (where the endometrium is thickest, at least 2 cm away from ostia). Nitrogen, an inert and non-embryotoxic gas, is used for uterine distension instead of CO_2.
- *Advantages:* Subendometrial deposition improves the chance for implantation, eliminates the possibility of ectopic gestation, prevents inadvertent excessive endometrial trauma that can happen in usual transcervical transfer, the mild endometrial injury can induce inflammation, and be favorable for implantation.
- *Disadvantage:* Inadvertent excessive endometrial injury.[25]

HOW TO PLAN A GOOD EMBRYO TRANSFER?

A good ET involves placement of a single good quality embryo in a primed endometrium, in the most atraumatic way, at the region of maximum implantation potential.

The optimal endometrial thickness has been described as 9–14 mm.[26] Following the achievement of optimal thickness, progesterone therapy is instituted, which can be either by vaginal or intramuscular route.

With timely progesterone level, a synchrony of activities is set in motion within the endometrium to optimize receptivity toward the embryo. The receptive period lasts only for a brief period of time known as the window of implantation (WOI).

Cleavage stage embryo is transferred on the 4th day of progesterone supplementation (P + 3 corresponds to the 3rd day of embryonic development) and blastocyst is transferred on the 6th day of progesterone supplementations (P + 5 corresponds to 5th day of embryonic development).

Steps of Embryo Transfer

Steps of ET are given in **Flowchart 1**.

FACTORS AFFECTING SUCCESS OF EMBRYO TRANSFER

Prior to Embryo Transfer

Uterine Cavity Evaluation

Cavity evaluation before ET would give an insight into cavitary abnormalities and provide opportunity to correct these. Hysteroscopy revealed 22.9% incidence of cavitary abnormalities and there is benefit for resection of submucosal fibroids, adhesions, and polyps. A three-dimensional (3D) saline sonohysterography is also useful in this regard.[27]

Uterine Position

Uterine position, anteverted (AV) or RV, should be known before the ET to prevent misdirecting the ET catheter. The uterine position is subject to changes between a mock transfer and the real ET.[28]

Mock Transfer

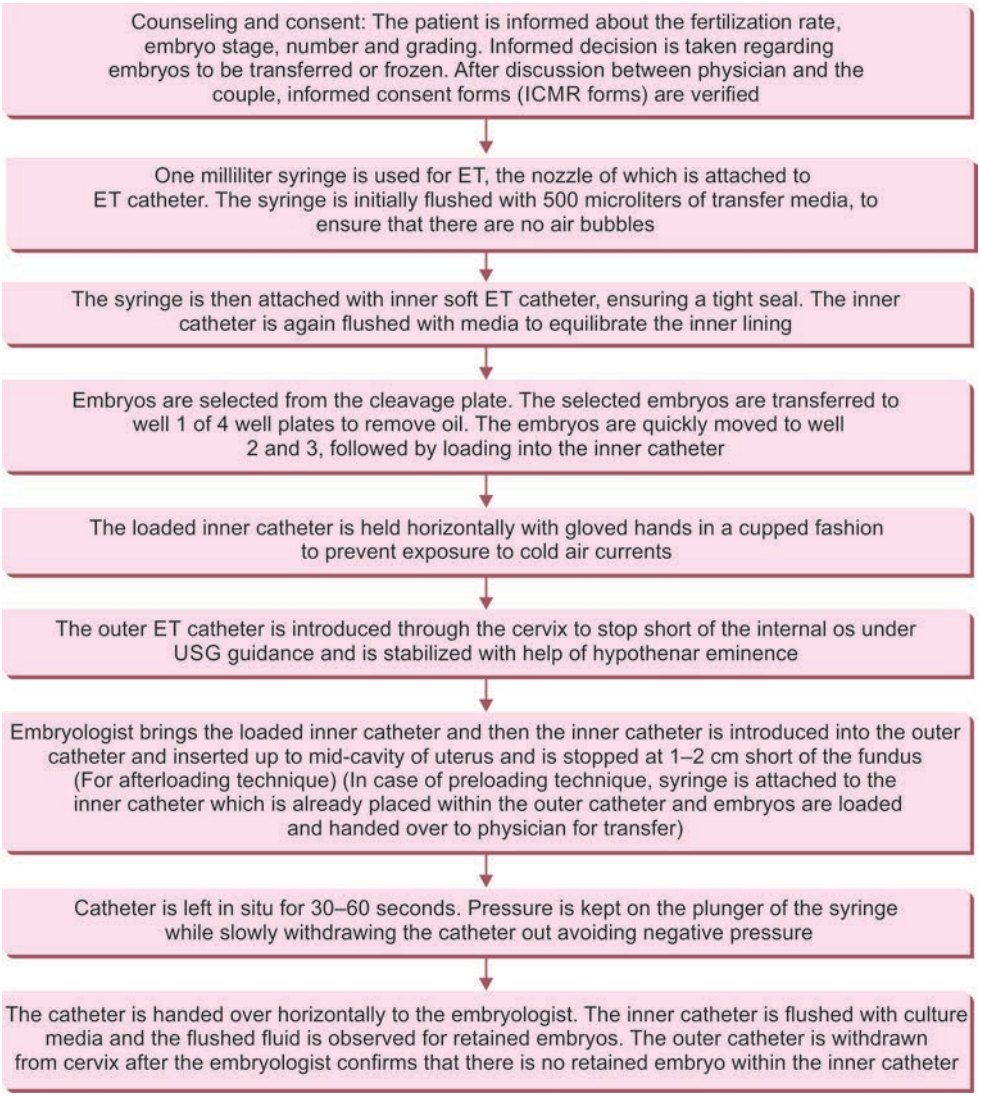
- ET aims to deposit the embryos gently with least trauma into the chosen portion of uterine cavity with maximum implantation potential.
- *Purpose:* Mock ETs are performed to assess the level of difficulty to be anticipated in the actual ET and modify the depth and direction of transfer accordingly. Anatomical deviations in cervix, cervical polyps, and fibroids, if any, can also be dealt with.
- *Timing:* The ideal timing to perform a mock transfer is just before the actual ET. Care must be taken to never go >0.5 cm beyond the internal os and this mock ET is always done under ultrasound guidance.
- *Cervical dilatation prior to ET:* Any unexpected cervical stenosis can be tackled prior to ET by cervical dilatation. Cervical dilatation done weeks prior to transfer can help in healing of any inadvertent endometrial injury caused by the same and has higher PRs than cervical dilatation during the hormone replacement therapy (HRT) cycle or during the procedure itself.[29] Hysteroscopic dilatation of the cervical canal results in easier ET in patients with cervical stenosis and history of difficult ET.[8]
- *Mock transfer at the time of ET:* The afterloading technique of ET can be also regarded as a form of mock transfer that is performed at the time of ET. The empty outer catheter is placed at or just beyond the internal os. The embryo loaded inner sheath is then introduced into the outer catheter. There is minimizing of the time that the embryo spends outside the incubator and till it is placed in uterus (ideally <120 seconds) and possibly reduced trauma to endometrium.
- *Pitfalls of mock transfers:* The uterine orientation can change from the time of mock transfer to the time of actual ET. For example, a RV uterus can become AV following heavy ovaries resting posterior to uterus following ovarian stimulation in cases of fresh ETs.

Borkar et al.'s very recent study concluded that mock embryo transfer (MET) prior to a first in vitro fertilization (IVF) cycle may not improve the success rate in young women without risk factors for a difficult ET.[30]

Embryo Quality

A significant factor that is pivotal in deciding whether to proceed with ET at all and its success thereafter is the embryo quality. Though a crude morphological assessment of the embryo does not give a sufficient insight into the viability and developmental potential of the embryo,

Flowchart 1: Steps of embryo transfer (ET).



(ICMR: Indian Council of Medical Research; USG: ultrasonography)

nevertheless, it may be used as an index for further noninvasive evaluation.

Embryo selection is aided by morphological appearance of the embryos and various metabolic and protein markers present in culture media.[20] Computer-assisted scoring system (CASS) has the potential to overcome the disadvantages with standard embryo evaluation and can predict PR and LBR better than with the standard scoring system.[31] Time-lapse imaging makes it possible to know the timing of embryo cleavage and to predict the time of implantation.[31] Blastocyst culture is yet another means of evaluating the viability and developmental potential of the embryo. Blastocyst culture helps to achieve better uterine and embryonic synchronicity and natural selection of more viable embryos, culminating in higher implantation rates.[32] However, the use of prolonged culture hinges upon the number of available embryos, infrastructural facilities, and cost issues.

Selective single embryo transfer (SSET) cycle in women under 35 years is reported to yield higher rate of "healthy baby" per transfer compared to transfer of two embryos.[33] Trophectoderm biopsy and chromosome screening with array CGH (comparative genomic hybridization) reduce the miscarriage rates, thereby providing a way to eliminate multiple gestation without compromising on the LBR.[34]

Assessing the viability of a blastocyst is still empirical and was yet nonreproducible. Badiola et al. recently developed an algorithm based on artificial vision and machine learning (and other classifiers) that predicts pregnancy from both the morphology of an embryo and the age of the patients.[35] They created a system consisting of different classifiers that is fed with novel morphometric features extracted from the digital microphotographs, along with other non-morphometric data to predict pregnancy. It was evaluated using five different classifiers: Probabilistic Bayesian, support vector machines (SVMs), deep neural network, decision tree,

and random forest (RF), using a k-fold cross validation to assess the model's generalization capabilities. Their results suggest that the system is able to predict a positive pregnancy test from a single digital image, offering a novel approach with the advantages of using a small database, being highly adaptable to different laboratory settings, and with easy integration into clinical practice.

Experience of the Physician

- The experience of the clinician in conducting an ET is among the most significant factors that influence the success rates of ART. For experienced physicians, choice of transfer catheter, difficult transfer, and blood on catheter do not cause significant reduction in pregnancy outcomes.[35] When different physicians used the same method of ET and similar number of embryos transferred, variation in PR was observed suggesting the importance of physician factor.[15] Hence, the resident physicians must be better monitored to avoid the lower PRs.[16]
- A cross-sectional survey was done by a specialized cell of the American Society for Reproductive Medicine (ASRM) to better understand practice patterns and opportunities for standardization of ET.[36] An anonymous 82-question survey was emailed to the Medical Directors of 286 IVF practices. A follow-up survey composed of three questions specific to the ET technique was emailed to the same Medical Directors. Descriptive statistics of the results were compiled. The survey assessed policies, protocols, restrictions, and specifics pertinent to the technique of ET. The study concluded that improved training and standardization based on outcomes data and best practices are warranted. A common practice procedure is suggested for validation by a systematic literature review.

Ramaiah et al. assessed the value of the American Society for Reproductive Medicine Embryo Transfer Certificate Course in confidence and skill-building for performing a live ET.[37] The main study outcomes included ET simulation scores of all exercises analyzed at various points of the training and self-assessed confidence before and after the completion of the Embryo Transfer Certificate Course based on a six-point Likert scale and association of both with the extent of prior live ET experience and year of their Reproductive Endocrinology and Infertility (REI) fellowship. The American Society for Reproductive Medicine Embryo Transfer Certificate Course data analysis demonstrated the effectiveness of simulator-based ET training for REI fellows across their 3 years of training, regardless of prior experience with live ET.

A recent study by McQueen et al. revealed striking differences between fellowship programs regarding the adequacy of ET training; nearly one-half of third-year fellows had performed fewer than 10 ETs.[38] The findings expounded that with appropriate supervision, there was no difference in LBR between ETs performed by fellows in training and attending physicians. Efforts should be made to set right barriers and set a compulsory minimum numbers of ETs for the trainees during their fellowship.

Continued performance analysis and the use of a digital simulator could help operators to test their expertise over time and either correct poor performance or avoid doing transfers.[39]

Role of Uterine Relaxants

Implantation failure is the main factor affecting the success rates of MAR. Studies have elucidated that uterine contractions (UCs) at the time of ET were inversely related to implantation and PR, hence bringing down PRs.

- Progesterone, beta-mimetics (ritodrine), and anti-prostaglandins (piroxicam, aspirin) have all been assessed for utility in depressing UCs. Only progesterone has been proven to have a uterine-relaxing effect.[40]
- Atosiban is vasopressin V1a and oxytocin receptor blocker that suppresses UCs. Routinely used in arresting preterm labor, it has found application during ET to prevent or ablate UCs. Studies have shown that in the general population of women undergoing IVF, atosiban enhances PRs but not LBR. In contrast, among women with recurrent implantation failure, atosiban improves both PR and LBR.[41-43]

  The findings of a recent study by Zarei et al. concluded that piroxicam administration before ET has no beneficial effects on PR among women undergoing IVF and frozen-thawed ET.[44] Various pharmacological agents, with the exception of calcium channel blockers, have been investigated to improve ET outcomes by reducing uterine activity. A double-blinded randomized, placebo-controlled trial was set up to determine whether nifedipine, a calcium channel blocker with potent smooth muscle relaxing activity and an excellent safety profile, can improve the outcome of patients undergoing ET.[45] 93 infertile women were recruited into one of two groups: placebo (n = 47) or nifedipine 20 mg (n = 46). The current double-blinded, randomized, and placebo-controlled trial clearly showed that the single use of 20 mg nifedipine given 30 minutes before ET did not improve implantation rates nor clinical PRs.
- *Role of adjuncts in ET*: Acupuncture is also used extensively as an adjunct during ET procedure. It involves passing several fine needles into the skin in a systematic pattern to alter the flow of energy in the body. A number of randomized controlled trials (RCTs) have been published to evaluate the role of acupuncture in ET with contradictory results. ASRM 2017 guidelines state that there is fair amount of evidence that acupuncture at the

time of ET does not improve LBR in IVF. Similarly, there is insufficient evidence to recommend massage therapy and transcutaneous electrical acupoint stimulation as adjuncts in ET.

Antibiotics Prior to Embryo Transfer

Vaginal or cervical microbial presence, especially *Enterobacteriaceae* and *Staphylococcus*, has been associated with reduced PRs, probably due to subclinical infection of endometrium.[46] Other isolated microorganisms do not impact the PRs significantly.[47] Though antibiotics (amoxicillin and clavulanic acid) prior to ET significantly reduce upper genital tract and catheter contamination rates, the routine use of antibiotics at ET did not translate into better outcomes such as clinical PRs.[48,49] Future research evaluating different antibiotic regimens and their impact on live birth and microbial colonization is warranted.

Hamdoun et al.'s study from Tunisia suggested that contamination of the transfer catheter by cervical passage decreases IVF results.[50] Prophylactic antibiotic prophylaxis should be used to reduce this negative impact.

During Embryo Transfer

- Anesthesia or analgesia is not routinely required for ET. Use of analgesics can improve patient comfort but are not beneficial in improving the PR (ASRM, 2017).
- *Position of patient:* In earlier days, position of patient during ET was based on uterine version. In case of AV uterus, knee chest position was practiced and dorsal position for RV uterus. However, the position of patient has not shown to influence the PRs and hence dorsal position with lithotomy is practiced commonly.[51]
- *Physician preparation:* Both powdered and non-powdered gloves are toxic to embryos when direct contact is established. The propensity for air-borne powder from gloves to harm embryos has been studied by a single RCT. There is fair evidence that powdered gloves do not impact embryos during ET. No particular glove is recommended as such for the ET procedure.[52]
- *Cervical mucus:* Removal of cervical mucus is an essential step in ET procedure since the presence of mucus can block the lumen of catheter and prevent the deposition of embryos in uterus as well as displace the embryos inadvertently within the cavity. Sterile gauze or cotton dipped in IVF media can be used to clean the cervical mucus. More persistent mucus especially from endocervix can be aspirated gently with a plastic syringe or by using a cytobrush. Alternatively, cervix can be flushed with culture medium. All manipulations should be of utmost care and gentleness in order to not to elicit UCs by excessive provocation. Removal of cervical mucus has been shown to have a higher PR.[53]

EMBRYO TRANSFER CATHETERS

The ET catheter has been shown in **Figure 1**.

What is an ideal catheter like?

- Soft and flexible:
  - Nontraumatic so as to not to produce any endometrial lesion. The reduction in success rate for a less experienced physician performing the transfer as compared to a well-experienced physician is directly correlated to endometrial lesions produced during the transfer. Hence, a nontraumatic catheter can reduce the endometrial lesions and improve the success rate.
  - Soft catheters induce less UCs especially when combined with the correct technique of not touching the fundus.
- Non-embryotoxic material
- Free of bacterial endotoxins
- Must be easy to maneuver inside the uterine cavity
- Must be clearly visible on ultrasound so that the depth of placement of embryos can be clearly assessed (desired depth being 15–20 mm from fundus).

Types of Embryo Transfer Catheters

Commercially available catheters can be divided into two major groups and are given in **Table 1**.

Meta-analysis of prospective RCTs compared soft versus rigid ET catheters and found statistically significant difference in clinical PR as well as birth rate in favor of soft

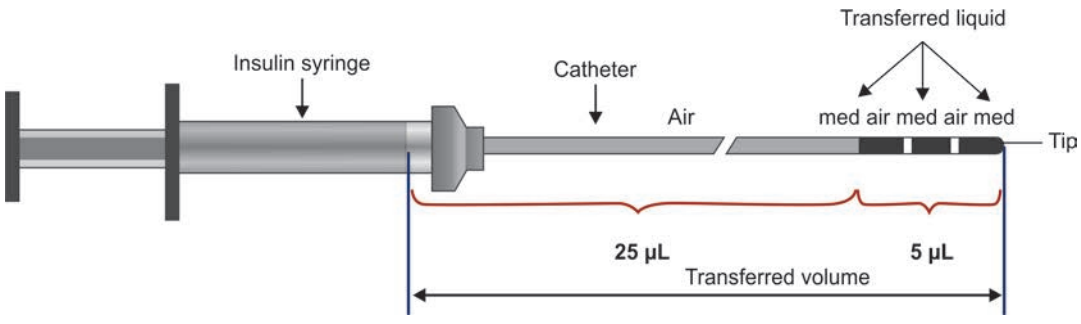


Fig. 1: Inner catheter with syringe.

TABLE 1: Types of embryo transfer catheters.

Soft ET catheters	*Firm (rigid) ET catheters*
(Including echogenic catheters)—Cook (Cook Ob/Gyn, Inc, Bloomington, OH) and Wallace catheters (Marlow Technologies, Willoughby, OH)	TDT (Laboratoire CCD, Paris), Frydman (Laboratoire CCCD), Tomcat (Kendell Healthcare, Hampshire, MA), Tefcat (Kendell Healthcare), and Rocket ET Catheters (Rocket Medical, Tyne and Wear, UK)

catheters.[54] Still rigid catheters cannot be overlooked as they often find use in difficult transfers where the os cannot be negotiated by a soft catheter.[55]

Components of embryo transfer catheter:

- Outer sheath or outer catheter also called guiding catheter—a thick hollow plastic tube (catheter) with a bulb, stopper, and markings (OD—2.5 mm).
  - Bulb—helps to bypass the blind endocervical crypts, which line the cervical canal and can cause the tip of the catheter to get trapped
  - Stopper—for depth adjustment
  - Markings—for easy positioning.
- Obturator or stylet also called mandrel—fits snuggly within the outer sheath allows to preshape the outer sheath—can negotiate the curvature of the endocervix. For difficult ET, OD—1 mm.
- Inner sheath also called transfer or loading catheter—a soft tube, with markings at distal end of the tip. Soft to minimize trauma to endometrium. The embryologist loads embryos into this sheath and then hands this to the doctor (OD—1.6 mm).
  - Handle with Luer lock fitting for secure connection to syringes
  - Total volume—0.2 mL
  - Sterilized with radiation.

POPULAR COMMERCIALLY AVAILABLE EMBRYO TRANSFER CATHETERS

- SureView **(Fig. 2)**:
  - Outer catheter—firm made of Teflon
  - 19 cm long
  - Inner catheter—23 cm long, made of polyethylene
  - External diameter of 1.6 mm (OD) with an open end
  - Visible under ultrasound from hub to tip
  - Highly visible in simulated uterine environment
  - Increased confidence of direction and position of the uterus
  - Optimal placement of catheter in the uterus
  - More accurate positioning for embryo expulsion.
- *Wallace–Smith Medicals:* Four types of Wallace–Smith Medicals are follows:
  - Classic (**Figs. 3A and B**)
  - SurePro **(Fig. 4)**
  - SurePro ultra **(Fig. 5)**
  - SureView.

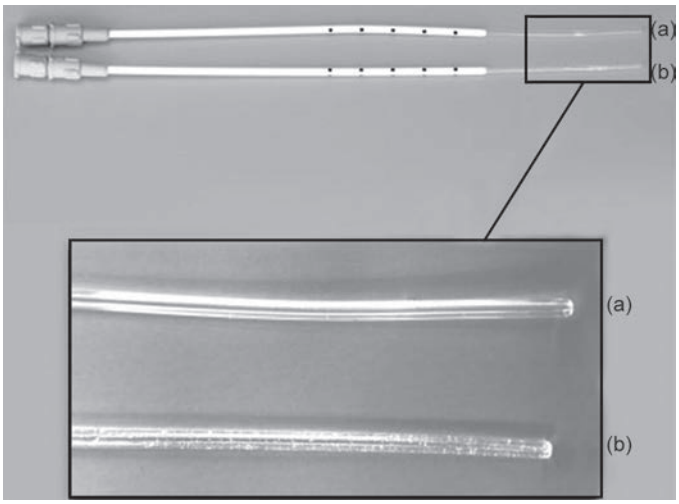

Fig. 2: Difference between standard and SureView Wallace catheters—small air bubbles are present in the wall of inner SureView catheter.

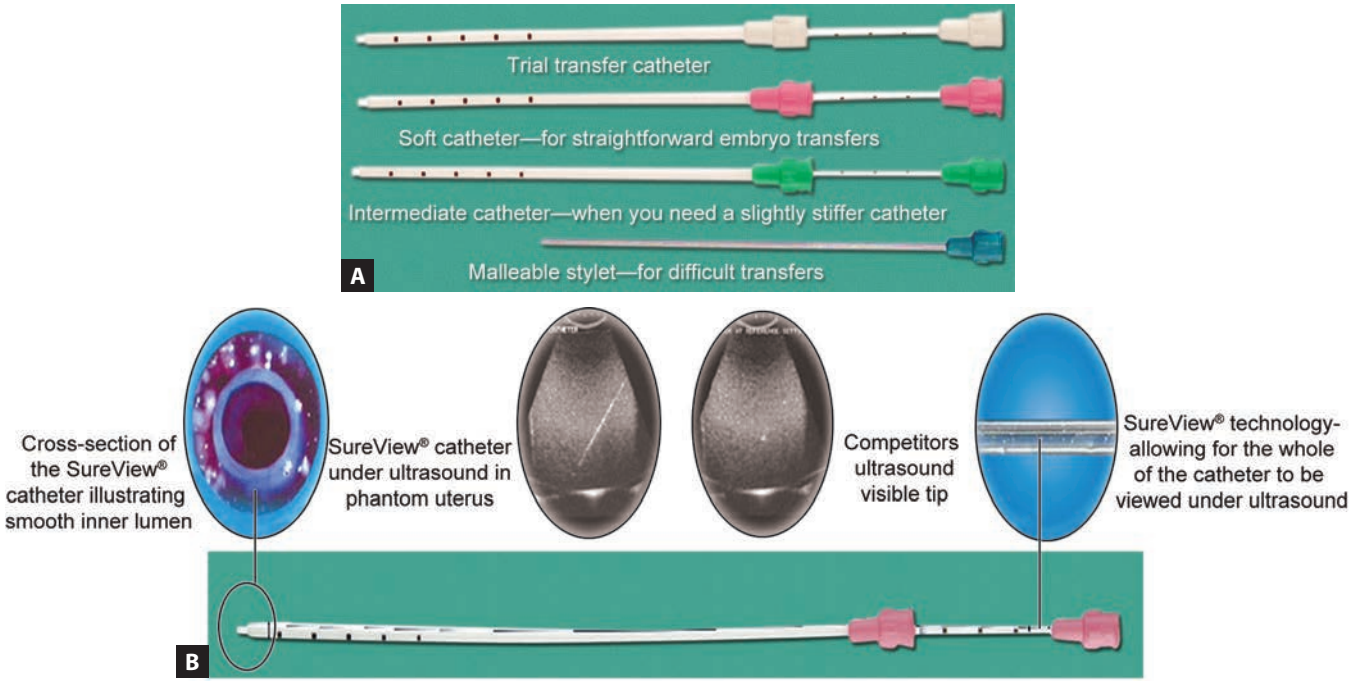
- Cooks catheter **(Fig. 6)**:
  - A double lumen catheter set
  - The guiding (outer) catheter is 19 cm long, has a polycarbonate hub, a bulb tip, and the distal end is angled.
  - The transfer (inner) catheter is 23 cm long and the tip is 2.8 French size.
  - The base of the transfer catheter fits onto a 1.0 mL plastic syringe.
  - Precurved guiding catheter facilitates catheter insertion.
  - Atraumatic bulb tip eases passage through cervix.
  - MicroVol® technology reduces medium volume required for ET.
  - Cervical stop comes set at 4 cm with additional stop at 5 cm.
- Gynetics (**Figs. 7A and B**):
  - It uses a combination of a soft, flexible intrauterine catheter, and a solid cervix catheter.
  - *Types:* Emtrac—combination of soft and rigid catheters
  - Semtrac—soft catheters and Tulip—soft catheters with bulb at tip.
- Frydman rigid catheters **(Fig. 8)**:
  - The Frydman catheter is a polyethylene open-ended catheter with an external diameter of 1.6 mm.
  - It has a 4.5 cm soft distal part and a 12.5 cm more rigid proximal part, and is graduated at 5.5 and 6.5 cm distances from the tip.



Figs. 3A and B: Classic Wallace–Smith medicals.

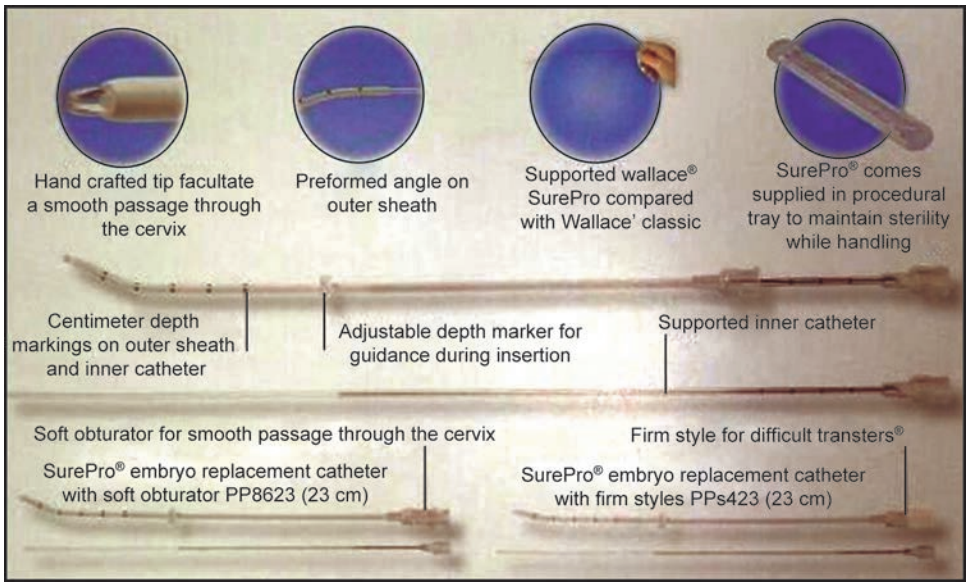


Fig. 4: Wallace SurePro medicals.

- There are several disadvantages for rigid catheters:
  - Bleeding due to disturbed endometrium
  - Trauma to cervical os
  - Incitement of UCs
  - Mucus plugging of catheter tip
  - Possibility of retained embryos.

- Labotect ET catheters **(Fig. 9)**:
  - Available in three lengths, i.e., 15, 19, and 23 cm
  - Labotect is an intermediate catheter.
  - It can be inserted without a malleable stylet.
  - Its unique curved stiff outer sheet with a ball-shaped spherical tip allows negotiation with difficult cervix more easily compared to soft ET catheters.

- Guardia™ proprotective ET catheter (**Figs. 10A and B**):
  - Designed to allow the controlled passage of embryos through cervical mucus and blood.
  - An outer sheath that protects the embryo through the cervix and then opens in petals to further advance the inner catheter and gently place the embryo.

An Egyptian study compared the use of semirigid and flexible catheters in terms of PR and level of difficulty of the ET procedure. The results suggested that a softer catheter may help with difficult ETs[56] and resulted in better implantation rates, while some authors reported significantly higher pregnancy and implantation rates with the ultrasoft catheter compared to the more rigid catheter.[8] The presence of blood

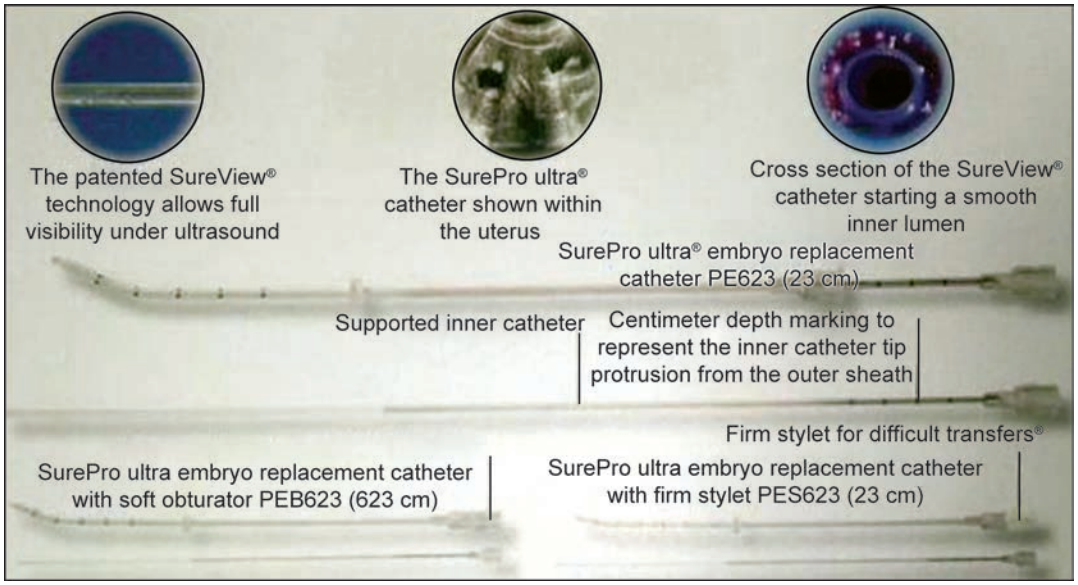

Fig. 5: Wallace SurePro ultra medicals.

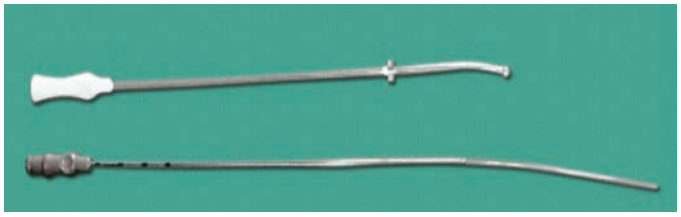

Fig. 6: Cooks catheter.

on the catheter signaled severe endometrial injury. Severe endometrial lesions were less frequent when soft catheters were used. Echogenic catheters offer better visualization owing to the ultrasonic contrast properties, minimizing

the need for catheter movement to identify the tip, and significantly shorter duration of the ET procedure.

Fluid Volume

The amount of fluid volume for transfer has a significant clinical impact. Montag et al. reported significantly higher PR following the use of a high-fluid volume of 40–50 µL compared to 15–20 µL.[57]

Embryo Loading Techniques (Fig. 11)

- Embryo loading (EL) is a stage immediately prior to ET and is performed by the embryologist. Preferred method is medium-air-embryo-air-medium, followed by medium in catheter with embryo, medium-air embryo, etc.
- There are several crucial choices in this procedure such as choice of syringe, the volume of transfer medium, the concentration of proteins, the catheter loading speed, the viscosity of the transfer medium, and embryo placement in the catheter. Among them, the volume of medium and the presence of an air bubble are very much debated.
- Meta-analysis has shown that the use of air brackets was neither beneficial nor detrimental when compared to the fluid—only technique of EL.[58]

Embryo loading probably affects the success of IVF. The study of Halvaei et al. compared the impact of two different techniques of EL on PR in IVF or ET cycles.[59] In Group A, the embryos were drawn directly into the ET catheter from culture microdrop under the oil. In Group B, the embryos were transferred from culture microdrop into G2 medium in center-well dish. Then, the embryos were drawn into the catheter and finally transferred into the uterus. Clinical pregnancy was higher in Group B compared to A, but the difference was insignificant, proving that there is no difference in the outcome by loading the embryo from microdrop or center-well dish.[59]

Omidi et al. compared two different EL techniques.[60] Two groups (A and B) were defined based on the EL technique used. In Group A, the entire catheter was flushed with Ham's F-10 medium. The embryos were then drawn into the catheter using one air bracket. In group B, 70 µL of air was aspirated into the syringe and the catheter was flushed using Ham's F10 medium. The medium, air, embryos, air, and finally another layer of medium were then sequentially drawn into the catheter. EL techniques did not have a significant impact on the delivery rate in either fresh or frozen embryo transfer (FET) cycles.[60]

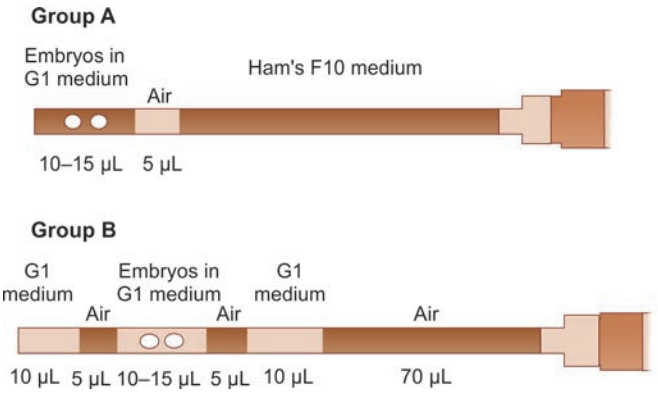

Fig. 11: Embryo loading techniques.

Nouri et al. aimed to ascertain the influence of EL time and the time interval between EL and ET. The paper concluded that time to ET does not impact IVF or intracytoplasmic sperm injection (ICSI).[61]

Embryo Transfer Techniques

- *Preloading of embryos:* The embryos are loaded into the transfer catheter by the embryologist by one of the methods described above and the loaded catheter is handed over to the physician. The embryos are deposited around 2.0 cm from the fundus under transabdominal scan (TAS) guidance. After approximately 5 seconds, the catheter is gently rotated 180° and removed, keeping the plunger of the catheter depressed until it has been entirely removed. The embryologist immediately flushes the catheter and checks for any retained embryo.
- *After loading of embryos:* This is a newer technique and was initially introduced in cases where difficult transfer is expected and also as a kind of mock transfer being performed at the time of actual ET. An empty Wallace catheter is passed to the level of the lower uterine segment under ultrasound guidance to a point just at the level of internal os, where the inner catheter enters the endometrial cavity, typically about 5 cm. The inner sheath is gradually removed, leaving the outer sheath just beyond the internal os. A second inner sheath already loaded with embryos by an embryologist is threaded into the catheter. The inner catheter is slowly advanced by the physician and the embryos are deposited 2.0 cm from the fundus. After approximately 5–10 seconds, the catheter is gently rotated and taken out.[62]
  - Advantages of after-loading of embryos:
    - It allows slow and gentle passage of catheter through the endocervix, reducing the duration of time that embryo remains in room condition (ideally this should be <120 seconds).
    - Embryos in the inner sheath are not exposed to the mucus in the cervix.

A very recent elegant study by Setti et al. suggested that the afterload technique seems to reduce the rate of difficult ETs.[63]

Ultrasound Guidance versus Clinical Touch

The ability to perform ET procedure under direct ultrasound visualization is a significant advancement in the field of

ART and an indispensable technology for ART practitioners. Both transabdominal (TA)[2-5] and transvaginal[6] ultrasound-guided transfers have been shown to increase PR and LBR in contrast to clinical touch method.[2-6]

A study measured the embryo-fundus distance (EFD) using transvaginal ultrasonogram performed immediately after ET. An EFD between 5 mm and 15 mm got significantly higher PR than an EFD above 15 mm. The abortion rate was much higher when EFD was below 5 mm than when it was between 5 mm and 15 mm. Ultrasound-guided ET could be advantageous compared to clinical-touch ET, as it allows to be more accurate in releasing embryos within the optimal EFD range.[64] PRs and ongoing PRs are higher if the embryos are replaced at a distance >10 mm from the fundal endometrial surface under ultrasound guidance. In addition, because significantly more embryos were replaced in cycles where the transfers occurred at a distance of >20 mm, a distance >10 mm to <20 mm seems to be the best site for ET to achieve higher PRs.[65]

The advantages of ultrasound-guided ET include:

- Facilitates placement of soft catheters leading to reduced requirement of use of tenaculum and less often presence of blood or mucus in the catheter tip[66]
- Avoids touching the fundus
- Enables evaluation of the uterine position, AV, or RV, during ET, thus facilitates catheter negotiation
- *Estimation of the cavity depth:* Pope et al.[12] suggest that the cavity depth by ultrasound is clinically useful to determine the depth beyond which catheter insertion should not occur.
- Confirms that the catheter is beyond the internal os in cases of an elongated cervical canal.
- Allows direction of the catheter along the contour of the endometrial cavity, thereby avoiding disruption of the endometrium, plugging of the catheter tip with endometrium, and instigation of bleeding.
- Full bladder required to perform TA ultrasound guidance is itself helpful in straightening the cervical uterine access and improving PRs.
- May facilitate an uncomplicated access through the cervix to access the uterine cavity, thus overcoming cervical stenosis.[5]

Both transvaginal ultrasound-guided ET and TA ultrasound-guided procedure yield similar pregnancy outcomes. Total time taken for transfer was significantly higher in the TVS group, whereas the TA-guided procedure reported increased patient discomfort due to the presence of bladder distension.[67]

3D ultrasound should not be currently recommended as a strategy to improve clinical outcomes in women undergoing ART treatment.[68]

Revelli et al. compared transvaginal ultrasound-guided uterine length measurement before transfer (ULMbET) with TA-UGET.[56] The ULMbET technique leads to IVF results comparable to those obtained with UGET and is better tolerated and easier to perform for a single physician.[69]

Depth of Embryo Transfer

Transfer distance from fundus (TDF) significantly affects PRs with 11% increase in PR for every millimeter that the embryos are deposited more away from the fundus.[12] Tiras et al. also reported higher pregnancy and ongoing PRs when embryos were replaced at a distance >10 mm from the fundal endometrial surface suggesting that a distance 10–20 mm seems to be the best site for ET to achieve higher PRs.[65] The objective of Santos et al.'s study was to determine the influence of the embryo placement depth on the endometrial cavity in relation to the reproductive outcomes, after frozen-thawed ET performed under transabdominal ultrasound guidance.[70] This retrospective cohort study evaluated the influence of the embryo placement depth in the endometrial cavity in relation to PRs. The patients were classified according to three variables: <10 mm, 10–15 mm, and >15 mm. Clinical and ongoing PRs were higher in the 10–15 mm and >15 mm groups, when compared to the <10 mm group; there was no statistical difference between the groups in terms of miscarriage and LBRs. They performed a subsequent analysis, using the same sample of patients, comparing only the <10 mm and ≥10 mm variables. The ≥10 mm group had better reproductive outcomes, with higher clinical and ongoing PRs. The authors concluded that PRs are influenced by the ET site, and better results can be achieved when the tip of the catheter is placed in the central area of the endometrial cavity, especially when the distance from the endometrial fundus is >10 mm. A study comparing the site of ET at 2 cm distance from the fundal endometrium (DFE) compared to the midpoint of the endometrial cavity length (ECL) revealed comparable results for both groups.[71]

Pacchiarotti et al.'s results also suggest that the depth of embryo replacement may be an important variable in ET technique. The authors recommend transferring at least >10 mm away from fundus.[72] In Ivanovski et al.'s study,[73] the transfer catheter was advanced to a defined distance from the uterine fundus, up to the point estimated for transfer: 10 +/– 2.5 mm and 15 +/– 2.5 mm, respectively in A and B groups. Analysis of their results demonstrated that PR was significantly influenced by transfer distance from the fundus where the PR decreases from 46.2% in group B to 28.8% in group A (p <0.05).

A total of 180 consecutive patients undergoing ultrasound-guided ET were randomized to three study groups according to the distance between the tip of the catheter and the uterine fundus at the moment of the embryo deposition in the lumen of the endometrial cavity:

Group 1: 10 +/– 1.5 mm; group 2: 15 +/– 1.5 mm; group 3: 20 +/– 1.5 mm. Implantation rate was significantly higher (p <0.05) in groups 2 (31.3%) and 3 (33.3%) compared with group 1 (20.6%). The depth of the embryo replacement into the uterine cavity may influence implantation rates, and thus it should be considered as an additional procedure among factors recently proposed as associated with successful ET after IVF.[74] Davar et al.'s recent study suggested that the depth of intrauterine embryo placement at a distance of 25 ± 5 mm below the fundal endometrial surface gives better IVF outcomes.[75]

Bakas et al. examined the accuracy of ET based on the previous measurement of cervical length and total uterine length.[76] All patients had transvaginal ultrasound measurement of cervical length and endometrial cavity length prior to ET and measurement of embryo distance (intrauterine air bubbles) from fundal surface of uterine cavity and internal cervical os immediately after ET. Primary outcome was to estimate the accuracy of ET based on the measurement of the embryo distance from middle of uterine cavity after ET and secondary outcome was to assess the effect of embryo distance from uterine fundus and internal cervical os to clinical PR. Multiple regression analysis showed that the embryo distance from middle of cavity was related to endometrial cavity length and to the embryo distance from the fundus and it was not related to Cx length, total uterine length, embryo distance from internal Cx os, and ET length. The study concluded that ET by a single operator with the previous measurement of total uterine length and estimation of ET length was very accurate.[76]

Pain during Embryo Transfer

In a prospective observational study, 284 women under 40 years undergoing IVF or ICSI cycles followed by fresh or frozen ETs were recruited. Pain was measured using a 100 mm visual analog scale. Several factors relating to both pain and also the nature of the ET procedure were recorded: Use of vulsellum, uterine contractility, depth of ET, duration of ET catheter insertion, urgency of micturition, psychological profile tests, salivary α-amylase, and salivary cortisol. Women who experienced pain during ET had a significantly lower clinical PR compared with women who did not (42.2% vs. 53.8%; p = 0.03).[77]

Injection Speed

Catheter injection speed determines the depth and positioning of the embryo into the cavity and is a highly varying factor during ET, even for the same physician. Caanen et al. developed automated pump-regulated embryo transfer (PRET) device.[78] Standardization of the injection speed and pressure with this PRET results in a better controlled positioning of the transferred embryo(s) with minimal variability. The ongoing PR was 21% in the PRET group versus 17% in the manual transfer group; frozen-thawed ETs resulted in 17.5 versus 10.9%, respectively. These findings need to be investigated in a multicenter trial for further validation.

Grygoruk et al. evaluated the impact of varying injection speed on embryo development and reported that a reduction of the ejection speed reduces injury to the embryos.[79] Embryos exposed to fast ET had the slowest development rate and a higher mean apoptotic index of embryos compared to the group exposed to the slow ET and the control group. It is advisable to transfer the embryos at the lowest possible speed.[79]

Prior Cesarean Delivery

Despite the apparently more difficult transfers, pregnancy outcomes were not different between cesarean delivered patients and those without prior cesarean delivery.[81] RCT showed that ETs took longer (approximately 30 seconds longer) in the CD group and were more likely to have mucus or blood on the catheter.

Temperature Control during Embryo Transfer

Twenty-nine simulated ET procedures were carried out across five clinics. A thermocouple probe was used for standardized measurements inside each of the ET catheters to record the changes in temperature that occur in the time period between loading the catheter and placing the catheter in the uterus. In all cases, the temperature at the loaded catheter tip fell rapidly to ambient temperature during transit from the ET workstation in the IVF laboratory to the ET procedure room. Considering the sensitivity of the preimplantation embryo to its immediate environment, the rapid and profound drop in temperatures observed at the catheter tip that houses the embryo during its transit from the IVF laboratory to the uterine environment may affect embryo viability and health. The authors suggested that the issue be addressed to ensure that the tight temperature control continues throughout the ET procedure, and could improve clinical outcomes.[81]

Difficult Embryo Transfer

There is no single definition for difficult ET. An easy procedure with no additional maneuvers required is assumed to be an easy transfer. Each additional instrument required such as holding of cervix with vulsellum, use of cervical dilators are associated with lowering PRs and are deemed as a difficult transfer. Other parameters include poor ultrasound visualization, touching the fundus of uterus, retained embryos, coiling of inner catheter inside the cavity, resistance to expulsion of embryos, and presence of blood on catheter tip. Poor ultrasound visualization of

uterine cavity and inner catheter is associated with lower PRs. Other parameters mentioned above are not significantly correlated with poor outcome.[13]

The aim of a 2019 study was to determine whether a continuous visual analog scale (VAS) is a reliable tool to grade ET difficulty when assessing IVF outcomes.[82] ETs were stratified into three levels of ET "difficulty": (A) "easy"—no resistance; (B) "medium"—resistance overcome by advancing the catheter's outer sheath; and (C) "difficult"—a malleable stylet was required to overcome resistance; and these are compared to the VAS scores.

No significant relationship ($p>0.05$) was seen in clinical pregnancy or LBRs in either the standard difficulty or the VAS groupings suggesting the VAS is not itself a reliable enough tool to record ET difficulty in isolation.[82]

Alvarez et al. investigated the relationship between the difficult ET and LBR in frozen euploid (blastocyst) embryo transfers (FEET).[83] No significant reduction in LBR was observed after adjustment for confounders between difficult and easy FEET, or when use of stylet without or with a tenaculum was required for ET. The authors concluded that the lack of significance may be due to factors such as the sample size or the use of array comparative genomic hybridization analysis.[83]

Postembryo Transfer

Embryos transferred into the uterine cavity can be expelled due to many factors including uterine peristalsis and contractions, low site of deposition, and negative pressure generated when removing the transfer catheter. RCTs of interventions used to prevent post-transfer embryo expulsion in women undergoing IVF and ICSI[84] showed that there is insufficient evidence to support any specific length of time for women to keep lying down following ET nor is there evidence to recommend the use of fibrin sealants added to the ET fluid.

Catheter Rotation during the Exit Process after an Embryo Transfer

Literature suggested that catheter rotation during an ET could discharge mucus entrapped in the embryo to neutralize embryo displacement. The aim of Eftekhar et al.'s study was to compare the outcome of FET based on catheter rotation during withdrawal.[85] Patients were divided into two groups (n = 120/each), including (1) the rotation treatment group (360°) that underwent ET using catheter rotation and (2) the control group including the subjects who experienced ET with no catheter rotation. Their results demonstrated that catheter rotation during withdrawal increased the implantation rate and clinical pregnancy. On the other hand, Gurbuz and Yildiz's 2021 study found that 360° rotation while pulling catheter during ET had no effect on pregnancy and clinical pregnancy.[86]

Catheter Removal Time

Data on the timing of catheter removal technique following ET are quite limited. Cycles in which the transfer catheter was removed immediately were compared with those in which the catheter was removed after a delay period, to evaluate the impact that the time interval before removal of the catheter following embryo deposit may have on the pregnancy outcomes. The comparison of reproductive outcomes revealed no significant differences in pregnancy, clinical pregnancy, ongoing pregnancy, multiple pregnancy, and implantation rates between the groups. There appears no requirement to delay the withdrawal of the catheter to improve the outcomes in ICSI cycles.[84]

Blood on the Catheter

A significant decrease in the PRs, implantation rates, and LBRs follows the presence of blood on the catheter tip[55] or in the catheter[87] after the ET procedure. PRs were unaffected by mucus on the catheter that appeared to be a simple contamination, though the association between macroscopic or microscopic presence of blood or mucus and PRs has not found support from others.[80]

Plowden et al. attempted to estimate the effect of blood at the time of ET and the difficulty of ET on LBRs.[88] ETs were subjectively graded (easy, medium, or hard) by a physician at the time of transfer. The presence of blood at ET was associated with more difficult ETs, retained embryos, and presence of mucus in the catheter. ET with blood was not associated with live birth, while the degree of difficulty for ET had a negative impact on LBR.[88]

Retained Embryos

The retention of the embryo in the transfer catheter after ET during IVF is a fairly common feature, encountered by even the most experienced IVF physicians, and embryos retained in the ET catheter or within its sleeve require a repeat ET. The incidence and effect on PRs of having embryos retained in the transfer catheter, followed by immediate completion of transfer, were studied.[89] Immediate retransfer was found to not have any significant effect on clinical PRs.[89,90] The type of ET catheter used did not show any difference in terms of embryo retention.

The exact mechanism of embryo retention has not been explained. Therefore, Kozikowska et al.'s study aimed to investigate the mechanism of embryo retention in the catheter during ET by using a transparent uterus model equipped with pressure sensors and a video recorder.[91] Their results indicated that pressure changes in the uterine cavity during ET can influence the distribution of the

transferred fluid containing the embryo. Under certain conditions, the transferred fluid can flow backward in the catheter, which may lead to retention of the embryo in the catheter.

Air Bubble Position

Does the air bubble (embryo flash) position and migration as visualized with ultrasound within 60 minutes of ET correlate with clinical outcome following fresh ART transfer cycles? Studies assessing the relation between the PR and the position of the catheter tip and/or the position of the air bubbles following ET show conflicting results to date. Air bubble location following ET is the presumable placement spot of embryos.[92] Confino et al. recorded the air bubble position immediately, 30 minutes later and when the patient stood up after embryo transfer.[93] Bubble migration analysis supported a rather random movement of the bubbles and possibly the embryos, suggestive of active UCs.

A study assessed the embryo flash position by 3D ultrasound at 1, 5, and 60 minutes after ET. The distance of the embryo flash from the fundus was measured at these time points. There was no significant association between the embryo position or movement and the PR at 1 and 5 minutes. At 60 minutes, however, the pregnancy and implantation rates among subjects with embryo flashes located <15 mm from the fundus were significantly higher than those with embryo flashes located >15 mm from the fundus.

Although the air bubbles seen at the time of ET are thought to represent the position of the embryo, they are in fact a surrogate marker of the embryo itself, as this cannot be directly visualized. These findings may challenge the traditional notion that the exact position of the embryo flash immediately following ET is related to clinical outcome.[94]

Speed of Embryo Injection at the Time of Embryo Transfer

Mo et al. set up a study to evaluate the location of transferred embryos under various parameters during ET in IVF by applying an in vitro experimental model for ET.[95] Mock ET simulations were conducted with a laboratory model of the uterine cavity. ET catheter was loaded with a sequence of air and liquid volumes as well as development-arrested embryos donated by patients. The transfer procedure was recorded using a high definition video camera. An orthogonal design, including three independent variables (uterine orientation, distance of the catheter tip to the fundus, and injection speed) and one dependent variable (final embryo position), was applied to the algorithm by the scientific team. The uterine cavity was divided into six regions and the distribution of the transferred embryos varied according to the uterine orientation. The medium speed-injected embryos were usually located in the static region while fast- and slow-speed injected embryos were mostly localized at the uterine fundus and the cervical region, respectively. The probability of embryo separation from the air-bubble interface increased from 11.1% in slow injection cases to 29.6% and 48.1% in the medium and fast injection cases, respectively. The authors suggested that faster injection of embryos into a retroverted uterus usually results in the embryo dissociating from the air bubble.[95]

Mechanical Pressure on Portio Vaginalis

Applying gentle mechanical pressure on the portio vaginalis of the cervix for few minutes post-ET by loosening the screws of vaginal speculum significantly improved the clinical pregnancy and implantation rates by reducing embryo expulsion from the uterus caused by UCs. Some authors, however, have expressed concern that this approach increases uterine contractility and may reduce the chances of successful ET.[96]

Bed Rest after Embryo Transfer

Bed rest for the variable durations of time is commonly advised after an ET carried out almost universally. This practice is based on beliefs that supine position and the reduction of physical activity—to the minimum—might prevent the risk of embryo expulsion once it is transferred to the uterus. Cozzolino et al.[97] designed a meta-analysis based exclusively on evidence from published RCTs, in the attempt to define the real effectiveness of bed rest after an ET to improve the PRs in IVF. The analysis of 1,002 women did not show any significant change in clinical PR between groups and the collated findings showed that immediate mobilization after an ET does not have a negative influence over the success rates of IVF.

RECENT ADVANCES

A recent meta-analysis by Yang et al.[98] evaluated the effects of intrauterine perfusion of peripheral blood mononuclear cells (PBMCs) on the pregnancy outcomes including clinical PRs, embryo implantation rates, LBRs, and miscarriage rates of infertile women who were undergoing IVF treatment. By searching Pubmed, Embase database, five articles meeting the inclusion criteria were included, and 1,173 women were enrolled (intrauterine PBMC group: $n = 514$; NO-PBMC group: $n = 659$). The paper summarized that current published evidence suggested that intrauterine perfusion of PBMC can significantly improve pregnancy outcomes in patients who have three or more IVF implantation failures.[98]

Abdallah et al. designed a parallel, RCT on 181 infertile women scheduled for fresh or vitrified-warmed ET, randomized in a 1:1 ratio to receive either human chorionic gonadotropin (hCG) (500 IU in 0.1 mL of tissue culture media) or culture media (0.1 mL of tissue culture media) via intrauterine injection 4 minutes before ET.[99] In both

groups, an intrauterine insemination catheter was used for administering the medication. Primary outcome was live birth, with ongoing pregnancy and clinical pregnancy as secondary outcomes. Intrauterine injection of hCG before ET did not improve LBRs in women undergoing IVF. Laokirkkiat et al.'s recent study contrarily summarized that intrauterine infusion of a small volume of hCG at the time of ET can significantly improve the implantation rate, while the clinical PR may only be improved in younger patients (aged <40 years).[100]

Ochiai et al. studied the role of resveratrol, a polyphenolic compound in IVF-ET outcomes.[101] The outcomes of ET cycles in women receiving resveratrol supplementation (200 mg/day) continuously (RES group) with a control group (non-RES group) were studied. Their preliminary findings suggested that showed that resveratrol supplementation is strongly associated with a decrease in clinical PR [odds ratio (OR) 0.539, 95% confidence interval (CI) 0.341–0.853] and an increased risk of miscarriage (OR 2.602, 95% CI 1.070–6.325).[101]

Recent advances in the area of ET address the influence of the variation in injection speeds in manual ET and PRET that generate a standardized injection speed with the aim to standardize the ET process. Seven laboratory technicians performed simulated transfers, using the conventional ET technique, and compared their injection speeds with that of a PRET device.[102] The results indicated that in manually performed transfers, even after standardization of the protocol, there is still a large variation in injection speed, while a PRET device generates a reliable and reproducible injection speed and therefore brings new possibilities for further standardization of the ET procedure. Future research should reveal whether these experiments mimic real clinical circumstances and if a standardized injection speed results in more exact positioning of the transferred embryos and therefore higher PRs.

Ying et al. studied the effect of ET catheter contact with intravaginal progesterone preparations on mouse embryo development.[103] In a simulated ET model, ET catheters were loaded with culture medium, placed in contact with intravaginal progesterone gel (crinone 8%) or micronized progesterone intravaginal inserts (endometrin 100 mg), and the intracatheter culture medium flushed. Embryos were cultured in the flushed culture medium at variable dilutions for variable lengths of time. The contamination of ET catheter with intravaginal progesterone significantly impairs mouse embryo development, likely due in part to increased programmed cell death. The take home message is to absolutely avoid intravaginal progesterone dosing on the morning of the planned ET.[103]

Ultrasound elastography is a noninvasive medical imaging technique able to quantitatively characterize the stiffness of a given tissue. It has been shown to predict the risk for cervical insufficiency and preterm delivery, and to allow differentiation of malignancy from normal tissue. Cervical ultrasound elastography, by allowing the identification of cervical tissue dishomogeneity, may be of help in predicting the ET ease in infertile women candidates to IVF or ICSI.[104]

Riestenberg et al. compared the LBR between patients who undergo personalized embryo transfer (pET) after endometrial receptivity array (ERA) versus frozen embryo transfer (FET) with standard timing in first single euploid FET cycles.[105] Total of 228 single euploid FET cycles were included in their study. Of those patients, 147 (64.5%) were ERA/pET cycles, and 81 (35.5%) were standard timing FET cycles. Endometrial receptivity array was receptive in 60/147 (40.8%) and nonreceptive in 87/147 (59.2%) patients. Nonreceptive ERAs were prereceptive in 93.1% of cases. The LBRs were similar between patients who underwent FET with standard timing and patients who underwent ERA/pET, 45/81 (56.6%) and 83/147 (56.5%), respectively. The data from this study does not support the routine use of ERA in an unselected patient population undergoing first autologous single euploid programmed ET.[105]

Yenigul et al.[106] from Turkey published a study suggesting a scoring system by including all of the factors that are recommended for an ideal ET and to investigate its correlation with the beta human chorionic gonadotropin (β-hCG) results. The embryo grade, ET day, distance between the fundus to ET site measured via ultrasonography, endometrial thickness on ET day, and presence of mucus and blood in the catheter after transfer were the variables evaluated. Antral follicle count (13.3 ± 8 vs. 14.6 ± 8.2, p = 0,001), endometrial thickness on the ET day (9.9 ± 2 vs. 10.3 ± 2, p = 0.006), and number of mature oocytes (8.6 ± 6 vs. 9 ± 5.1, p = 0.003) were significantly higher in patients with positive β-hCG values. The total score in the β-hCG positive group was 9.8 ± 1.4 versus 8.9 ± 1.4 in the

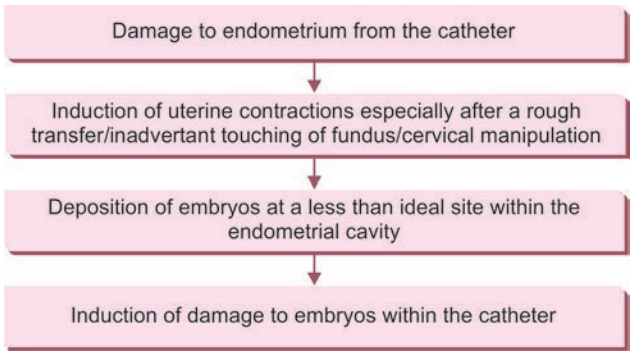
BOX 1: ASRM 2017 guideline recommendations.

Grade A evidence:
- Transabdominal ultrasound-guided ET improves CPR and LBR
- Use of soft ET catheters improves CPR
- Bed rest after ET is not recommended

Grade B Evidence:
- Acupuncture does not increase LBR
- Routine use of prophylactic antibiotics such as amoxicillin is not recommended.
- Use of powdered gloves has no impact on pregnancy outcome
- There is benefit in removing cervical mucus
- ET catheter placement affects implantation and pregnancy rates.
- Immediate withdrawal of ET catheter is recommended
- Presence of mucus on ET catheter is not associated with lower CPR
- Retained embryos in catheter and immediate retransfer do not affect pregnancy rates

(ASRM: American Society for Reproductive Medicine; CPR: clinical pregnancy rate; ET: embryo transfer; LBR: live birth rate)

Flowchart 2: Problems in embryo transfer procedure.



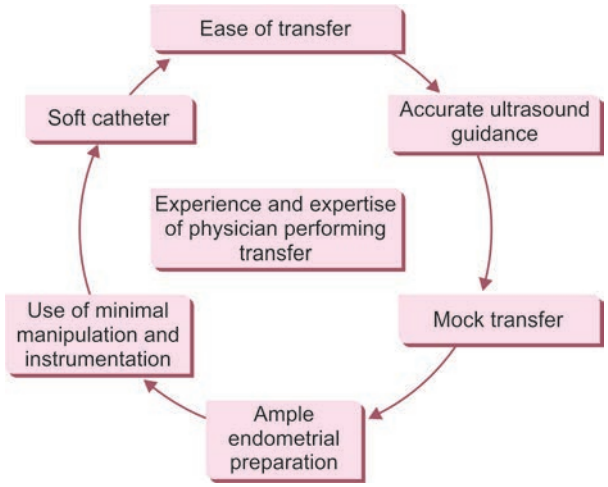


Fig. 12: Cornerstones of a perfect embryo transfer.

β-hCG negative group (p <0.001). The best ETSS cut-off value for predicting β-hCG positivity was 9.5, with 82% sensitivity and 67% specificity [area under curve (AUC): 0.808]. They concluded that their scoring system was an important step toward standardization, as it offered a new, practical, cost-free, and useful scoring system based on pre- and post-ET measurements and laboratory data.[106]

CONCLUSION

Many women undergoing an ART cycle will not achieve a live birth. Failure at the ET stage may be due to lack of good-quality embryo/s, lack of uterine receptivity, or the transfer technique itself. Standardization of the transcervical intrauterine transfer of embryos in larger randomized higher quality study with better explained methods, more specified inclusion, and exclusion criteria is needed to arrive at conclusion. Until more such properly designed studies are conducted, with the available evidence on the factors that are important in achieving an atraumatic ET and positively influencing the pregnancy outcome, we believe that the experience of the clinician performing the ET and adequate knowledge of the factors that are crucial to the success of the technique are paramount **(Box 1)**.

What can go wrong in an ET procedure (**Flowchart 2 and Fig. 12**)?

A poor ET technique accounts for up to 30% of all IVF failures.

CHAPTER 58

Troubleshooting in Assisted Reproductive Technology

Harpreet Kaur, Mir Jaffar

INTRODUCTION

There has been a significant increase in cases of infertility in the last decade which may be due to environmental factors, lifestyle factors such as obesity and stress, increase in late marriages, and postponement of first childbirth. This is paralleled with development in the treatment for infertility including in vitro fertilization (IVF).

In vitro fertilization involves the retrieval of oocytes after ovarian stimulation, their fertilization in vitro, growth of resulting embryos in the laboratory, and subsequent transfer of selected embryos back to the uterus and/or freezing of (excessive) embryos. The whole process is highly sophisticated and there can be mistakes at nearly every level throughout this procedure which can compromise the success rates in an IVF cycle. Troubleshooting is identifying the source of problems and finding the right solutions to get optimal IVF results with no complications. There has been tremendous development in the field of IVF in the last years, the same is accompanied by its associated complexities and problems as well. Maintaining a consistent and good success rate in an IVF program is a challenge.

Despite four decades of progress in reproductive medicine and technology, problems still occur. Our tools have increased in complexity and complex systems bringing problems that can be tackled with an in-depth knowledge of the associated scientific problems.

"Troubleshooting" is defined as a form of problem-solving, applied to repair failed products or processes. The assisted reproductive technology (ART) represents multiple complex systems and a single problem can have many possible causes.

Any changes in stimulation protocols, drug batches and doses, sperm characteristics, and oocyte quality can have negative effects on results. The same holds true for changes in culture conditions, incubators, temperature, pH, gasses, dishes, and culture media. When problems arise, it can be very difficult to know the source. Therefore, the process of troubleshooting can be simplified by a summary of steps:

- Define the problem.
- Produce a step-by-step process of analysis.
- Re-define the problem, find the root cause, and suggest a solution to the problem.

For any successful IVF unit, it is important to have a dedicated team of qualified staff with committed working hours and good team work. Standard operating procedures (SOPs), customized treatment protocols, and regular audits to evaluate performance are the key to success in an IVF program. Any adverse events should be discussed in detail and a root cause analysis is done without a blame culture so as to learn from incidences. Each laboratory should be prepared to encounter one or more of the problems and should have clear cut established systems to handle these problems.

It is important to report your success rates clearly.[1] Success in an ART cycle means birth of a healthy baby through a healthy mother. It is important to define success rate as live birth rate, clinical pregnancy rate, and implantation rate or biochemical pregnancy separately. Success rates should be compared with the national and international standards and the same conveyed to patients clearly.

Troubleshooting involves solving any problem related to clinical or laboratory parameters so as to get the optimum outcome from an IVF cycle.

CLINICAL PARAMETERS

Right from patient selection, choosing the appropriate stimulation protocol, a well-monitored stimulation, right choice of gonadotropins, right dose, timing of human chorionic gonadotropin (hCG) trigger quality control of drugs, and laboratory conditions—all put together finally affect the success rate of an IVF cycle.

Patient Selection

Today ART has become very individualized. One treatment does not suit all. Before starting an IVF cycle, it is very important to have proper patient selection to get optimal results.[2-4] Success of an IVF cycle depends on many variables.

It is important to consider the following factors *before starting an IVF cycle:*

- *Age:* Age of the female partner is the most important factor determining the success of an IVF cycle. It is very important to check ovarian reserve and take age into consideration while deciding the stimulation protocol and the amount of gonadotropins during an IVF cycle. Counseling the patient about success rate is important as chances of successful pregnancy decline with increasing age, especially after 35 years of age.
- *Body mass index (BMI):* If the patient has high BMI (i.e., >30), it is better to advice for weight reduction before embarking on to IVF as the dosage requirement of gonadotropins is higher in obese patients and the results of IVF are poor if BMI is >30 kg/m^2.
- *Medical disorders:* Any pre-existing medical disorders of the male or female partner need to be treated and in optimal condition before going ahead for IVF.
- *Screening for viral markers:* Rule out any infectious diseases such as hepatitis and HIV.
- Based on age, baseline scan, and anti-Müllerian hormone (AMH) of the female partner, make an assessment of ovarian reserve.[5] Women with advanced age and poor responders need to be dealt with separately. These women may need a higher dose of follicle-stimulating hormone (FSH) or addition of luteinizing hormone (LH) to stimulation and it has been seen that the antagonist cycle gives better pregnancy results in these select groups.
- *Records of previous IVF cycle:* This gives a lot of information regarding a patient's response to stimulation so that if needed, any changes can be made in this cycle.
- *Repeated implantation failures:* It is important to workup and find out any underlying cause, e.g., hydrosalpinx which should be removed before attempting further IVF, use of blastocyst transfer, and preimplantation genetic screening (PGS) in selected women may be helpful.[6]
- Rule out any contraindications such as active infection and current pregnancy before embarking on an IVF.
- *Thorough counseling:* Regarding procedure, success rate, failure rate, and alternative treatment, it is important to have psychological counseling particularly in cases of third-party reproduction. Dealing clinician should understand the emotional and interpersonal strain the couples undergo while taking treatment for infertility. A well-conducted IVF counseling allays anxiety and enables patient participation in the treatment.[7]
- *Consent forms:* Informed valid consent to be signed by the patient and where needed by the partner as well, in a language patient can understand.
- *It is always a good practice to have a checklist for all essentials before starting an IVF cycle including investigations, consents, and prior medications so as not to miss anything.*

During Stimulation

- *Cold chain maintenance for drugs:* The outcome of IVF cycle depends upon the quality of stimulation which in turn is influenced by the potency of gonadotropins. Therefore, it is very important to maintain the cold chain during transportation and storage of gonadotropins so as to ensure potency.
- *Selection of protocol:* Stimulation during IVF needs to be individualized, e.g., type of ovarian stimulation protocol, amount of gonadotropins, and type of gonadotropins administered. Nowadays, it is more or less individualized ovarian stimulation (iCOS) protocols which are used in IVF. Special care has to be taken in cases of polycystic ovary syndrome (PCOS) who are at high risk of ovarian hyperstimulation syndrome (OHSS) and poor responders where response may be suboptimal to conventional stimulation.[8,9]
- Dose titrations of gonadotropins have to be individualized. This depends upon BMI, ovarian reserve, prior ovarian response, and ovarian morphology.
- Be vigilant about OHSS—especially cases of PCOS, those who have had prior history of hyperstimulation. In this population, strategies proposed are—antagonist cycle, low-dose gonadotropins, agonist trigger, and no hCG for luteal support.[10]
- *Premature progesterone rise:* There is some evidence that premature progesterone rise during the follicular phase may affect the oocyte quality, endometrial receptivity, and finally success of an ART cycle. The effect is more pronounced in young good responders (i.e., the ideal patient) with large follicular response who is treated with gonadotropin-releasing hormone (GnRH) agonist and pure FSH.[11,12] The risk of premature progesterone rise appears to be associated with the number and size of follicles and the intensity of FSH stimulation. Various strategies proposed to prevent premature progesterone rise include—giving trigger early in these cases, to adopt mild stimulation protocol, and if progesterone levels on the day of hCG trigger are more than cutoff (1.5 ng/mL), then solution might be to vitrify all embryos and transfer subsequently in natural cycle.[13-15]
- *Trigger*: In cases of high risk of OHSS and undergoing antagonist cycle, it is safe to give GnRH agonist trigger which has been shown to give comparable results. Timings from trigger to oocyte pick-up (OPU) have to be specific, i.e., 34–36 hours.
- *Premature rupture of follicles:* The most common reason for premature rupture of follicles is ill-timed trigger. This needs to be looked at and there has to be a mechanism in place to ensure that OPU happens at the specified time after trigger. There should be sufficient gap between the cases or a provision for alternate operation theater (OT) in case of multiple OPU happening the same day. Special

care needs to be taken in case a patient gives such history in previous cycles.

- *Fluid in the endometrial cavity:* Presence of fluid in the endometrial cavity in the late follicular phase may compromise the success of ART cycle. In such cases, it is important to rule out infections, presence of hydrosalpinx, and if there is significant fluid, solution might be to vitrify embryos and transfer in the subsequent cycle.
- There has to be a frozen semen sample as a backup in case of any problems for semen collection on the day of OPU.

During Oocyte Pick-up

- *World Health Organization (WHO) Checklist:* Follow WHO safety checklist in all OT procedures. Always check the equipment, media, and scan machine are in order and there is adequate supply of disposables. Confirm the timings in relation to trigger. The WHO safety checklist should mention the timings and the date of trigger given and this should be signed off before shifting the patient to OT for OPU.
- *Empty follicle syndrome (EFS):* Problem of empty follicles can be frustrating to both the clinician and the patient where no oocytes are retrieved in spite of apparent normal mature follicles and normal estradiol levels. There may be many factors leading to all empty follicles, some still unknown, like genetic,[16] dysfunctional folliculogenesis,[17] and human errors.[18] It is important to check the timings and potency of hCG trigger which can be done by beta-human chorionic gonadotropin (bhCG) test. Various strategies proposed for EFS include—rule out any human errors, change the protocol, change batch of hCG, use of rhCG if not used earlier, rescue protocol by readministering second dose of hCG, and rescheduling OPU 24–36 hours later.[19]
- Problems during procedure:
  - Always check the pressure before starting OPU. It is important to use the specially designed pumps for OPU and the pressure should be maintained at 100–120 mm Hg to avoid damage to the oocytes. In case of suction pump failure, staff should be trained to use mechanical suction in case of emergency situations.[20]
  - *Connections:* Ensure all the connections are right. It is always wise to flush the media through the OPU needle to check all the connections before starting the procedure. If the system is not working, check for leakage—it may be due to broken tube, lid not tightly fitting, problem with the tubing, or the suction pump.
  - Tubes and other disposables should be prewarmed and checked for breakage. And there should be sufficient backup in case of damage during the procedure.
  - *Mobile ovary:* This can lead to difficulty in OPU. It is important to master the technique in such cases as the ovary is highly vascular and at risk of torsion as well when hyperstimulated. Sometimes gentle counter pressure from the abdomen may help.
  - *Excessive bleeding:* It is always important to know your patient in detail, rule out any bleeding disorders, and any medications which might increase the risk of bleeding. Always localize the iliac vessels before putting in the needle so as to avoid inadvertent injury to the major vessels. In case of excessive bleeding from the vault, vaginal packing with a roller gauge may be helpful.

Optimizing Embryo Transfer Technique

Finally, the success of an IVF cycle depends upon a meticulous embryo transfer (ET) procedure. ET with soft catheter and under ultrasonography (USG) guidance has been shown to give better pregnancy rates.[21] A mock ET before the actual ET may give valuable information, especially in cases of suspected cervical stenosis as it allows timely cervical dilatation. ET should be as atraumatic as possible and embryos placed in the mid-cavity under USG guidance.[22,23]

A variety of semirigid catheters or stylet should be available in cases of difficulty to negotiate the os during ET.

Appropriate Luteal Phase Support

Use of GnRH analogs and supraphysiological hormonal levels in ART cycles produce inherent luteal phase defect in all ART cycles. So it is important to give appropriate luteal phase support (LPS) in all IVF cycles. It is advisable to avoid use of hCG as LPS, especially in cases at high risk of OHSS and preferred agent for LPS is micronized progesterone either as tablets, vaginal gels, or suppositories. Estrogen support should be given wherever indicated.[24] One of the recent studies showed better LPS[39] in patients with reduced ovarian reserve, by stimulation with identical protocol in the follicular and luteal phase of the same menstrual cycle which resulted in similar number of blastocyst, thereby reducing the increased risk of aneuploidy when compared with standard stimulation.[1]

LABORATORY PARAMETERS

Troubleshooting in ART laboratory may be broadly categorized under the following headings:

- Environmental factors
- Equipment and instrument-related issues
- Culture conditions
- Technical aspects.

Environmental Factors

It is important to have a proper air purification system to avoid volatile organic compounds (VOCs) in the laboratory.

The gas supply to the incubators should go through the filters after purification and the filters should be changed on a regular basis. An unforeseeable rise in the VOC could be detected purely by smell and can be circumvented by increasing the room temperature and/or placing a dish with oil in the incubator or workstation to absorb hydrophilic VOC-sink in effect.[2]

Equipment and Instrument-related Issues

In case of incubator breakdown, there should be an alternate arrangement to store the embryos and media. Ideally, in a running IVF center, there should be more than one incubator. The incubator has to be fitted with an alarm system to raise an alert in case of interruption in power supply or any change in gas or temperature or humidity.

Culture Conditions and In Vitro Fertilization Culture Systems

The success of an ART cycle depends upon a good and well-maintained IVF laboratory.[40] By following the basic principles in the IVF laboratory, we can strive for a good outcome. Some good practice points include:

- Power backup in the form of UPS to ensure uninterrupted power supply
- *Asepsis:* Sterile precautions to be ensured in OT, laboratory, and semen preparation. The entire complex should be air-conditioned with filtered air under positive pressure and restricted entry of personnel to the laboratory.
- *Workstations:* It is important to maintain temperature, asepsis, and avoid vibrations.
- Standard operating procedures for the procedures.

In Vitro Fertilization Culture System[41,42]

Attention must be paid to any element in the culture system that might cause physiological stress to embryos, resulting in compromise to their potential viability.[28,29]

Gametes and embryos are maintained in a culture system in buffered media that provide a stable environment via complex interplays between physicochemical parameters of pH and temperature. These parameters are dependent upon the composition of media and its buffering systems as well as gas atmosphere and incubation conditions.[30,31]

Guidelines for handling the media:

- Ensure that the cold chain is not broken during transport of media.
- Check the production schedule of media so that media arrives with maximum shelf-life.
- Store the media continuously at the appropriate temperature.
- Media should be equilibrated for temperature and pH for 4–6 hours before use or by overnight incubation.
- Ensure that the media and disposables are checked for quality and proved to be nontoxic to the embryos by appropriate assay.

pH Regulation in Gamete and Embryo Culture Systems

Dishes that are used without an overlay are extremely sensitive to pH changes when placed in or removed from the incubator. Therefore, culture dishes with oil overlay are important. In this case, oil also requires equilibration in the CO_2 incubator up to 12 hours.[3] Do not expose the HEPES [4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid]-buffered media to 5% CO_2 conditions, i.e., prepare dishes or tubes with tight lids which contain HEPES-buffered media.

pH is a critical parameter; in practice, it is not easy to monitor effectively. A standard glass probe pH meter can be used for solutions but it cannot measure pH under culture conditions. A number of devices are available for use in culture systems. Whatever device is used, careful validation and calibration are essential. Sample pH is measured after two-point calibration, with one buffer in an acid range and other in alkaline range.

Temperature Control in In Vitro Fertilization Laboratory

Control of temperature fluctuation is important to successful IVF culture. The optimal temperature range for human IVF culture is assumed to be between limits of 36.7 and 37°C. Temperature above 37°C may induce the formation of heat shock proteins, with detrimental effects on development.[32,33]

Two brief exposures of embryo/blastocyst culture dish to room temperature in a day show compromised development.[4]

Infections in In Vitro Fertilization Culture

In vitro fertilization culture systems are designed to promote and sustain cell metabolism and optimal cell growth and therefore also represent an ideal environment for microorganisms to thrive. Microbial growth has the potential to not only affect the health of gametes and embryos but also compromise the treatment of other patients via culture system.[34,35]

STRATEGIES TO MINIMIZE INFECTION

- Restrict access to the laboratory, only authorized personnel should be allowed into the IVF laboratory, wearing specific laboratory clothing and footwear in the sterile area of the laboratory.
- Wash and dry hands on entering the laboratory.
- Hair should be netted in surgical hats.
- Make sure that plastic sleeves containing dishes or tubes are clean before taking them to the culture environment.

- No eatables should be allowed in the sterile area.
- Laboratory must be cleaned and decontaminated. Separate waste materials according to hazard type, with sharps always discarded into sharps bins.
- Examine culture droplets on a regular basis for any evidence of gross bacterial or fungal infection. Incubators, centrifuges, and microscopes must be cleaned and serviced at regular timings.

TROUBLESHOOTING A CRYOPRESERVATION SYSTEM

Cryopreservation of oocytes, embryos, and reproductive tissue is an integral part of an ART service. But if vitrification results show consistently poor survival, then need to troubleshoot. Troubleshooting in cryopreservation requires an understanding of basic principles of cryobiology.[36-38]

Practical Tips for Vitrification

Pre-equilibrate all the media to the correct temperature and label each vitrification device fully prior to use because timing is crucial to effective vitrification and warming. Adhere to the correct timings strictly, use timers. Ensure that there are no air bubbles on the surface of the initial warming solutions as embryos tend to adhere to bubbles. The speed of warming is considered to be more important in avoiding lysis. If warming is too slow, the intracellular cyclopiazonic acid concentration is too low to prevent ice from recrystallizing and supercooled liquid forms lethal ice crystals. Embryo survival may not be immediately obvious after warming and survival is routinely assessed after a minimum period of 2 hours in culture. This is particularly important in blastocysts, which may appear collapsed immediately after warming but will re-expand within 2 hours when culture under optimal conditions.

Problems may arise if liquid N2 levels are not maintained, due to spillage, lack of proper labeling, and wrong freezing techniques.

TROUBLESHOOTING INTRACYTOPLASMIC SPERM INJECTION PROCEDURE

Make sure that all the controls are in the central position before starting a micromanipulation procedure. Coarse and fine controllers should be central. Keep all equipment clean, dust settling into joints can prevent further movement and create problems. Oil inside the tubing often remains in place for long periods, any change in color to yellow or brown is a sign of deterioration. Air bubbles in the oil will interfere with syringe pressure and should always be removed.

Sometimes when fitting a new injection pipette, a blockage in the pipette holder prevents full insertion, then undo the pipette holder and check for the presence of previously broken pipette. Remove that broken pipette and fit a new injection pipette. Angle of the injection pipette should be correctly set so that sperm can easily be trapped using injection needle.

Table 1 shows some practical tips to troubleshooting in the laboratory.

Finally, it is very important to review your performance and the areas of improvement and for that *audit your results regularly*.

Quality Management Systems

Essential elements of quality management systems (QMS) include process flowchart, SOPs, quality of all consumables and media in use, and contracts for service and documented calibration which are required for incubators, microscopes, manipulator stations, heated surface or microscope stages, centrifuge, refrigerators or freezers, and air filtration equipment.[25-27]

The staff working in the laboratory should be trained and there should be a clear policy to document any adverse incident and the actions taken after that.

The recordkeeping should be meticulous and all records pertaining to any ART-related procedure has to be maintained for 10 years as per Indian Council of Medical Research (ICMR) guidelines.

Tools to Understand and Minimize Risk

Double check for identity—witnessing to avoid accidents or mix-ups. Electron witnessing system is a step forward to ensure further that there is no mixing up of gametes and embryos and it saves time and increases patient's confidence level.[43,44]

CONCLUSION

The concept of benchmarking or key performance indicators (KPIs) is well known in many operations in science, medicine, and business. Systematic KPIs monitoring allows early detection of problems and the prompt adoption of corrective actions to prevent a clinical impact. Laboratory KPIs mainly cover the safety, effectiveness, efficiency, and timeliness dimensions of care. This can minimize adverse effects.

QUESTIONS

1. What is the threshold value of progesterone in the follicular phase of an IVF cycle and how to manage premature progesterone rise?
2. Highlight causes of EFS and how to manage it?
3. What should be the ideal temperature in an incubator and how to measure this?
4. How to check for contamination in the laboratory? What steps are important to prevent contamination in an IVF laboratory?
5. Your pregnancy rates have dropped consistently over the last 3 months. How to troubleshoot?

TABLE 1: Practical tips to troubleshooting in the laboratory.

Problem	*Which area best describes the problem?*	*Check*
A bottle of media appears cloudy when dishes are prepared	IVF culture system	• Refrigerator temperature • Media bottle capped? • Can clear media be sourced immediately?
All media in CO_2 incubator dishes are observed to be pink	pH	• Check incubator CO_2 level • Check CO_2 connection
Poor ICSI embryo quality since the ICSI station was moved to a different part of the laboratory, closer to air vents	Temperature	• Reset heated stage to compensate for any temperature loss • Consider relocating the ICSI station away from the air vent • ICSI should take place at the correct temperature
New fluorescent lighting installed in IVF laboratory. Pregnancy rates have dropped	Light	• Install a dimmer switch to control lighting level • Consider having fewer lights switched on • Light levels should be optimal for ART laboratory
Hissing sound noticed when new CO_2 cylinder is connected to the regulator indicating a leak	Gas	• Turn off the gas cylinder • Unscrew regulator, check, and clean thread • If still leaking, contact the gas company immediately • Check the regulator matches cylinder type
Bacteria are observed in a single dish from one patient on day 3 of embryo development	Infections	• Check infection is restricted to one couple only • Isolate the dish • Sample media to identify infection • Send culture for incubator
Vitrification results show consistently poor survival	Cryopreservation system	• Check SOP validation • Check nitrogen level in can • Check equilibration time in freezing solution • Check freezing media equilibrated at correct temperature • Check correct loading of embryos on straw
Sperm cannot be trapped using the injection pipette for ICSI	Micromanipulation	• Check the angle of injection pipette is correctly set • Remove air bubbles from tubing • Refill injector with oil
Poor fertilization after ICSI	Micromanipulation	• Check correct injection in cytoplasm • Check correct sperm immobilization • Select vital sperms • Check temperature of heating stage • Reduce exposure time for oocytes

(ART: assisted reproductive technology; ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization; SOP: standard operating procedures)

KEY POINTS

- The success of an IVF unit depends on both clinical and laboratory parameters.
- A well-selected patient with individualized stimulation protocol and ensuring quality control in an IVF laboratory can give the best results in ART cycles.
- It is very important to have SOPs and audit your results regularly and have in depth root cause analysis of any adverse events so as to learn lessons from such events.

CHAPTER 59

Luteal Phase Support

Sonal Agarwal, Neha Tyagi, Kamini A Rao

INTRODUCTION

Owing to the increasing incidence of infertility in the current era, assisted reproductive technology (ART) has seen a lot of advancements. The use of gonadotropin-releasing hormone (GnRH) analogs has achieved controlled ovarian stimulation (COS) by causing pituitary desensitization and reducing cycle cancellation rates. COS, however, impairs pulsatile release of luteinizing hormone (LH) from the anterior pituitary gland, which disrupts the function of corpus luteum. There is now a general consensus on luteal phase support (LPS) in in vitro fertilization (IVF) cycles to optimize outcomes.[1]

PHYSIOLOGY

The luteal phase is the time period between ovulation and either the establishment of a pregnancy or the onset of menses, which occurs 2 weeks later.[2] Corpus luteum is a unique endocrine gland that plays an important role in the regulation of menstrual cycle and early pregnancy. Corpus luteum is formed following follicular rupture causing theca and granulosa cells to separate from the basal lamina **(Fig. 1)**, thereby causing bleeding into the central cavity. The blood filled corpus luteum is known as "corpus hemorrhagicum". Corpus luteum secretes estrogen and progesterone **(Flowchart 1)**, which support the implantation process.

In a successful implantation, the growing blastocyst secretes human chorionic gonadotropin (hCG), which maintains the corpus luteum and its secretions until luteo-placental shift occurs during the fifth gestational week when placental steroidogenesis begins. Luteal vascularity, peaks at around 7 days following ovulation, which correlates with peak serum progesterone levels.[3]

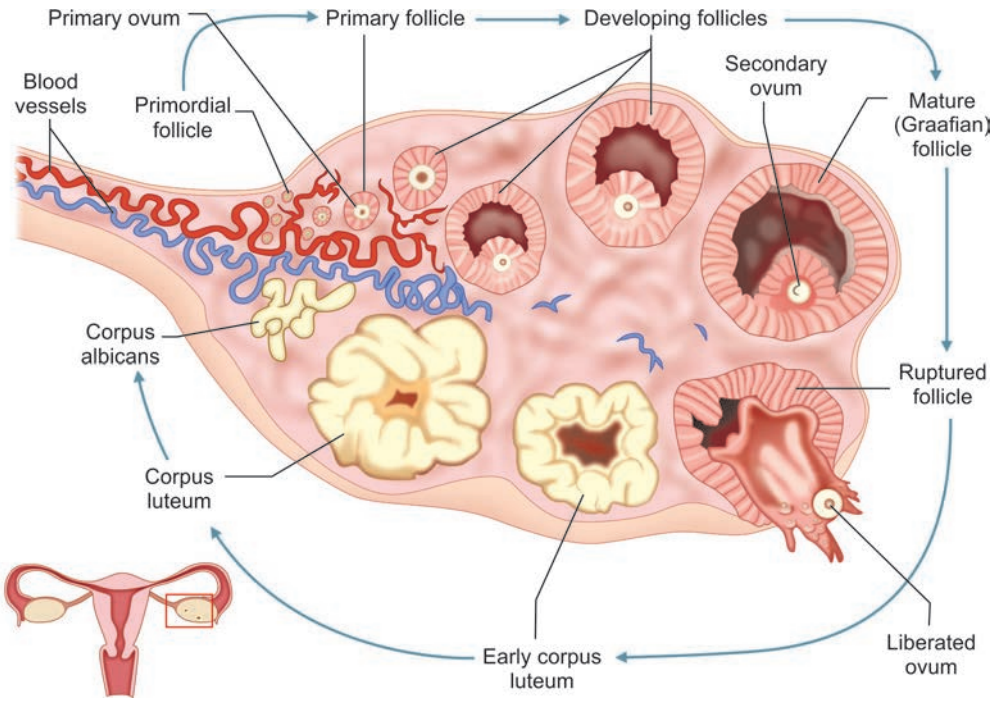

Fig.1: Physiology of corpus luteum.

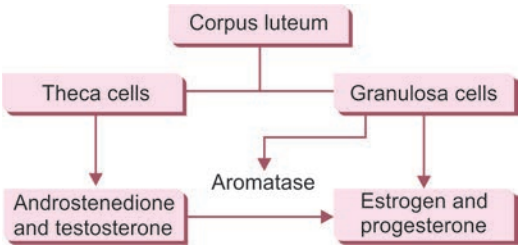
Flowchart 1: Role of corpus luteum in luteal phase.



LUTEAL PHASE DEFECT

Luteal phase defect (LPD) can be described as failure to develop a receptive secretory endometrium due to disruption in the function of corpus luteum. Aberrant folliculogenesis results in defective neoangiogenesis leading to inadequate production of progesterone. Progesterone plays a pivotal role in the maintenance of endometrial integrity to sustain implantation. LPD presents clinically as short menstrual cycles, recurrent implantation failure or recurrent pregnancy loss (RPL).

Pathophysiology of Luteal Phase Defect

An intact functional hypothalamic-pituitary-ovarian (HPO) axis is essential for normal regulation of menstrual cycle and maintenance of early pregnancy **(Flowchart 2)**.

LUTEAL PHASE SUPPORT IN ART: WHY IS IT NEEDED?

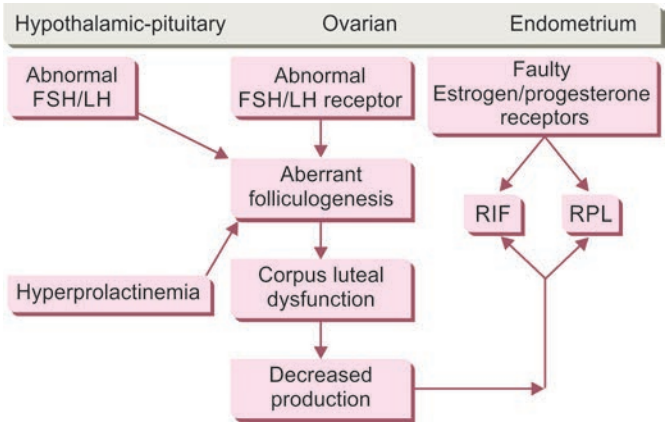
Many postulations have been described and studied as to why there is a LPD in the ART cycles.

- There is loss of pulsatile secretion of LH from the pituitary gland due to downregulation of LH receptors in GnRH agonist cycles.[4]
- It has been observed that there is premature luteolysis in GnRH antagonist treatment cycles leading to poor pregnancy rates and shortened luteal phase in unsupported cycles.[5]
- It has been postulated that supraphysiological levels of steroid hormones secreted by multiple corpora lutea in an IVF stimulation may cause reduced LH secretion due to negative feedback inhibition of the hypothalamic-pituitary axis. Currently, this is the most widely accepted theory of LPD in ART.[6]
- There is mechanical disruption of corpus luteum due to loss of granulosa cells during follicular aspiration for oocyte retrieval.[7]
- The administration of hCG to mimic the LH surge in IVF has been implicated as a cause of LPD by inhibition of endogenous LH secretion from the pituitary.[8]

LUTEAL PHASE SUPPORT

Luteal phase support may be defined as administration of pharmacological agents aimed at supporting implantation process to enhance the probability of pregnancy with a successful outcome.

Flowchart 2: Pathophysiology of luteal phase defect.



(FSH: follicle-stimulating hormone; LH: luteinizing hormone; RIF: re-current implantation failure; RPL: recurrent pregnancy loss)

Indications of Luteal Phase Support

- Recurrent pregnancy loss—LPD has been associated with RPL although causation is yet to be established. It is, however, a common practice to provide LPS to these patients.
- Controlled ovarian stimulation in IVF or intracytoplasmic sperm injection (ICSI) cycle.
- Frozen embryo transfer (FET) cycles—since there is no corpus luteum to support the pregnancy, there is a mandatory requirement of LPS.
- Ovulation induction with gonadotropins in intrauterine insemination (IUI) cycle.
- Luteal phase defect in cases of hyperprolactinemia, hypothyroidism, obesity, autoimmune disorders causing disruption of HPO axis.

Agents Used for Luteal Phase Support

A variety of agents have been used and studied so far, all with varying degrees of success. The mainstay of LPS still remains progesterone in various forms.

Progesterone

After adequate estrogen priming, progesterone causes secretory changes in the endometrium, which improves endometrial receptivity wherein endometrium acquires a transient ovarian steroid-dependent state favoring blastocyst adhesion. The endometrial glands become tortuous and secretory, and stromal vascularity increases which enhance the endometrial receptivity.[9] Progesterone induces nitric oxide synthesis in the decidua, which helps in promoting local vasodilatation and uterine musculature quiescence. Excessive uterine contractility has been found to play a role in causing ectopic pregnancies and miscarriages.[10] Hence, progesterone has been studied widely as an agent for LPS.

The two forms of progesterone that are used are natural or micronized progesterone and synthetic progesterone.

Micronized progesterone: It is available as oral, vaginal, rectal, and parenteral preparations.

- *Oral:* It is no longer recommended due to poor bioavailability (as less as 10%), owing to high first-pass hepatic metabolism. Hence, higher doses are required to reach an effective serum level, which causes sedative and anxiolytic central nervous system (CNS) side effects. Progesterone metabolites bind to gamma amino butyric acid (GABA), a receptor complex in CNS and cause headache, vertigo, and postural hypotension. According to a study oral doses of progesterone, even as high as 1 g/day have not been able to induce predecidual changes in the endometrium to help implantation.[11]
- *Transdermal:* Administration of progesterone through this route is not possible due to presence of an enzyme in the skin, 5α-reductase, which inactivates progesterone.
- *Intramuscular:* The use of intramuscular form of progesterone for LPS was first introduced during IVF in 1985.[12] It is associated with various side effects such as injection site pain, skin irritation, inflammatory reactions, and rarely abscess formation as these are oil-based preparations. Single daily dosing of 50 mg progesterone in oil produces physiological serum progesterone levels of 25 ng/24 hours. Intramuscular progesterone has been associated with highest serum levels compared to other routes.[13]

There have also been studies comparing the intramuscular route of progesterone administration versus vaginal route. A meta-analysis of such studies done in 2009 showed comparable results in terms of clinical pregnancy rates and ongoing pregnancy rates between vaginal and intramuscular preparations.[14]

A Cochrane review published in 2011 showed no difference in clinical pregnancy rate or live birth rate between intramuscular and vaginal route progesterone; however, it did find a difference favoring intramuscular progesterone in ongoing pregnancy rates.[15]

Although more randomized controlled trials (RCTs) are needed to confirm these findings, such studies hold particular promise in cultures where women feel uncomfortable using the vaginal route for drug administration.

- *Vaginal:* Vaginal preparations of progesterone have become the mainstay of LPS nowadays owing to the ease of use compared to daily painful injections and a comparable efficacy. Progesterone can be administered vaginally in various forms as tablet, suppository, 8% gel preparation, and vaginal spray.

The unique feature of 8% bioadhesive gel is its property of sustained-release delivery over time allowing for once daily administration. It comes with a prefilled applicator. Each applicator contains 1.125 g 8% (w/w) gel equivalent to 90 mg progesterone per dose. Vaginal preparations have an upper hand when compared to oral or parenteral route due to its first-pass uterine effect **(Fig. 2)**. Progesterone concentration in endometrial tissue is greater than would be expected based on serum levels.[16] However, a few patients report distress due to unavoidable vaginal discharge caused by these preparations.

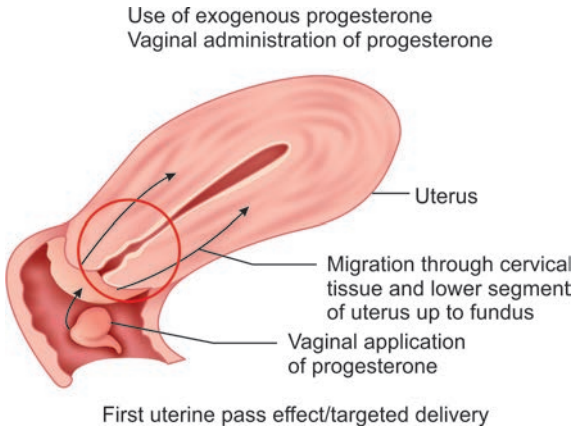


Fig. 2: Vaginal progesterone exhibiting first uterine-pass effect.

According to a recent systematic review comparing different vaginal formulations for efficacy and safety in LPS during ART cycles, it was shown that there was no significant difference between them.[17]

- *Subcutaneous:* To avoid the painful intramuscular progesterone in oil injection, aqueous progesterone preparation was introduced. It is made by encapsulating progesterone in a starch residue called cyclodextrin, which increases the polarity, thus making it water-soluble. The aqueous form comes as 25 mg and 50 mg/day preparation, both found to reach serum progesterone levels resembling pulsatile progesterone levels in the luteal phase of menstrual cycle.[18]

According to an RCT, it was concluded that subcutaneous progesterone was well-tolerated and non-inferior to micronized vaginal progesterone as LPS in ART cycles.[19] Similar findings have been concluded by a meta-analysis, which showed that no statistically or clinically significant differences exist between subcutaneous and vaginal progesterone for LPS.[20]

Synthetic progesterone: Dydrogesterone was introduced to overcome the side effects of natural oral micronized progesterone and its less bioavailability. Its structure is closely related to progesterone and has a highly selective action on progesterone receptors. It lacks androgenic, estrogenic, and corticoid properties. It is available as 10 mg oral preparation.

According to a recent phase III multicenter RCT, dydrogesterone was shown to be non-inferior to micronized vaginal progesterone as an LPS in IVF cycles with respect to

ongoing pregnancy rates (up to 12 weeks of gestation).[21] A meta-analysis done in 2016 comprising eight RCTs had also concluded that oral dydrogesterone seems to be as effective as vaginal progesterone for LPS in ART cycles, and appears to be better tolerated.[22]

Human Chorionic Gonadotropin

Human chorionic gonadotropin is similar to LH in its molecular structure, mode of action, and physiological effects. However, hCG has a longer half-life and potency owing to the presence of higher sialic acid residues. This formed the basis of its use as an agent for LPS. Two types of hCG have been in use:

- Intramuscular
- Subcutaneous—recombinant form.

Various studies have been done comparing the efficacy of hCG with respect to traditional progesterone preparations. Although luteal hCG has a similar efficacy to luteal progesterone in terms of pregnancy outcomes, hCG has rarely been used as a sole agent for LPS in ART clinics, and even this use has been declining. Human chorionic gonadotropin has been associated with increased rates of ovarian hyperstimulation syndrome (OHSS). More popularly, it is used in addition to progesterone preparations.[23,24]

Progesterone versus hCG with progesterone: According to a Cochrane review published in 2015, it was shown that there was no significant difference between the two groups in terms of live births and ongoing pregnancy rates. However, use of progesterone alone was associated with lower incidence of OHSS.[25]

Gonadotropin-releasing Hormone Agonist

Gonadotropin-releasing hormone was introduced as a new means of providing LPS in 2005. The concept behind its use was that it would increase LH secretion from the anterior pituitary, thereby supporting the corpus luteum. It was also hypothesized that it may have effects on the endometrial GnRH receptors or direct effects on the embryo.[29] It is available in three forms—subcutaneous, intramuscular, and intranasal. It has been used as either a single dose subcutaneous injection decapeptyl 0.1 mg on day 5 or day 6 of oocyte retrieval, or intranasal form with nafarelin 200 mg twice daily initiated on the evening after oocyte retrieval. As per a Cochrane review by van der et al. published in 2015, it was found that there was an increased live birth rate and ongoing pregnancy rate with the use of GnRH agonist along with progesterone in the luteal phase, compared to using progesterone alone.[25]

Despite promising early evidence, additional studies are needed given the lack of clear biologic mechanism before wide acceptance of this practice.

Estrogen

Estrogen pretreatment has a role in priming the endometrium in FET cycles, especially in donor egg recipients. Due to lack of endogenous estrogen production, there is inadequate endometrial priming, which hampers embryo implantation. It is available in various forms such as oral, transdermal, and intramuscular.

Oral dose of estradiol valerate is 4–8 mg/day. It has a high first liver-pass effect, hence it should be given with caution in patients at risk for venous thromboembolism. Transdermal gel or patch preparation should be considered in such patients. Transdermal preparations have been found to be less effective in hot and humid weather, and obese patients due to reduced absorption.

There has been no fixed protocol regarding dose and duration of estrogen administration in LPS. Scheffer et al. found no significant difference in pregnancy rates when either of oral or transdermal patch or transdermal gel of estrogen was used for LPS.[25]

However, according to the Cochrane review, there was no conclusive evidence of difference between patients using either progesterone alone or progesterone with oral estrogen for outcomes such as clinical pregnancy rate and ongoing pregnancy rates. It should be noted that there might be some benefit with the use of transdermal or oral with transdermal estrogen supplementation.[26]

Duration of 10–14 days of estrogen administration is usually sufficient in artificial protocol but for patients who do not respond,[27] it should not extend beyond 40 days, can lead to breakthrough bleeding.[28]

Optimal Timing of Luteal Phase Support

In ART cycles, there is substantial endogenous production of progesterone starting after the hCG trigger. Although it is important to give LPS in IVF cycles, it is equally important to time it correctly. LPS, if given early, might advance the endometrial maturation making it out of sync with the growing embryo, thus, hampering the implantation process.

It has been studied that administration of intramuscular progesterone early in the cycle, that is, prior to oocyte retrieval compared with within 24 hours after oocyte retrieval, will result in lower pregnancy rates.[30] According to an RCT, comparing the timing of onset of start of LPS in patient undergoing IVF cycles, there was no significant difference in the ongoing pregnancy rates between the three arms—starting LPS on the day of hCG administration, the day of oocyte retrieval, and the day of embryo transfer.[31] It may be concluded from the published data that there is an acceptable window of 24–48 hours of starting LPS after oocyte retrieval for optimum cycle results.

In a prospective study, it was shown that prolongation of progesterone supplementation beyond positive beta

hCG test had no effect on miscarriage rate or delivery rate.[32] Another study randomized IVF patients into two groups comparing the impact of progesterone supplementation, beyond first ultrasound showing viable pregnancy. It concluded that there was no significant difference in miscarriage rates or bleeding in early pregnancy between the two groups.[33]

From the current available evidence, it has been found that continuation of progesterone supplementation beyond first viability ultrasound in patients undergoing IVF treatment is generally unnecessary.

Luteal Phase Support in Special Situations

Luteal Phase Support in IUI Cycle Using Various Ovulation Induction Protocols

Controlled ovarian stimulation in IUI cycles is similar to IVF or ICSI cycles with respect to multifollicular development. According to the published data available at present, it may be suggested to use LPS in gonadotropin-stimulated IUI cycles with multifollicular development.

In 2017, a large systematic meta-analysis was undertaken to evaluate the role of LPS in ovulation induction in IUI cycles and the conclusions from it were as follows:[34]

- Progesterone supplementation improves clinical pregnancy and live birth in gonadotropin ovulation induction–IUI (OI–IUI) cycles.
- There does not seem to be a benefit of exogenous progesterone in Clomiphene Citrate OI–IUI cycles.
- There is insufficient evidence that progesterone support improves outcomes in OI–IUI cycles using letrozole or clomiphene citrate plus gonadotropins.

Luteal Phase Support in IVF: Fresh Transfer Cycles Using GnRH Agonist as Trigger

With the advent of GnRH antagonist protocol to prevent premature LH surge in COS cycles, it became possible to use GnRH agonist as a trigger, thus reducing the risk of OHSS. However, it has a deleterious effect on the luteal phase of the IVF cycle compared to that of a natural cycle.[35,36]

There is a significant difference in the luteal phase of GnRH agonist trigger cycle compared to hCG trigger cycle owing to the shorter half-life of endogenous LH (~60 minutes) compared to that of hCG (>24 hours).[32] This leads to low circulatory levels of estrogen and progesterone throughout early or mid-luteal phase, causing premature luteolysis and implantation failure.

Modified Luteal Phase Support after GnRH Triggering

Earlier RCTs have shown high incidence of early pregnancy loss with the use of standard LPS with vaginal progesterone and oral estrogen in cycles where GnRH agonist was used as a trigger for final oocyte maturation.[37,38] This necessitated the use of modified LPS in such cycles:

- *hCG bolus:* Various RCTs have shown that hCG when used in small bolus (1,500 IU) after GnRH agonist trigger gives similar ongoing pregnancy rates and clinical pregnancy rates as compared to hCG triggered cycles, without increasing the risk of OHSS, thus allowing fresh embryo transfer.[39-42] A proof-of-concept study was conducted by Kol et al.[39] including women undergoing IVF or ICSI treatment with GnRH agonist trigger. The women were supplemented by two bolus doses of hCG (1,500 IU) on the day of ovum pick up and second dose 4 days later, with no exogenous progesterone support. The study reported an ongoing pregnancy rate of 47% with no incidence of OHSS. It may be said that a small dose of hCG rescues the luteal phase in GnRH agonist triggered cycles, however, more studies are needed to establish a protocol.
- *Recombinant LH (rLH):* According to a proof-of-concept study, similar reproductive outcomes were obtained using rLH as LPS in GnRH triggered cycles compared to hCG triggered cycles. rLH was used in doses of 300 IU on alternate days starting from the oocyte retrieval day along with daily vaginal progesterone. Larger studies are needed to establish the safety and efficacy of this protocol. Another drawback is the high cost associated with it.
- *Intensive progesterone and estrogen support*: Various studies have been performed using intensive LPS protocol consisting of estrogen and progesterone only, for GnRH agonist triggered cycles compared to cycles using hCG trigger. While some studies favored this protocol, others discouraged its use reporting a low reproductive outcome. There seems to be a need for larger RCTs to justify the use of intensive LPS.[43,44] Although, various protocols of modified LPS have shown promising reproductive outcomes after GnRH agonist triggering, without increasing the incidence of OHSS, the most optimal LPS still remains to be found out.[45]

Luteal Phase Support in Natural FET Cycles: Is there Any Role?

It is well-known that progesterone supplementation improves implantation rates in fresh embryo transfer cycles. It has also been observed that there is a positive role of luteal support in hormonally controlled frozen-thawed ET cycles. In general, endogenous production of progesterone is sufficient to support implantation in a natural ovulation cycle in a fertile female.

In a large retrospective cohort study involving 1,158 frozen-thawed ET cycles, it was concluded that vaginal progesterone supplementation significantly improves pregnancy rates in natural FET cycles.[46] This suggested that

TABLE 1: Adjuvants in luteal phase support.

	Adjuvant	*Rationale*	*Evidence*
1.	Intravenous immunoglobulin	Inhibiting (NK) cell production and/or activity correcting abnormal Th1:Th2 ratio	No convincing evidence for the use and safety of IVIg
2.	Anti-TNF alpha agents	Increased TNF-alpha:interleukin-4 ratio-role in RIF	Lack of evidence to support its use owing to adverse effects like lymphoma
3.	Intravenous lipids	Inhibits Th1 cytokines and reduces the cytotoxic effect of NK cells	Routine use not recommended
4.	Corticosteroids	• Anti-inflammatory and immunosuppressive activity • Improves intraendometrial milie	Limited evidence to improve pregnancy rate (PR) in women undergoing conventional IVF and in those with autoimmune disorders and unexplained RIF
5	Low-dose aspirin	Increases uterine blood flow, enhances endometrial receptivity and improves implantation rates	• Lack of evidence supporting routine use • Limited evidence to support use in RPL
6.	LMWH (Low molecular weight heparin)	• Anti-thrombotic effect • There is increased incidence of thrombophilia in women with RIF. LMWH reduces formation of microthrombi at implantation site	• Routine use not warranted • Should be considered in women with thrombophilia and RIF
7.	Metformin	Modulation of insulin like growth factors	Beneficial effects in PCOS patients undergoing IVF by reducing risk of OHSS and improving CPR
8.	Myo-Inositol[51]	Acts on insulin, FSH, and LH receptors	Pivotal role in the development of oocytes and embryos
9.	Probiotics[52]	Reduces IL-6 and hs-CRP and increases IL-10 level	Beneficial effects in PCOS patients undergoing IVF by improving CPR
10.	L-Arginine[53,54]	Activates immune system and increases uterine vascular flow	Role in patients with recurrent thin endometrium

(CPR: clinical pregnancy rate; FSH: follicle-stimulating hormone; IVF: in vitro fertilization; IVIg: intravenous immunoglobulin; LH: luteinizing hormone; OHSS: ovarian hyperstimulation syndrome; PCOS: polycystic ovary syndrome; RIF: recurrent implantation failure; RPL: recurrent pregnancy loss; NK: natural killer; IL: interleukins; hs: high sensitivity)

patients undergoing ART treatment and FET cycles have suboptimal endogenous progesterone production.

Di Guardo[47] et al. developed a web based questionnaire for 1,480 clinicians on when to start, route, dosage, and duration of progesterone in luteal phase supplementation. It was concluded that most common practice is to start progesterone on day of oocyte retrieval via vaginal/intramuscular route and continue until 12 weeks gestation. Ten-year follow-up done by Shoham[48] et al. has further proved that practice of starting progesterone on day of egg retrieval has not changed yet. Survey has shown gradual increase in use of vaginal progesterone for LPS instead of intramuscular or oral route. Drakopoulos[49] et al. studied the role of dydrogesterone as LPS and found high oral bioavailability and specificity for P receptors suggesting higher efficacy than micronized progesterone. Decreased incidence of preeclampsia has been found in this study after use of dydrogesterone in natural and IUI cycles.

Adjuvants in Luteal Phase Support

Endometrial receptivity is considered critical for successful implantation. Potential mechanisms implicated for embryo implantation failure include endometrial immune hostility, suboptimal uterine perfusion, inadequate LPS, and increased myometrial contractility.

Adjuvant therapies have been used in IVF cycles in order to counteract the reasons for recurrent implantation failure, and to optimize IVF outcomes.

Various adjuvants that have been studied so far are listed in **Table 1**.[50]

KEY POINTS

- Luteal phase support is mandatory in assisted reproductive technology (ART) cycles to optimize reproductive outcomes.
- Progesterone and human chorionic gonadotropin (hCG) use in the luteal phase confers benefit to infertile women undergoing in vitro fertilization (IVF) treatment.
- Use of hCG for trigger is associated with greater risk of ovarian hyperstimulation syndrome (OHSS).
- Natural micronized progesterone as a luteal phase agent is not effective if taken orally.
- Vaginal and injectable progesterone have similar implantation and clinical pregnancy rates.
- Synthetic progesterone, dydrogesterone, has been found to be equally effective as vaginal micronized progesterone for luteal phase support (LPS) in ART cycles.
- Concomitant use of estrogen with progesterone does not seem to enhance the probability of implantation and pregnancy rates.

- Gonadotropin-releasing hormone agonist along with progesterone may have a promising role in improving IVF outcomes but more studies are needed to adopt this approach.
- Optimal timing of LPS is important, the window of starting LPS being within 24–48 hours from the oocyte retrieval.
- According to the literature available, there is no role of continuation of LPS beyond first positive beta hCG or first ultrasound showing viability. Although, the common practice by clinicians is to continue LPS till 12 weeks.
- Modified LPS in GnRH agonist triggered cycles in the form of hCG bolus and rLH has shown positive effect on pregnancy outcomes, but more studies are needed to support its use.
- Despite widespread use of adjuvants in LPS, current evidence does not recommend their routine use in all IVF cycles.

Dilemma in ART

CHAPTER 60

Poor Responders

Madhuri Milind Patil

INTRODUCTION

The successful endpoint of any infertility treatment is a live birth. This depends on various factors, including adequate number of follicles being stimulated, adequate number of oocytes retrieved in an assisted reproductive technology (ART) cycle, and quality of oocytes, and this, in turn, depends on ovarian response. According to the Bologna criteria,[1] poor ovarian response (POR) is defined as the presence of any two of the following three criteria:

1. Advanced maternal age (≥40 years) or any other risk factor for POR.
2. A previous POR (≤3 oocytes with a conventional stimulation protocol).
3. An abnormal ovarian reserve test (ORT) [i.e., antral follicle count (AFC), 5–7 follicles or anti-Müllerian hormone (AMH), 0.5–1.1 ng/mL].

All patients above the age of 40 years with an abnormal ORT are also considered poor responders. Apart from the above any two points, episodes of POR even after maximal stimulation are also sufficient to diagnose poor response, in the absence of advanced maternal age or abnormal ORT. At least one stimulated cycle is considered essential for the diagnosis of POR.

There are eight subgroups of poor responders according to the Bologna criteria as shown in **Table 1**.

But Bologna criteria are not considered ideal, thus making it difficult to manage women with POR.

TABLE 1: Eight subgroups of the ESHRE (European Society of Human Reproduction and Embryology) Bologna criteria.

Categories	*Subgroups*	*ESHRE criteria fulfilled*
No previous IVF attempt	≥ years (+ risk factor for POR) + abnormal ORT	1 + 3
One previous IVF attempt with POR	≥ 40 years (+ risk factor for POR)	1 + 2
	Abnormal ORT	2 + 3
	≥ 40 years (± risk factor for POR) + abnormal ORT	1 + 2 + 3
Two previous IVF attempts with POR	No risk factor for POR and normal ORT	Supplemental criteria 4
	≥ 40 years (± risk factor for POR) but normal ORT	1 + supplemental criteria 4
	Abnormal ORT but no risk factor for POR	3 + supplemental criteria 4
	≥ 40 years (± risk factor for POR) and abnormal ORT	1 + 3 + supplemental criteria 4

(IVF: in vitro fertilization; ORT: ovarian reserve test; POR: poor ovarian response)

Why is the Bologna Criteria not Ideal?

Bologna criteria are not ideal due to:

- Heterogeneity of subgroups due to absence of homogeneous subgroups for live birth rates (LBRs) **(Fig. 1)**
- Specific profiles of abnormal ovarian response like hypo- and suboptimal response not being included **(Fig. 2)**.
- Age-related aneuploidies affecting the "oocyte quality": It was observed by Colls et al.[2] that euploidy rate is independent of the number of blastocysts obtained but not of the age. Thus, we may obtain good-quality blastocysts, but they still could be aneuploid.

Thus came the *new classification* of patients with poor prognosis by the Patient Oriented Strategies Encompassing IndividualizeD Oocyte Number (POSEIDON) working group.[3]

The patients were then classified into four groups as follows:

Group 1:

- Young patients <35 years with adequate ovarian reserve parameters (AFC ≥5; AMH ≥1.2 ng/mL) and with an unexpected poor or suboptimal ovarian response
- Subgroup 1a: <4 oocytes*
- Subgroup 1b: 4–9 oocytes retrieved*

*After standard ovarian stimulation.

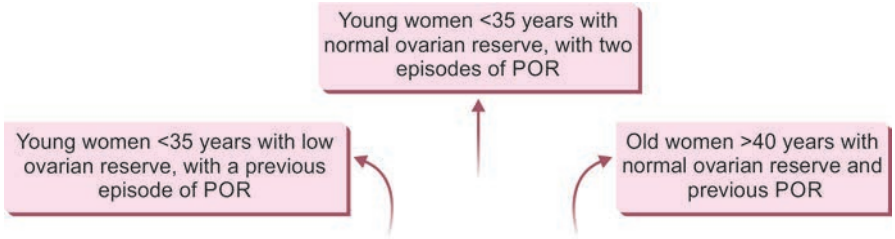

Fig. 1: Heterogeneity of subgroups for live birth rate. (POR: poor ovarian response)

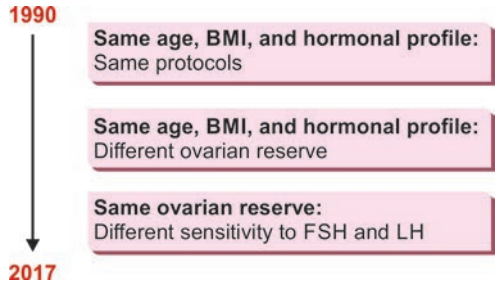

Fig. 2: Specific profiles and treatment over the last three decades. (BMI: body mass index; FSH: follicle-stimulating hormone; LH: luteinizing hormone)

Group 2:

- Older patients ≥35 years with adequate ovarian reserve parameters (AFC ≥5; AMH ≥1.2 ng/mL) and with an unexpected poor or suboptimal ovarian response
- Subgroup 2a: <4 oocytes*
- Subgroup 2b: 4–9 oocytes retrieved*

*After standard ovarian stimulation

Group 3: Young patients (<35 years) with poor ovarian reserve prestimulation parameters (AFC <5; AMH <1.2 ng/mL)

Group 4: Older patients (≥35 years) with poor ovarian reserve prestimulation parameters (AFC <5; AMH <1.2 ng/mL)

Thus, we must not only consider decreased ovarian reserve (DOR) patients as poor responders but also look at those patients with normal ovarian reserve who are hyporesponders. This is then based on the follicular output rate (FORT) after controlled ovarian stimulation (COS).[4] Thus, there could be women with good ovarian reserve but still having a poor response or vice versa where women with poor ovarian reserve have a good response to stimulation **(Fig. 3)**.

Thus, the first group of women are hyporesponders and have hyposensitivity to follicle-stimulating hormone (FSH) and show suboptimal or unexpected poor response to exogenous FSH. This response is in no way related to their ovarian reserve.[5] These women at times even when the ovarian response is normal (i.e., >5 eggs) tend to show an increase in the cumulative FSH dose (i.e., >2,500–3,000 IU) required and in the stimulation length (hyposensitivity to FSH).[6] These normo-ovulatory normogonadotropic young patients may have an initial slow (poor) response to recombinant human FSH (r-hFSH) characterized by normal follicular cohort with no follicle >10 mm on day 8 of stimulation or "stagnation" between day 7 and day 10.[7,8]

This phenomenon reflects hyposensitivity of granulosa cells to standard FSH dose and is associated with higher FSH consumption, low FORT, unexpected poor response (i.e., <3 eggs retrieved), and lower pregnancy rates (PRs). If hyporesponse is identified early (i.e., day 5–8 of COS), recombinant human luteinizing hormone (r-hLH)/human menopausal gonadotropin (hMG) is effective in rescuing follicle/oocyte number (FORT) and embryo competence.

The POSEIDON group[3] labeled patients with POR as low prognosis group and categorized women with POR by age and ovarian reserve **(Flowchart 1)**.

For this, the regulation of activation and growth of the antral follicles should be known though till date it stands unclear. It is postulated that the activation and growth of the primordial and preantral follicles may be due to local growth factor such as transforming growth factor-beta (TGF-β) and bone morphogenic protein (BMP), release of inhibitory signal or increase in stimulatory signals, local milieu of the neighboring follicles or stroma, and several sources still unknown.

Another new classification was coined by Yovich et al. and was called "PIVET poor-prognosis criteria".[9] The criteria used for classification of patients as poor prognosis were as follows:[9]

- All women aged 40 years and above.
- All women categorized as poor prognosis from previous in vitro fertilization (IVF), meaning cases of (≥3).
- All PORs (generating ≤4 oocytes despite FSH dosing maximized at 450 IU daily).
- All cases with "E" categorization according to PIVET FSH-dosing algorithms (AMH <5 pmol/L and AFC <5 follicles) matching ORT according to Bologna criteria.
- All cases where resultant embryo quality rated poor, meaning no suitable blastocysts for cryopreservation (good prognosis in IVF generates 8–12 oocytes resulting in ≥3 blastocysts with gradings 3BB or better).

PREDICTION OF POOR RESPONDERS

One can predict DOR but not poor responder with good ovarian reserve. The ORTs are illustrated in **Flowchart 2**.

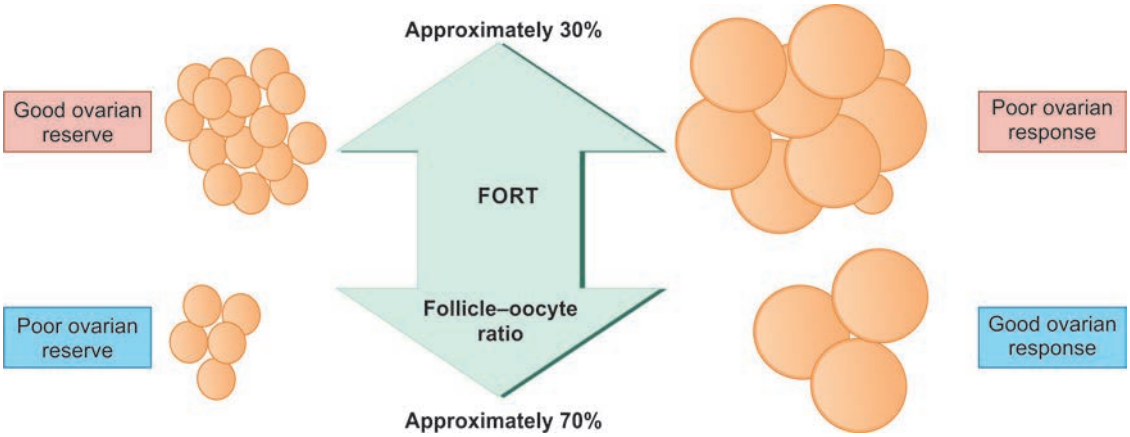

Fig. 3: Follicle–oocyte ratio. (FORT: follicular output rate)

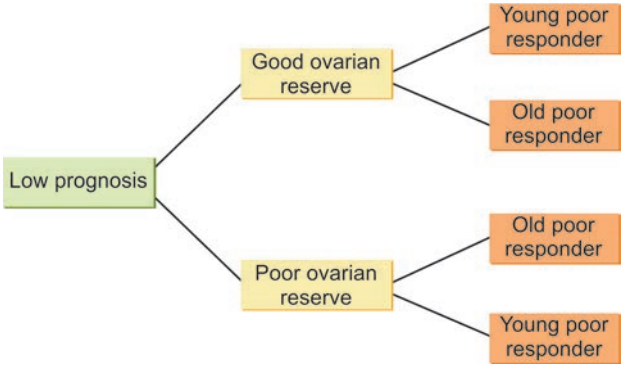
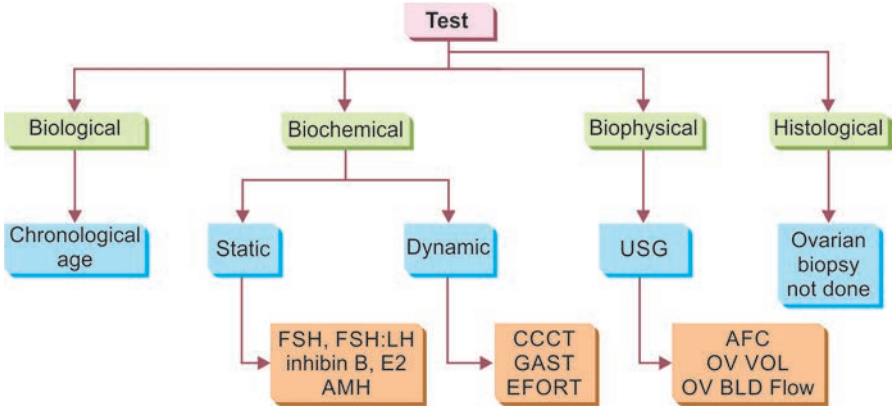
Flowchart 1: Classification of poor responders by age and ovarian reserve.



Flowchart 2: Ovarian reserve test.



(AFC: antral follicle count; AMH: anti-Müllerian hormone; CCCT: clomiphene citrate challenge test; E2: estradiol; EFORT: exogenous FSH ovarian response test; FSH: follicle-stimulating hormone; GAST: gonadotropin agonist stimulation test; LH: luteinizing hormone; OV BLD: ovarian blood; OV VOL: ovarian volume; USG: ultrasonography)

Markers of Ovarian Reserve that will Predict Poor Response

- Age >40 years
- 4–6 months of oligomenorrhea
- Elevated FSH level of >25 IU/L at two occasions >4 weeks apart or once accompanied by low (<100 pmol/L) estradiol (E2) during COS
- AMH <0.35 ng/mL
- Day 3 inhibin B levels <45 pg/mL
- Low testosterone <0.51 nmol/L
- Transvaginal ultrasonography (USG) showing an AFC of <5–6 and ovarian volume of <3 cm.[3]

Of these, AFC and AMH have the best sensitivity and specificity. Both AMH and AFC decrease with age. Optimum cutoff value for AFC is ≤10 but the post-test probability was highest at cutoff levels of <8.[10]

Ovarian volume correlates with the number of growing follicles, but not with the number of oocytes retrieved.[11] Women with small ovaries with a volume <3 cm^3 have a high cancellation rate of IVF cycles[11] but are of limited prognostic value for IVF when LBR is taken into consideration.

There is a direct relationship seen between AMH and DOR. The optimum cutoff value for AMH to predict DOR is 0.99 ng/mL, but posttest probability was highest at cutoff levels of 0.59 ng/mL.[12] Evaluation of AFC and AMH as combined test did not significantly improve the level of prediction [area under curve (AUC) <0.946] of POR.[10] Though AMH gives information about the primordial follicular pool, it is not a panacea in determining DOR as there is significant discordance seen between AMH values and AFC. Moreover, AMH sample instability is one of the causes of nonreproducibility and sample storage is of utmost importance to obtain correct values for prediction of response.[13-17]

Day 3 Follicle-stimulating Hormone

Evaluation has several limitations for prediction of POR. This is because FSH is only an indirect measure of the size of follicle cohort and reflective of decreased granulosa cell function.[18] FSH does not diagnose DOR until high threshold values are reached[19] and high levels do not correlate with oocyte quality decline.[20] Moreover, intercycle and intersample variations may result in disparity in FSH measurements.[21]

Elevated day 3 FSH levels may also constitute a heterogeneous group where the women could have true reduced ovarian reserve or it could also be due to the presence of heterophilic antibodies or FSH receptor polymorphism in patients with otherwise normal ovaries.[22] It was seen that the PRs are significantly higher ($p < 0.05$) in women with normal FSH and age <36 years compared to those who are 36 years or more.[23] Elevated day 3 FSH/luteinizing hormone (LH) ratio is also supposed to be associated with inferior outcome in IVF treatment cycles and may be used as an additional predictor for decreased ovarian response.[24] With the three-variable model (FSH, AMH, and AFC), the proportion of patients misdiagnosed (11%) is almost halved when compared to the best single-variable model of AFC (20%).[25]

Day 2 Serum Estradiol

Elevated day 2 E2 levels of >75–80 pg/mL indicate an inappropriately advanced stage of follicular development, consistent with DOR and ovarian aging or simply reflect the presence of functional ovarian cysts. Prediction of ovarian reserve using E2 levels is still debatable[26] and no relationship has been found between serum E2 levels and PRs.[27]

Inhibin B

Inhibin B has a sensitivity of 87% and specificity of 49% in predicting DOR. Using 45 pg/mL as threshold for DOR,[28] the positive likelihood ratio of having DOR is 1.7. Inhibin B levels can be influenced by the amount of fat in an individual and lower levels are seen in obese women.[29]

The odds ratio for clinical pregnancy rate (CPR) (basal serum inhibin >45 vs. <45 pg/mL) was 6.8 [confidence interval (CI) 1.8–25.6]. It has been observed that inhibin B level is a better predictor for cancellation of cycles than ovarian response.

By using the three-variable model (AFC, FSH, and inhibin B), the proportion of patients misdiagnosed (11%) is almost halved when compared to the best single-variable model of AFC (20%).[25]

Of the dynamic test, one could use only the clomiphene citrate challenge test, which is of value in unmasking poor responders to COS who would not have been detected by basal FSH screening alone. Abnormal test is associated with a reduced chance of pregnancy. Exogenous FSH ovarian response test (EFORT) and gonadotropin agonist stimulation test (GAST) are only for research purpose and not used routinely in clinical practice.

Evaluation of Androgens in Diagnosis of Decreased Ovarian Reserve

Dehydroepiandrosterone sulfate (DHEAS) concentration was not significantly different between poor and normal responders or between pregnant and nonpregnant women. Lower basal testosterone was predictive, but with limited ability as a single marker for DOR. DOR for testosterone at cutoff point <0.51 nmol/L has a sensitivity of 88.6% and specificity of 98.3%, whereas for CPR at cutoff point ≤0.22 nmol/L has a sensitivity of 75% and specificity of 62.5%. Thus, we can conclude that apart from age, AMH and AFC had better predictive values for DOR.[30] But age still remains a better predictor of PR in women undergoing IVF.[31]

MANAGEMENT OF POOR RESPONDERS

Therapeutic strategies used to improve the success rate of ART in women with DOR and those with poor response in previous cycles have not helped much.

All types of empirical interventions are being tried, some with a hypothesis behind them, which might be biologically plausible, others with less plausibility but it is extremely difficult to establish criteria to define the population that should be treated and/or how to treat them. The different strategies that can be advocated to this group of women are to alter treatment protocols, improve the results with adjuvants, refuse treatment, or advise egg donation.

Once identified with DOR, we need to divide these women into two groups, one young that is <40 years and the other old that is >40 years, as different strategies may be applied for management. If women are >40 years, probably egg donation may be a better option as against those who are <40 years, where one could try new strategies to improve

the outcome by focusing on oocyte competence since the number may be not be increased.

Interventions to enhance IVF outcome in women with DOR and poor responders are shown in **Table 2**.

Role of Adjuvants

Addition of Growth Hormone and Growth Hormone-releasing Factor

Growth hormone (GH) enhances the response of granulosa cells to gonadotropins[32] and basically acts by increasing the local production of insulin-like growth factor-1 (IGF-1), which modulates the action of FSH on granulosa cells, thus improving ovarian steroidogenesis.[33] GH is also known to induce LH receptor formation and also augment aromatase activity.[34] It is used in the dose of 8–12 IU/day starting on either day 2 or 3 of the menstrual cycle along with the gonadotropins and given till the day of human chorionic gonadotropin (hCG) injection. Initially, beneficial effects of GH were reported on the probability of live birth in women with DOR but as the sample size was small and statistical evidence was small, no firm conclusions could be drawn on its efficacy in improving ART cycle outcomes.

A recent publication by Bassiouny et al.[35] showed that GH co-treatment resulted in a higher number of oocytes collected, higher number of metaphase II (MII) oocytes retrieved with higher number of oocytes being fertilized, and higher number of embryos being transferred. The LBRs were also reported to be higher. Despite this, increase in the results did not reach statistical significance.[36] Therefore, it is mandatory for an individual clinician to decide on the use of GH according to their experience as one has to remember that the cost of treatment cycle increases considerably with the use of GH.

Ipsa et al. have shown that both GH and IGF have been demonstrated to promote steroidogenesis in granulosa and theca cells through alteration in metabolizing enzymes and work in synergy with gonadotropins. GH also promotes follicular selection and survival by decreasing follicular atresia through intracellular signaling pathways.[37] GH co-treatment increased the receptor density for granulosa follicle-stimulating hormone receptor (FSHR), bone morphogenetic protein receptor type 1B (BMPR1B), luteinizing hormone receptor (LHR), and growth hormone receptor (GHR) compared with the non-GH treated patients of the same age and ovarian reserve, which is supposed to increase GHR activity and result in a significant increase in PR.[38] GH supplementation reduced the cycle cancellation rate in women aged >40 years poor responders and promoted favorable ultrasonic endometrial pattern, with improved implantation and PR. This was related to the beneficial actions on embryo quality and endometrial receptivity.[39] Other publications have concluded that there is an increase in the number of oocytes retrieved but no difference was seen in the ongoing PR and LBR.[40,41] Two publications in 2020 have shown that the use of GH increases the CPR and LBR with an increased number of oocytes being retrieved with a lower cancellation rate.[42,43] Cozzolino et al. in a systemic review and meta-analysis showed a beneficial effect only on CPR, number of oocytes retrieved (mean difference 1.62), number of MII oocytes (mean difference 2.06), and number of embryos available to transfer but not on ongoing PR, LBR, or miscarriage rate.[44] Despite the evidence, European Society of Human Reproduction and Embryology (ESHRE) guidelines do not recommend the use of GH in poor responders.[45]

TABLE 2: Interventions to enhance IVF outcome.

Adjuvant therapy	*Change in OI protocols and ART*
• Growth hormone (GH) or GH-releasing factor (GHRF) • Pyridostigmine • Androgens: Transdermal testosterone, DHEA • Aspirin • L-arginine aromatase inhibitors • Antioxidants	• Modifications of long GnRH agonist protocol • Use of GnRH agonist short protocol • Use of GnRH antagonist protocol • Natural or mild cycle IVF • Modifications of ovarian stimulation • Use of LH in COS • Intracytoplasmic sperm injection • Day 2 versus day 3 ET

(ART: assisted reproductive technology; COS: controlled ovarian stimulation; DHEA: dehydroepiandrosterone; ET: embryo transfer; GnRH: gonadotropin-releasing hormone; IVR: in vitro fertilization LH: luteinizing hormone; OI: ovulation induction)

Growth Hormone-releasing Factor

Growth hormone-releasing factor (GHRF) results in a significant increase in GH and IGF-1 concentration, but no statistically significant differences were found in the number of oocytes retrieved, fertilization rate, and CPR.[46]

Pyridostigmine

Addition of pyridostigmine results in an increase in GH levels but has not shown to improve the ongoing PR or LBR in women with POR.

Initial studies which compared pyridostigmine with placebo reported lower number of ampoules used (38.4 vs. 48.3), higher number of oocytes collected (5.9 vs. 3.7), and improved PRs (25.7 vs. 11.4%) but did not improve the ongoing PR and LBR.[47,48] Thus, recent literature does not support the use of pyridostigmine as an adjuvant in poor responders.

Low-dose Aspirin

Addition of low-dose aspirin reported may improve gonadotropin responsiveness, implantation rates, and PRs due to enhanced blood flow to ovaries.[49] The evidence supporting the effect of a low dose of aspirin in women undergoing IVF is poor and controversial.[50,51] But beneficial

effect is not currently supported by literature as no significant increase in implantation and PR was noted.[52] There was another study which looked into the combined effect of aspirin and prednisolone and did not find any beneficial effects.[53]

L-arginine

Addition of L-arginine results in increased number of oocytes being retrieved but no beneficial effect was seen on PRs.

Addition of Estradiol in the Luteal Phase

One meta-analysis has concluded that addition of E2 in the luteal phase decreases the risk of cycle cancellation and increases the chance of clinical pregnancy in poor responder patients[54] by improving the synchronization of the follicular pool available for COS.[55] This meta-analysis was strongly criticized because of methodological pitfall and not including any randomized controlled trial (RCT).[56]

Androgen Supplementation

Androgen supplementation being a simple and inexpensive method has been widely used in poor responders despite there being no adequate evidence in the view of lack of adequately powered RCTs. Garcia-Velasco et al. have shown that testosterone in vitro does increase the expression of the FSH receptor in granulosa cells thus increasing the responsiveness to gonadotropins.[57] It was also seen that androgens play a critical role in early follicular development and granulosa cell proliferation.[58] However, the hypothesis of androgen use in poor responders is weakened by the finding of similar intrafollicular androgenic concentrations in both normal and young or old poor responders.[59] It is also known that androgen excess stimulates early stages of follicular growth increasing the number of preantral and antral follicles, which in turn may deplete the ovarian reserve faster.[60,61]

Transdermal Testosterone

It is known that the use of transdermal testosterone is a safe and effective way of increasing intraovarian androgen concentration.[62,63] Transdermal testosterone pretreatment is also associated with decreased duration and total dose of gonadotropins and increased number of cumulus–oocyte complexes (COCs) retrieved which increases CPR by 15% and LBR by 11% in poor responders undergoing COS for IVF. It is used in the dose of 10–12.5 mg/day or 20 μg/kg/day starting from day 15 for a maximum of 2–3 weeks in the menstrual cycle preceding ovarian stimulation.[64,65] However, Bosdou et al.[66] concluded in their recent publication in 2016 that transdermal testosterone pretreatment at a dose of 10 mg/day for 21 days did not increase the number of COCs retrieved by >1.5. They also reported that there was no increase in LBR though it may be associated with reduced duration of gonadotropins stimulation and total dose of gonadotropins required. ESHRE guidelines also do not recommend the use of testosterone before ovulation induction.[45]

Dehydroepiandrosterone Pretreatment

The effect of dehydroepiandrosterone (DHEA) in the management of poor response is controversial with some studies reporting beneficial effects while others reporting no significant benefit. DHEA given in a dose of 75 mg/day for at least 6–8 weeks before stimulation (Wiser et al., 2010) has been shown to raise the IGF-1 concentration, and thus to enhance the gonadotropin effect.[58,67]

But most studies published had insufficient sample size, and therefore its use cannot be supported in poor responders to increase CPRs, LBRs, or the number of COCs retrieved. The Cochrane review in 2015[68] concluded that pretreatment with DHEA or testosterone may be associated with improved LBRs though the overall quality of the evidence is moderate due to small sample size of the studies published. Thus, androgen supplementation prior to ovarian stimulation is not supported by the best available evidence though it may be associated with a slight improvement in LBR. Definitive conclusions regarding the clinical role of either androgen await evidence from further well-designed studies. There is a need to identify a subgroup of poor responders that have theca cell failure but retain a relatively preserved granulosa cell function. Identifying this particular population and modulating their intrafollicular androgen environment may improve their ovarian response. Use of pretreatment androgens may be a useful approach for patients known to be poor responders but having normal basal FSH concentrations. It may be an option in patients for whom other modalities of treatment have failed till further decision on treatment like oocyte donation and adoption may be considered. ESHRE guidelines on ovarian stimulation also do not recommend the use of DHEA, before and/or during stimulation in poor responders.[45] But the network study concluded that the use of DHEA and CoQ10 treatments as compared to controls resulted in a significantly higher chance of clinical pregnancy and resulted in lower requirement of gonadotropin dose.[69]

Antioxidants

Oxidative stress may be one of the causative factors for female infertility due to increased level of reactive oxygen species (ROS).[70-72] The oxidative stress and increased ROS play an important role in oocyte maturation, ovarian steroidogenesis, formation of the corpus luteum and luteolysis, fertilization, embryo development, and pregnancy.[71,73,74] Oxidative damage can affect the oocyte quality and this is then accompanied by poor oocyte fertilization. Antioxidant

therapy for 3 months before IVF cycles may decrease oxidative stress both in serum and in follicular fluid proteins and improve the follicular microenvironment and consequently increasing the number of good-quality oocytes.[75]

CHANGE IN PROTOCOL

Change in the Gonadotropin-Releasing Hormone Analog Protocol

Gonadotropin-releasing Hormone Agonists

Controlled ovarian stimulation strategies using gonadotropin-releasing hormone (GnRH) agonist and gonadotropins use GnRH agonist either in long, short, or ultrashort protocol. Microdose protocol has also been tried in women with poor response to ovarian stimulation.

Gonadotropin-releasing hormone agonist long protocol ***(Fig. 4A)****:* Here, GnRH agonist is started in the midluteal phase of the previous menstrual cycle in the dose of 500 µg and then the dose is reduced to half once the gonadotropins are started.[76] This protocol resulted in lower total gonadotropin dose, shorter stimulation time and increased number of oocytes retrieved, better quality of embryos obtained, and low cancellation rates.[77,78] Published data have reported conflicting outcomes, some reporting improvement while others not.[79-81]

"Stop" GnRH agonist protocols: This protocol involves stopping GnRH agonist once pituitary suppression has happened and COS has started. Two prospective RCTs did not show any statistical improvement in PRs or in cancellation rates.[82,83] But other prospective trials with historical controls have shown improved outcomes with an increased number of oocytes collected, high PRs, and lower cancellation rates.[84-86]

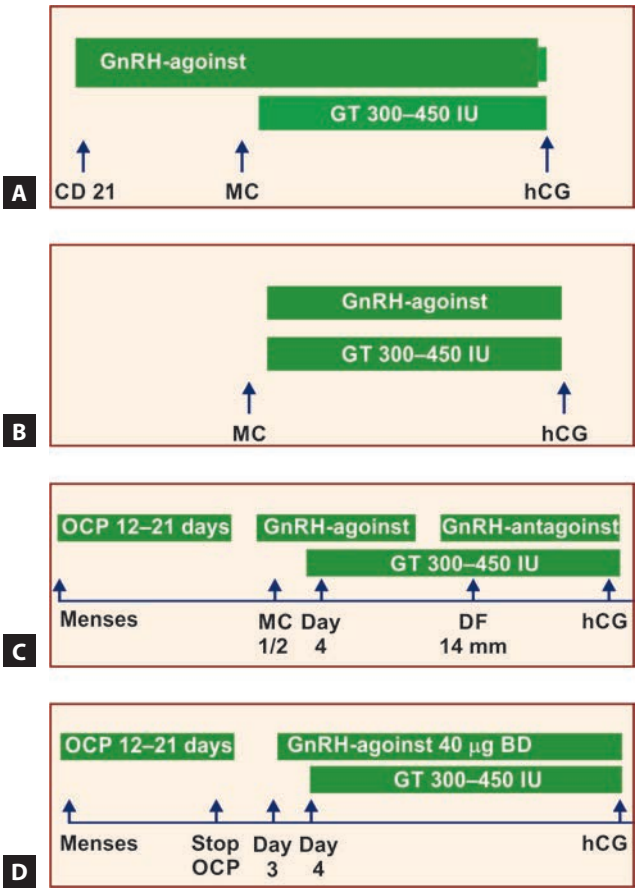
Gonadotropin-releasing hormone agonist flare or short protocol ***(Fig. 4B)****:* In this protocol, gonadotropins are started 2–3 days following the initiation of GnRH agonist. This protocol takes the advantage of the initial flare of gonadotropin secretion that occurs due to initial stimulatory effect on pituitary hormone levels once the GnRH agonist is started. This improves the ovarian response without excessive ovarian suppression.

The results of this protocol are also conflicting in the literature. Some publications have reported higher implantation and PRs, lower cancellation cycles, decreased miscarriage rates, and decreased total gonadotropin dose.[87-89] There are other studies which have reported poor outcome with GnRH agonist short protocol in women who are poor responders. The poor outcome is attributed to premature rise in the LH and progesterone levels in the follicular phase; these high levels could affect the oocyte quality, endometrial receptivity, or both.[90-97]

Modified flare protocol: High dose of GnRH agonist is administered for the first 4 days, followed by standard agonist dose for the rest of the period along with gonadotropins till the day of hCG administration. PRs reported with this protocol in one study were between 14 and 33.3%.[98,99]

Ultrashort GnRH agonist protocol ***(Fig. 4C)****:* Here, the oral contraceptive pills (OCPs) are given in the previous cycle and GnRH agonist in the dose of 500 µg is started on day 1 of menstrual cycle, and on day 4, gonadotropins are started in the dose of 300–450 IU. To prevent LH surge, GnRH antagonists are started once the dominant follicle is 14 mm and continued till the day of hCG administration. In this protocol, the incidence of high LH in the early follicular phase was higher with subsequent high progesterone levels in the early follicular phase and on the day of hCG.

Microdose flare regimen ***(Fig. 4D)****:* In 1994, the use of microdose flare protocol for poor responders was reported by Scott et al. In this protocol, the GnRH agonist is administered after pretreatment with OCPs for 12–21 days in the dose of 40 µg twice a day. It is started on the 3rd day after the OCP is stopped and then on day 5, the gonadotropins are started in



Figs. 4A to D: (A) Long protocol; (B) Short protocol; (C) Ultrashort protocol; (D) Microdose protocol. (CD: cycle day; DF: dominant follicle; GnRh: gonadotropin-releasing hormone; GT: gonadotropin; hCG: human chorionic gonadotropin; MC: menstrual cycle; OCP: oral contraceptive pill)

the dose of 300–450 IU.[100,101] Pretreatment with OCP prevents ovulation and thus the problem of persistent corpus luteum with high progesterone levels in the early follicular phase.[102] OCPs also reduce the early follicular phase LH levels.[102] Most published studies have shown significant improvement in peak E2, follicle recruitment, and number of mature oocytes at retrieval, fewer cycle cancellations, improved implantation rates, and ongoing PRs.[100,103]

When the microdose flare protocol was compared with a long luteal with decreasing dose of GnRH agonist, higher cancellation rates and lower clinical pregnancies were observed with the microdose protocol.[104] However, the choice between the different GnRH agonist protocols in poor responders remains controversial. Some investigators have shown improvement with the short protocol while others have not.[105,106]

In the study of Detti et al.,[107] when stop protocol, microdose flare protocol and short protocol were compared, it was concluded that the microdose flare protocol demonstrated a trend toward higher delivery rates.

*Gonadotropin-releasing hormone antagonist regimens **(Fig. 5)**:* The use of GnRH antagonists has given new hope in the management of poor responders as it prevents premature LH surge without minimizing the suppressive effect on pituitary as seen with GnRH agonist.[108] The GnRH antagonist protocol provides several advantages with shorter duration of stimulation, lower total doses of gonadotropins,

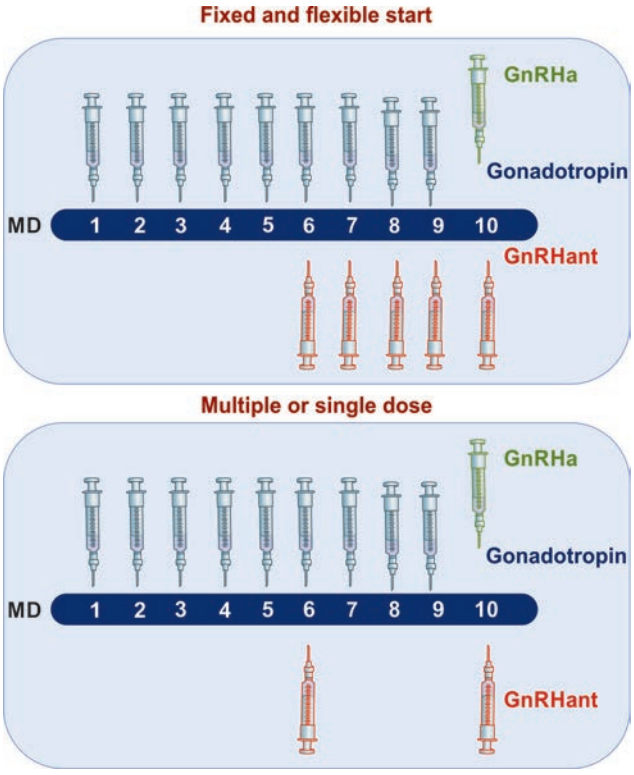


Fig. 5: GnRH antagonist protocol.
(GnRHa: gonadotropin-releasing hormone agonist; GnRHant: gonadotropin-releasing hormone antagonist; MD: menstrual day)

no increased risk of cyst formation, and no hormonal withdrawal symptoms.[109-111] However, GnRH antagonist cycles can result in lower E2 levels than agonist cycles[112] with consequent lower implantation and PRs.

Pretreatment with OCP in a GnRH antagonist cycle may help in scheduling flexibility with a more uniform cohort of follicular recruitment, but it is then associated with higher total doses of gonadotropins for ovarian stimulation.

Gonadotropin-releasing Hormone Antagonist versus Gonadotropin-releasing Hormone Agonist in Poor Responders

A meta-analysis[113] published in 2006 compared the efficacy of GnRH antagonist versus GnRH agonist in poor ovarian responders and did not show any difference in cycle cancellation rate, number of mature oocytes and CPR, per oocyte retrieval, or per embryo transfer (ET). The Cochrane review reported that the GnRH antagonist protocol produced a higher number of oocytes and used a lower dose of gonadotropins compared with the GnRH agonist long protocol. The GnRH agonist flare-up protocol had an increased frequency of IVF cancellation compared with the GnRH agonist long protocol.

A recent RCT by Sunkara et al. concluded that both the GnRH agonist long protocol and the GnRH antagonist protocol are equally efficient for COS in poor responders with a comparable number of oocytes retrieved.[33,105] The GnRH antagonist regimen is beneficial by reducing the burden of treatment as the number of days of gonadotropin stimulation and the dose required is much less with GnRH antagonist protocol. Moreover, as the cycle is not downregulated earlier, one can assess the ovarian reserve which gives the flexibility on whether or not to initiate COS. The cost of the cycle is also lower with lesser number of days of stimulation and lower total gonadotropin dose along with lesser incidence for cycle cancellation once stimulation is initiated in view of absent response. There were certain publications which showed conflicting and varied results when long GnRH agonist was compared with the GnRH antagonist regimen.[114-117]

Though the short and ultrashort GnRH agonist regimens are being used frequently due to their flare effect at the beginning of stimulation, they have been shown to be less effective than the GnRH agonist long protocol and GnRH antagonist protocol. The inferior outcome with the short agonist protocol is related to the elevated progesterone levels during the early follicular phase as a result of the initial flare effect of the GnRH agonist.[118] No relevant differences in PRs or oocyte numbers between GnRH agonist and GnRH antagonist protocols were also reported by Griesinger et al. in their meta-analysis.[119] ESHRE guidelines have concluded that GnRH antagonist and GnRH agonist are equally recommended for predicted low responders.[45]

Change in the Gonadotropin Type and Dose Increase the Dose of Follicle-stimulating Hormone

Most clinicians think that the oocyte yield will be better if the gonadotropin dose is increased. However, this increment in oocytes number and PR with increase of FSH dose was not seen in the studies published.[120-123] Berkkanoglu and Ozgur found no differences between the starting dose of 300, 450, and 600 UI of gonadotropins in terms of retrieved oocytes, number of embryos obtained, and PRs.[124]

Loutradis et al.[125] in their study concluded that FSH receptor gene polymorphisms may play a role in FSH response. Infertile women with ovarian dysfunction tend to carry the Ser/Ser allelic variant, whereas good responders carry the Asn/Ser allelic variant. It was observed that women with Asn/Ser allelic variant have a higher FSH sensitivity and respond with an increased number of follicles and oocytes. The Ser/Ser genotype variant requires a significantly higher gonadotropin dose.

Several clinicians use high doses of gonadotropins (450–600 IU) in the hope of getting a good response but a high-dose gonadotropin regimen using >450 IU has not shown to increase the number of oocytes retrieved or improved the probability of pregnancy in poor responders.[121,122,126]

Today, most clinics use a starting dose of 300–375 IU and a maximum daily dose of 450 IU. A worldwide survey of IVF clinics reported that 24% of the respondents said that their starting dose is >450 IU and when it came to the maximum daily dose that could be considered acceptable, about 93% of respondents reported to have used 600 IU, 5.9% reported to use 900 IU, and 1% would consider a dose as high as 1,200 IU.[127] According to the ESHRE guidelines on ovulation induction, a gonadotropin dose higher than 300 is not recommended for predicted poor responders.[45]

Use of Recombinant Follicle-stimulating Hormone

There is no conclusive evidence on using recombinant follicle-stimulating hormone (rFSH) instead of urinary FSH or hMG in poor responders.[128-132] In poor responders where the total dose of gonadotropins is going to be higher, using hMG is a more cost-effective option.[133] All randomized prospective trials have documented equivalence and similarity in results with both rFSH and hMG.[134,135]

Luteal Initiation of Follicle-stimulating Hormone

We know that follicular recruitment begins in the premenstrual period due to rise in intermenstrual FSH levels. Luteal initiation of FSH might increase the number of recruited follicles by opening the recruitment window in the late luteal phase of the preceding cycle.[136] In a prospective randomized trial,[137] the results with luteal initiation of FSH had high cancellation rates and lower PRs.

Use of Luteinizing Hormone in Controlled Ovarian Stimulation

Small doses of LH when used early in ovarian stimulation in IVF-ET cycles have beneficial effects in quality of oocytes, especially in poor responders.[138] We know that LH is necessary to have optimal levels of E2 during COS and levels <1.5 IU/L have shown to be detrimental.[139] Low periovulatory levels are associated with impaired fertilization and increased early pregnancy loss.[140,141] It was also observed in women with low ovarian reserve and poor responders that the number and quality of the embryos along with the developmental potential and embryogenesis is much better when the follicles are exposed to LH from the beginning of the stimulation protocol, rather than only during the later phase of the follicular stimulation.[142]

Addition of LH either in the form of hMG or recombinant LH (rLH) from the beginning of stimulation did not show a significant difference in the total dose of gonadotropin required for ovarian stimulation, in the duration of stimulation, or in the number of oocytes retrieved. There was also no significant increase in the CPR but there was a significant increase in the LBR.[8,143] A recent meta-analysis, however, showed higher implantation and CPRs in the rLH-supplemented group compared with rFSH alone.[144]

Addition of LH to POSEIDON groups 1, 2, and 3 has been shown to improve FORT and follicle-to-oocyte index (FOI) by overcoming hyposensitivity to FSH with a significant increase in CPR by 30%.[145-148] Poor Responder Outcome Prediction (PROsPeR) score is defined as the sum of two conditions: age over 40 years and fewer than two oocytes in a previous cycle or an AMH concentration <0.5 ng/mL.[149] The score can be used to categorize three levels (0, 1, and 2) of increasing baseline severity.[149] LH supplementation increases the cumulative LBR in moderate and severe POR groups.[149]

Low Human Chorionic Gonadotropin Dose in Early Stimulation Phase

Human chorionic gonadotropin can be used as an alternative to rLH or hMG. hCG can be used in the dose of 200 IU either for the first 5 days of stimulation, entire period of stimulation, or could be added in the late follicular phase. Addition of hCG was also associated with a lower number of gonadotropin ampoules used, higher fertilization rate, higher implantation rate, and better PR. It was also observed that the percentage of mature oocytes and the number and quality of embryos were comparable between rLH and hCG, as well as hMG and hCG. It was the longer plasma half-life of hCG (half-life of hCG is 33 hours while half-life of rLH is 10–12 hours) that resulted in a better and prolonged effect in the COS protocol. The longer half-life also permits highly effective and more stable occupancy of the LH/hCG receptors, which resulted in higher E2 levels.[150]

Addition of Clomiphene Citrate or Aromatase Inhibitors to Gonadotropin Therapy

Clomiphene Citrate

Clomiphene citrate results in the flare of endogenous gonadotropin secretion. When used with GnRH antagonist, it can prevent the premature rise of LH.

Using mild stimulation protocol which utilizes clomiphene citrate with gonadotropins in a GnRH antagonist protocol resulted in a higher number of oocytes being retrieved and a significantly lower cancellation rate with higher implantation and PRs.[151,152] When using clomiphene citrate, one needs to keep in mind the negative effect on endometrial receptivity because of its antiestrogenic effects and it is preferable to freeze all embryos and transfer them in a hormone replacement treatment (HRT) cycle.

There is insufficient evidence to recommend mild stimulation in normal or hyper-responders but it may be recommended in poor responders to decrease the burden of treatment (conditional low-quality evidence).[45] There is moderate- to high-quality evidence on pregnancy outcomes. There was no significant difference in the CPR and live birth rate despite high-grade embryos in the mild stimulation IVF in poor responders. Fewer oocytes and embryos were obtained with mild stimulation though the number and proportion of high-grade embryos were similar in both mild IVF and conventional IVF.[153,154] Mild IVF also resulted in reduced gonadotropin use and cost.[153,154] There were two papers published in 2021, which concluded that mild ovarian stimulation for IVF can be considered for poor responders without compromising pregnancy outcomes but reducing treatment burden and cost.[155,156] No difference was noted in the LBR, cumulative LBR, ongoing PR, cancellation rate, and proportion of high-grade embryos between mild and conventional stimulation.[155,156] With mild stimulation, the number of oocytes retrieved and embryos created were significantly less in the mild stimulation group.[155,156] The dose of gonadotropins required was also significantly less in the mild stimulation group.[155,156] ESHRE guidelines recommend the use of clomiphene citrate either alone or in combination with gonadotropins in poor responders.[45]

Aromatase Inhibitors

Aromatase inhibitors block estrogen synthesis and decrease its circulating levels, thus resulting in withdrawal of the negative feedback effects on the pituitary resulting in increased release of endogenous gonadotropins. Decrease in aromatase activity results in accumulation of follicular androgens, which may increase the follicular sensitivity through amplification of FSH receptor gene expression[157] or stimulate IGF-1 which may act in synergy with FSH.[158] Recent data suggest that letrozole when used in poor responders may improve ovarian response to FSH and also reduce gonadotropin dose required for stimulation.[159] It also increased the number of preovulatory follicles without having a negative effect on PRs.[160] Letrozole and other aromatase inhibitors have not been extensively used in women of reproductive age, so they have to be evaluated more carefully with larger randomized studies. Addition of letrozole to ovarian stimulation is not recommended in poor responders.[45] Polyzos et al. in their paper concluded that treatment in poor responders should be individualized rather than a "one fits all" mild stimulation approach where clomiphene citrate or letrozole is used with gonadotropins.[161]

Dual Stimulation (Fig. 6)

Dual stimulation protocol is based on the presence of multiple waves of follicle recruitment occurring regularly during a normal menstrual cycle. The follicles in each wave are similar, but not identical in diameter.[162]

Stimulation in the follicular and luteal phases of the same menstrual cycle resulted in the formation of a similar number of blastocysts in patients with POR. Blastocysts obtained from luteal phase stimulation contributed significantly to the final transferable blastocyst yield, thus increasing the number of patients undergoing ET per menstrual cycle.[163] Dual stimulation using corifollitropin alfa and a subsequent individualized FSH dose appears to be a valid alternative to conventional follicular stimulation, decreasing the risk of cycle cancellation.[164] The greatest benefit of dual stimulation is the accumulation of oocytes in a single cycle of stimulation, minimizing the time in which it will be performed. It also allows the production of a larger number of embryos, which can then be genetically evaluated, thus favoring the final clinical result.

But according to the ESHRE guidelines, dual stimulation in poor responders should be used only in the context of clinical research.[45] Nonconventional start of ovarian stimulation in the luteal phase is not recommended.[45]

Natural Cycle

Though the first successful IVF treatment was performed in a natural cycle,[165] it was abandoned later due to the occurrence of the premature LH surge which resulted in high cancellation rates. Though the cancellation rates with a natural cycle are higher, it is postulated that a natural cycle can provide a single oocyte of a much better quality with a better fertilization and implantation rate as compared to the stimulated cycles. This will allow us the transfer of a healthy embryo into a more receptive endometrial environment which may not be the case in COS cycles due to high E2 levels.[166-169] Moreover, the cost of the cycle is also very low and more patient friendly.[170]

Gonadotropin-releasing hormone antagonists can be started once the follicle is 14 mm which will prevent premature LH surge and thus lower the risk of cycle cancellation.[171] The other option to prevent cycle cancellation is in vitro maturation (IVM), but the CPR and LBR are very low with it.[172] Natural cycle IVF should be avoided in those who have elevated FSH levels on day 2 of the cycle. There was a paper published in 2019, which looked at modified natural cycle IVF (MNC-IVF) and conventional high-dose ovarian stimulation (HDOS) in advanced-age Bologna poor responders. The authors concluded that in advanced-age Bologna poor responders, after adjustment for relevant confounders like number of oocytes retrieved and presence of at least one top-quality embryo, the ongoing pregnancy was similar in both groups. Thus, MNC-IVF may have a role in elderly poor responders who do not want to opt for oocyte donations and it may be more patient-friendly than conventional high-dose stimulation.[173] ESHRE guidelines do not recommend the use of natural cycle in poor responders.[45]

Trigger

Trigger maybe dual or double. Trigger may improve the results in a small subset of patients who are poor responders.

Dual Trigger

Gonadotropin-releasing hormone agonist and hCG were administered concomitantly at 35–37 hours prior to oocyte retrieval. A combination of recombinant hCG 250 μg (6,500 IU) or urinary hCG (5,000 IU) and 0.2 mg of triptorelin was administered.

Double Trigger

Gonadotropin-releasing hormone agonist (0.2 mg of triptorelin) and hCG (recombinant hCG 250 μg (6,500 IU) or urinary hCG (5,000 IU) administered 40 and 34 hours, respectively, prior to oocyte retrieval indicates double trigger.

When a dual or double trigger is used, GnRH agonist triggering mimics the natural cycle surge (endogenous LH and FSH) aiming to significantly improve outcome–oocyte maturity, fertilization rate, CPR, and LBR.[174-176]

Other studies did not demonstrate improved oocyte maturation, CPR, and ongoing PR with dual/double trigger.[177] According to the ESHRE guidelines, dual/double trigger in subgroups of patients with low maturation, recovery, or fertilization rate cannot be recommended until data on its efficacy and safety from RCTs are available.[45]

Laboratory Options in Poor Response Cycles

Intracytoplasmic Sperm Injection for Low Oocyte Yield

Intracytoplasmic sperm injection (ICSI) can be used instead of IVF in poor responders to prevent complete fertilization failure.[178] But several studies have shown similar fertilization, implantation, and PRs with ICSI and conventional IVF in women with POR without male factor.[179] Gabrielsen et al. found that most oocyte defects in poor responders are not overcome by ICSI.[180]

Preimplantation Genetic Screening for Poor Responders

As poor responder patients are either old or have low ovarian reserve, the chance of aneuploidy is higher in the embryo.[181] Therefore, preimplantation genetic screening (PGS) may have a role in identifying a euploid embryo for transfer, thus optimizing the treatment outcome. But studies have not shown increased LBR despite increased implantation rate.[182]

Ideal Day of Transfer—Day 2 Transfer Instead of Day 3 or 5[156-158]

We know that extending in vitro culture allows a better selection of embryos with higher implantation potential and CPR. Because of concerns regarding the impact of in vitro culture conditions on the limited number of developing embryos in poor responders, it has been proposed that shortening the duration of embryo culture might be associated with an improvement in PRs by increasing the number of embryos available for transfer. The ongoing pregnancy for day 2 versus day 3 ETs is 27.7 versus 16.3%.[183-185] The number of embryos transferred was also significantly more in the day 2 versus day 3 group (2.0 ± 0.8 vs. 1.7 ± 0.8 embryos).[183-185] Thus, shortening the duration of embryo culture is associated with an improvement in PRs probably by increasing the number of embryos available for transfer. Therefore, in poor responders where fewer oocytes and embryos are available for transfer, transferring embryos at an earlier stage of cleavage is beneficial.

Number of Embryos for Transfer

Today, when we are moving to single ET for optimal IVF outcome, increasing the number of embryos transferred in women with advanced reproductive age, poor ovarian reserve, and poor response may improve the outcome.

The guidelines by the American Society for Reproductive Medicine in 2009 for the number of embryos to transfer[186] suggest the transfer of up to two embryos in women aged <35 years, up to three embryos in women aged <38 years, and up to four embryos in women aged <41 years.

Donor Oocytes

In women who have repeated IVF failures, those with predicted poor prognosis, age >40 years or in patients with FSH over 15 mIU/mL or low AMH, oocyte donation may be an option.

Accumulation of Vitrified Embryos or Oocytes

Accumulation of vitrified embryos followed by frozen ET can be considered as a new strategy to improve PR in poor ovarian responders. Kwon et al. reported a significantly higher biochemical PR (31.6 vs. 11.9%; $p = 0.02$). Though the ongoing PR (15.8 vs. 8.7%; $p = 0.24$) and LBR (15.8 vs. 6.6%; $p = 0.1$) were higher, they did not reach statistical significance.[187] Accumulating vitrified oocytes over several stimulation cycles and fertilizing them later can give higher LBR per patient treated and potentially reduce the dropout rate in women with POR.[188] The advantages of accumulation of oocytes and embryos result in less cycle cancellations, reduce dropout rate, result in higher LBR per intention to treat, and reduce psychological distress caused by repeated failures. The disadvantage is that unnecessary stimulations are done if the pregnancy could be achieved from the first cycle. Multiple COS cycles with IVF and freezing increase the cost of the treatment.

ASSISTED REPRODUCTIVE TECHNOLOGY TREATMENT OUTCOME ACCORDING TO POSEIDON CLASSIFICATION

There was no statistical difference in LBR per ET following ART between POSEIDON groups 1 and 2 and women with a good prognosis, while the LBR was significantly lower in POSEIDON groups 3 and 4. Simple modifications, such as an increase in gonadotropin dosage and/or a protocol change, resulted in treatment outcomes that were comparable between POSEIDON groups 1 and 2 and the non-POSEIDON group.[189]

NEWER TREATMENT MODALITIES

Ovarian Fragmentation and in Vitro Activation (Flowchart 3)

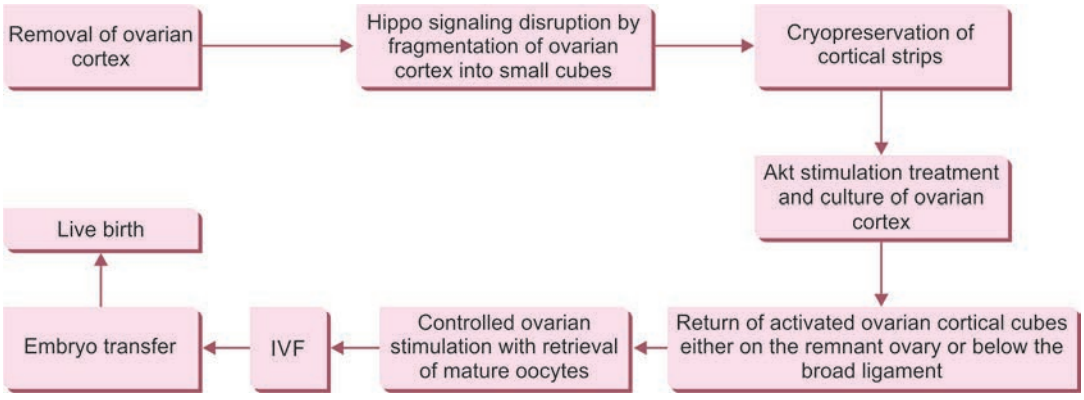
Ovarian fragmentation and in vitro activation (IVA) promote follicle growth via different mechanisms. Kawamura et al. found that fragmentation of ovaries promoted actin polymerization and disrupted ovarian Hippo signaling, leading to increased expression of downstream growth factors, promotion of follicle growth, and generation of mature oocytes. They also reported additional follicle growth, when ovarian fragmentation was combined with Akt stimulator treatment followed by autografting.[190]

OUTCOME AFTER ASSISTED REPRODUCTIVE TECHNOLOGY IN POOR RESPONDERS

Poor response to COS for ART has been a therapeutic challenge to the clinician. Over the years, several treatment modalities have been suggested but have been in wane. Till date, there are hardly any publications on conception rates in poor responders who elect to undergo oocyte retrieval.

There was one study published by Blake et al. and Ulug et al.[183,191] who looked at the outcome of ART in poor responders. They reported PR of 15.9% in patients in whom four oocytes were retrieved and compared with patients in whom one or two oocytes were retrieved (2.3 and 4.3%, respectively). Younger patients <34 years had significantly higher PR (19.5%) as compared to older patients. Women <39 years had a PR of 7.2%, whereas those more than 39 years had a PR of 1.5%. The implantation and PRs when compared in poor responders and normal responders when three embryos were transferred were significantly lower (IR—6.6 vs. 15.3% and PR—16.6 vs. 37.3%). Patient age, number of oocytes retrieved, and number of embryos available for transfer determine prognosis for the success of

Flowchart 3: Ovarian fragmentation and in vitro activation treatment.



(IVF: in vitro fertilization)

IVF in patients who are subjected to assisted reproductive techniques and respond poorly to COS. There was another study by Moolenaar et al.[192] who looked at the response and LBR in the second cycle after an unexpected first cycle poor response. They correlated female age and basal FSH in the first cycle and IVF outcome in the second cycle. Poor response was seen in 5.7% of the total women subjected to COS for ART; of these 46.5% had a repeat poor response in the subsequent cycle.[192] An LBR of 21.8% was reported in the second cycle in women who had a good ovarian response.[192] So they concluded that unexpected poor response in the first COS cycle should not be a reason to discontinue further IVF treatment. Between the FSH and female age in the first cycle, only female age was a predictor of response and LBR in the second cycle, though the predictive value was very low.

Later in a retrospective study where the women were identified to be poor responders according to Bologna criteria they demonstrated very low LBRs, irrespective of age and treatment protocol used. An increase in the number of oocytes retrieved (>3 vs. 1–3 oocytes) is an independent variable related to LBRs. LBRs were similar in women <40 years and >40 years per cycle (7.1 vs. 5.2%) or per patient (11.6 vs. 8.8%).[193]

The most recent publication in 2017 by Bozdag et al., which was also a retrospective study of 821 patients, reported an LBR of <10%. Higher implantation (p = 0.024) and LBR per ET (p <0.001) or cycle (p = 0.001) were noted in group C (AFC <7 with a previous poor response). It was also noted in this study that the LBRs are not homogeneous and "young proven" poor responders have a more favorable pregnancy outcome.[194]

KEY POINTS

- Despite the numerous predictive tests for diminished ovarian reserve including age, the POR most times is diagnosed only when subjected to ovarian stimulation. No uniform definition of poor response makes the clinical trials incomparable till date. Moreover, majority of published trials on POR suffer from methodological flaws and are, thus, regarded as being at high risk for bias. This makes it very difficult to offer one particular management strategy or treatment protocol for optimal outcome in this group of women.[195]
- There is no evidence for any particular COS protocol to improve treatment outcome but GnRH antagonist protocols may reduce treatment burden.
- Addition of LH to COS protocols seems to increase the number of oocytes retrieved (+0.75) and the CPR (+30%).
- Natural and modified natural cycles may also improve the outcome in a small subset of women with poor response.
- There is insufficient evidence for most of the adjuvants to improve outcome in women who are poor responders.
- There may be a role for newer modalities of treatment such as oocyte and embryo accumulation, PGS to rule out aneuploidy, and IVA of ovarian cortical tissue. But before we bring them into routine clinical use, they need to be assessed in large-scale randomized controlled studies to assess the efficacy for poor responders.
- As poor responders are not homogeneous for pregnancy prospects, female age and number of oocytes retrieved will modulate the chances for pregnancy in current and subsequent cycles.[1,196]
- Management of poor ovarian responder still represents a therapeutic challenge for the clinician as it is heterogeneous group with no uniform protocols, and the prognosis for these patients may vary greatly depending on patient characteristics. One must also remember that one cannot recruit follicles that do not exist in a case of DOR and the egg quality cannot be fundamentally altered.

CHAPTER 61

Recurrent Implantation Failure

Divyashree PS

INTRODUCTION

Implantation is a highly complex process, which relies on the collaboration between two partners, i.e., the embryo and the endometrium. Failure of implantation is a consequence of embryo and/or uterine factors. The exact mechanism of implantation is far from clearly understood. Recurrent implantation failure (RIF) refers to failure to achieve a clinical pregnancy after transfer of at least four good-quality embryos in a minimum of three fresh or frozen cycles in a woman under the age of 40 years. RIF is a frustrating event for both patients and their clinicians. The aim of this chapter is to condense the reported etiologies for RIF, focus on the suggested investigations to be implemented, and analyze the suggested treatment strategies.

When a gestational sac is visible on ultrasound (US), which is usually 3 weeks after oocyte retrieval, implantation is said to be successful.[1,2]

Embryo implantation is the bottleneck for in vitro fertilization (IVF) success. Successful implantation involves two important players, a receptive endometrium and a normal and functional blastocyst, in association with a synchronized dialog between maternal and embryonic tissues.[1]

Recurrent implantation failure is a challenging and frustrating condition from both patient and clinician perspective. High rates of drop out (up to 50%) from IVF programs after fewer than three cycles is primarily because of the reason, failure to achieve pregnancy.[3,4]

DEFINITION OF RECURRENT IMPLANTATION FAILURE

Despite many publications on this topic,[5-8] there is no universally accepted definition till date. There are various definitions suggested for RIF, which are derivations of expert opinions and lack sound scientific evidence.

It is a matter of debate whether the diagnosis of RIF is based entirely on the number of embryos transferred or on the number of embryo transfer cycles. It is more logical and scientific to define RIF based on the number of embryos transferred, whereas it is difficult for the patients to comprehend. It is more practical and easily understood by patients if the RIF definition is based on the number of transfer cycles.

Various definitions suggested by different authors are given here.

Simon and Laufer[9] defined RIF as the failure to obtain a clinical pregnancy after three consecutive IVF attempts, in which one or two embryos of high-grade quality are transferred in each cycle.

Polanski et al.[10] defined RIF as the absence of a total implantation after two consecutive cycles of IVF, intracytoplasmic sperm injection (ICSI), or frozen embryo replacement cycles where the cumulative number of transferred embryos was no less than four for cleavage-stage embryos and no less than two for blastocysts, with all embryos being of good quality and of appropriate developmental stage.

Coughlan et al.[11] suggested the definition of RIF as the failure to achieve a clinical pregnancy after transfer of at least four good-quality embryos in a minimum of three fresh or frozen cycles in a woman under the age of 40 years.

Somigliana et al.,[12] however, have cautioned about overdiagnosis of RIF, if diagnosis of RIF is drawn after only two to three IVF cycles. Indeed, the rate of false-positive diagnosis remains above 50% in all sensitivity analyses, if diagnosis of RIF is considered after three IVF cycles.

It is after six cycles that the diagnosis of RIF becomes more reliable.

INCIDENCE

The actual prevalence of RIF is unidentified and randomly set at 10% (but then varied in sensitivity analysis from 5 to 25%). Even if an accurate estimation of this prevalence cannot be extrapolated from published research, data from studies reporting on the cumulative chance of pregnancy after seven

to eight treatment cycles propose that the frequency of this condition is at least below 20%.[12]

IMPLANTATION

Human embryo implantation is a three-stage process (apposition, adhesion, and invasion) involving synchronized crosstalk between a receptive endometrium and a functional blastocyst.

A well-synchronized event, which includes cellular adhesion, invasion, and immune regulatory mechanisms, is required for embryo implantation. During most days of the menstrual cycle, endometrium is essentially hostile toward the embryo. To reverse this paradoxical condition, a major physiological endeavor is thus needed by the endometrium. During the first half of the menstrual cycle, rising estrogen levels cause endometrial cell proliferation. After ovulation, progesterone released by the corpus luteum causes secretory transformation. At this point, the endometrium is mature and primed for embryo implantation. This process is rigorously controlled both temporally and spatially. Prostaglandins control this fine-tuning of the window of implantation (WOI) timing. After entering the uterine cavity through the tubal ostia, blastocyst appears to move freely under the influence of selectins, which helps in suitable rolling. It is important for the blastocyst to attach to the endometrium in a polarized way and the "rolling" phenomenon will ensure that the blastocyst will settle in the proper area and in the correct orientation. Mucin-1 (MUC-1), by its repellent activity, prevents the blastocyst from adhering to the endometrium, which has got poor receptivity. Pinopods are the landing platforms for the blastocysts, which get attracted toward particular endometrial areas under the influence of chemokines and growth factors. Pinopods extend over the tips of the microvilli expressing the repellent MUC-1, and they are fully developed for only 1 or 2 days. To ensure adhesiveness between the endometrium and the embryo, adhesion molecules such as integrins and cadherins play an important role at this stage.

ASSUMED ETIOLOGIES FOR RECURRENT IMPLANTATION FAILURE

- Gamete and embryo factors
- Factors affecting endometrial receptivity (ER)
- Multifactorial effectors.

Gamete and Embryo Factors

Embryo quality is a very important variable for successful implantation. Embryo quality clearly depends on oocyte and sperm quality.

Oocyte quality is very important for the resulting embryo quality as it forms the majority of the volume of the embryo. Compromised oocyte quality as a cause of RIF can be suspected in following cases:

Oocyte yield in too extremes, i.e., too high and too low oocyte numbers, is associated with poor oocyte quality. High oocyte yield due to aggressive ovarian stimulation is associated with poor oocyte quality.[13]

Advanced maternal age, high follicle-stimulating hormone (FSH), low antral follicle count (AFC), low anti-Müllerian hormone (AMH) when it is associated with poor response to stimulation, fewer number of oocytes retrieved, high number of immature oocytes, reduced fertilization rate and embryo utilization rate, poor oocyte quality as a cause for RIF can be suspected.[14] Association between advanced maternal age and increased chromosomal nondisjunction, aneuploidy, increase mitochondrial damage, and decrease in mitochondrial membrane potential has been noted.[15]

Sperm quality is equally important to achieve fertilization, good embryo quality, and implantation. Conventional semen analysis may not reflect defects in sperm quality, which can give answers for RIF. There is a recent surge in interest in evaluating sperm DNA damage as cause for RIF. Association between DNA fragmentation and recurrent miscarriage has been proven, but its association with RIF is not very clear.[16]

Embryogenesis can be impaired by chromosomal abnormalities of the male or female partner, the gametes, or the developing embryo itself. Maternal cytoplasmic factors or mutations in cell cycle control genes can cause disruption of the normal sequence of chromosome replication and segregation in early human embryos, which can be a common cause for RIF. Despite good morphology and development rate, embryos fail to implant and it can be hypothesized that in RIF patients, majority of these embryos are chromosomally abnormal.[17]

To prevent polyspermy and to preserve the integrity of the preimplantation embryo, zona hardening is an essential process in mammalian fertilization. Factors such as aging, which is nonmodifiable and in vitro culture, which can be modified can induce zona hardening and thus affect hatching. Defective hatching due to zona hardening as a cause for RIF has been suggested by a few studies.[18,19]

Factors Affecting Endometrial Receptivity (Fig. 1)

Uterine Factors (Anatomical)

Congenital or acquired uterine abnormalities can affect ER.

Congenital uterine anomalies: It is well recognized that *Hox* genes, in particular *HOXA10* and *HOXA11*, play an important role not only in Müllerian duct development[20] but also in endometrial development in preparation for implantation.[21] Hence, it can be hypothesized that congenital uterine anomalies may be associated with RIF. There are studies supporting this hypothesis, one in which it was demonstrated

that women who had undergone septal resection had better outcome following IVF treatment compared to women who were untreated.[22] Another study showed that the miscarriage rate was reduced to 30% after septal resection compared to 80% before septal resection.[23]

Acquired uterine abnormalities: Undiagnosed uterine pathology may be a cause for RIF. In patients with RIF, the frequency of undiagnosed intrauterine pathologies varies between 25% and 50%.[24] Repeat hysteroscopy revealed abnormalities such as myomas, adhesions, endometritis, polyps, and hyperplasia in 18–27% of women with RIF.[25] Various mechanisms by which these acquired uterine abnormalities could affect implantation are depicted in **Table 1**.

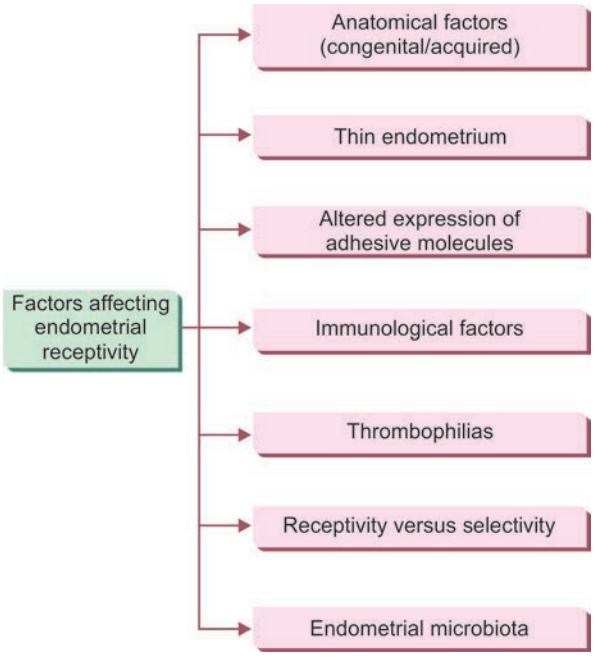

Fig. 1: Factors affecting endometrial receptivity.

Thin Endometrium

There is conflicting evidence regarding cutoff for endometrial thickness affecting implantation. Thin endometrium during embryo transfer did not influence the cumulative pregnancy rate, in a large prospective cohort study,[27] especially when transfer was done with high-quality embryos.[28] In tubal factor infertility, presence of thin or hyperechogenic endometrium or persistent fluid in cavity impaired IVF outcome whereas this did not affect outcome when same factors were present in polycystic ovary syndrome (PCOS).[29]

It was also noted that endometrial thickness predicted pregnancy outcome in IVF, but not for ICSI.[30] This is because thin endometrium was a prognostic indicator of pregnancy only in the case of a female indication for infertility (IVF). A thin endometrium in cases of female infertility may reflect a previous or present uterine pathology, whereas in indications of male infertility (i.e., cases using ICSI), in the absence of any associated uterine pathology, the presence of a thin endometrium is not predictive.

Altered Expression of Adhesive Molecules

Various cytokines are involved in implantation. Local dysregulation of normal expression or action of cytokines can cause implantation failure. Elevated endometrial natural killer (NK) cells, dysregulation of interleukin (IL)-12, -15, and -18, high IL-1β, and low interferon-γ and IL-10 were found in

TABLE 1: Uterine abnormalities and mechanism of disrupted implantation.

Uterine abnormality	*Anatomical*	*Physiological*	*Molecular*
Myoma	• Distorts endometrial lining • Disordered uterine contractility	• Altered uterine vascular perfusion • Increased uNK cells	• Decreased HOXA10, BTEB1, and LIF expressions • Altered TGF-β pathway • Decreased glycodelin and IL-10 in mid-luteal phase[26]
Polyps	Mechanical interference with embryo transport and implantation	• Increased cellular proliferation and apoptosis • Increased estrogen receptors	• Abnormal secretion of E2 and progesterone regulated implantation markers • Low IGFBP-1 and osteopontin levels • Impaired expression of HOXA10, HOXA11, and interferon-γ[26]
Adenomyosis	Disturbed endomyometrial junction	• Altered uterine vascular perfusion • Progesterone resistance • Alteration in PR-A to PR-B ratio	• Reduced αvβ3 - integrin and LIF expressions in the window of implantation • Absence of HOXA10 and HOXA11 peak in secretory phase[26]
Synechiae	Prevents the embryos from attaching to the luminal surface of the endometrium	Thought to impair ER by reducing pregnancy rates and increasing the risk of miscarriage	

(E2: estradiol; ER: endometrial receptivity; IGFBP-1: insulin-like growth factor binding protein 1; IL: interleukin; PR: progesterone receptor; TGF-β: transforming growth factor beta; uNK: uterine natural killer)

RIF. Failure of appearance of a specific integrin αϖβ3 in the endometrium at the time of implantation was suggested as a cause of implantation failure. High levels of aromatase p450 messenger RNA (mRNA), changes in pinopode expression, and high matrix metalloproteinases have been suggested to be associated with RIF.[17]

Contribution of Immunology and Thrombophilia Toward Alteration in Endometrial Receptivity

Advances in reproductive medicine have allowed us to select euploid embryos for transfer, eliminating embryonic factors for failed implantation. However, even transfer of a euploid blastocyst does not lead to successful implantation and delivery in >30% of cases.[31] Apart from the above-mentioned causes for altered ER affecting implantation, the immune system has been the next possible and most debated cause. The three main players of immune system affecting implantation are as follows:

1. T helper (TH)1–TH2 balance
2. NK cells
3. Autoantibodies.

- *TH1–TH2 imbalance:* There are two broad classes of T helper lymphocytes, TH1 and TH2. Proinflammatory cytokines are released from TH1 cytokines, which include interferon-γ, tumor necrosis factor (TNF), and IL-1, -2, -12, -15, and -18. TH1 cytokines are counteracted by the TH2 cytokines, which are IL-4, -5, -6, -10, and -13 and granulocyte macrophage colony-stimulating factor. Depending on the type of immune challenge faced with, humans see variation in the balance of TH1 and TH2 cytokines.[32,33] Pregnancy is one such immunological change, where there is a shift toward TH2 dominance, which is very important to maintain pregnancy. In early pregnancy, following changes occur:[34,35]
  - Rising levels of progesterone
  - Increased secretion of TH2 cytokines such as IL-4 and -6
  - Decreased secretion of TH1 cytokines such as IL-2, -12, and interferon-γ
  - Even the embryo directly contributes to TH2 dominance by secreting IL-10 and transforming growth factor beta (TGF-β).

Several studies report association between loss of TH2 dominance and poor pregnancy outcomes such as an embryonic gestation and recurrent pregnancy loss (RPL). Whether this association is the cause or effect is not clearly understood.[34,35]

- *NK cells:* NK cells and their role in RIF are among the most debated and poorly understood topics. There are two types of NK cells, peripheral (pbNK) and uterine (uNK). pbNK and uNK are two different immune cells with different immunologic properties. pbNK cells are the first line of defense against tumor cells, viruses, and they are cytotoxic in nature. uNK cells are less cytotoxic in nature, unless they are posed with viruses such as cytomegalovirus (CMV). As previously misunderstood, they are not educated to reject or kill healthy embryos. There are conflicting evidences regarding association between NK cell parameters and pregnancy outcome.[36-39]

A systematic review and meta-analysis on pbNK and uNK, including 12 studies, failed to show any association between pbNK cell number or activity or uNK cell density and pregnancy outcome.[40] Hence, it is not just enough to know about quantity and activity of NK cells, it is important to understand the interaction between the maternal killer immunoglobulin-like receptors (KIRs), expressed on uNK, and their ligand human leukocyte antigen C (HLA-C), expressed by the extravillous trophoblast as shown in **Figure 2**. Various studies have proposed that this NK cell allorecognition mediates placentation process.[41,42] Accruing evidence suggests an important role of uNK KIR and HLA-C interaction in both normal and abnormal placentation. Further research should focus on determining the combination of maternal KIR haplotype and parental/donor HLA-C, which could segregate the benefits of single embryo transfer (SET) versus double embryo transfer (DET) or from donor selection according to HLA-C. This may increase the live birth rate (LBR) per cycle, which in turn would help to reduce the number of embryos transferred by promoting the increase in elective SET.[43]

Placentation is regulated by interactions between maternal KIRs, expressed by uNKs cells, and fetal HLA-C molecules, expressed by extravillous trophoblasts. Maternal and paternal HLA-C (HLA-Cm and HLA-Cp, respectively) are nonself (*foreign*).

(HLS: Human leukocyte system; NK: natural killer; uNK: uterine natural killer)
Source: Reproduced with permission from Alecsandru and García-Velasco (2017).[43]

- *Autoantibodies:* Another aspect of the immune system altering ER is related to autoimmunity. To understand this aspect, three meta-analyses will be highlighted here. In 2000, meta-analysis by Hornstein et al., analyzing, seven studies failed to show any difference in clinical pregnancy rate (CPR) or LBR in women undergoing IVF with or without antiphospholipid antibodies (APAs).[44] In 2008, the committee opinion of the American Society for Reproductive Medicine (ASRM) concluded that there is no statistically significant impact of the presence of APAs on IVF outcomes, after reviewing 12 studies with >2,000 patients in total.[45]

One more recent meta-analysis in 2011, involving 29 studies of >5,000 patients, concluded that the presence of one or more APAs was associated with increased risk of assisted reproductive technology (ART) failure. Further subgroup analyses showed that presence of lupus anticoagulant and antibodies antiphosphatidylserine, antiphosphatidylinositol, antiphosphatidic acid, and antiphosphatidylglycerol were more often present in women with ART failure and anticardiolipin antibodies, anti-β2 glycoprotein I antibodies, and antiphosphatidylethanolamine were less often associated with ART failure. However, the overall methodologic quality was poor due to inappropriate control group selection.[46]

At present, the association between autoantibodies and ART failure remains inconclusive, due to practical challenges faced in determining a more definitive answer. With an assumed 16% prevalence APAs, to prove the difference of 20% with 80% power in a cohort study, it is estimated that 1,300 patients with APAs and 8,200 controls would have to be enrolled.[46] At present, ASRM advises against the routine assessment of APAs in ART.[45]

Receptivity versus Selectivity

Recent studies have challenged the term endometrial "receptivity" as it denotes a more passive function of the endometrium. Decidual function is not only related to this passive act of receptivity but also has a more active role in biosensor function of selectivity, which has a key role in directing the maternal response to the implanting embryo. This biosensor function of the decidua is very important, when it comes to selection of the human embryos (unlike embryos of other species), which are characterized by their high rate of chromosomal abnormalities, the implantation of which can result in futile investment of maternal resources on these invasive but poorly viable embryos.[47] Impaired endometrial selectivity would result in superfertility but at the cost of recurrent early pregnancy loss. Conversely, an excessive biosensor function of the decidua would make the endometrium more choosy, decreasing recurrent miscarriage, but increases the likelihood of implantation delay or RIF[47] **(Fig. 3)**.

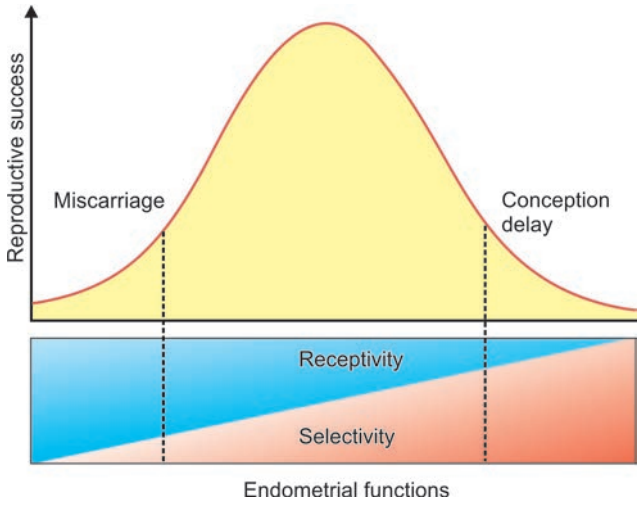

Fig. 3: Endometrial receptivity versus selectivity. Excessive receptivity and poor selectivity result in recurrent miscarriage and vice-versa result in recurrent implantation failure (RIF).
Source: Reproduced with permission from Macklon and Brosens (2014).[47]

Endometrial Microbiota

It was assumed that the uterus is sterile, and this was based on vaginal samples. *Lactobacillus* species is the predominant microbiome in the vagina;[48] however, this could vary according to the age and hormonal milieu.[49] Before puberty, vaginal flora is a mixture of both anaerobic and aerobic bacteria, while after puberty, vagina is predominantly colonized by *Lactobacillus* species, which is due to acidic environment created by rising glycogen.[50] Moreno et al. have analyzed the vaginal and endometrial microbiota in healthy nonpregnant women using next-generation sequencing (NGS) of the 16S ribosomal RNA (rRNA) gene and have identified bacterial communities in all the endometrial samples analyzed. *Lactobacillus* is the predominant microbiome, followed by *Gardnerella*, *Prevotella*, *Atopobium*, and *Sneathia*.[51] Study by the same group analyzed the endometrial fluid from 35 women with RIF and correlated between endometrial microbiome profiles with reproductive outcome. They found that non-*Lactobacillus* dominated microbiota correlated with adverse reproductive outcome such as failure of implantation and miscarriage.

Multifactorial Effectors

Multifactorial effectors include endometriosis, PCOS, and hydrosalpinx. The mechanism by which they cause implantation failure is summarized in **Table 2**.

INVESTIGATIONS

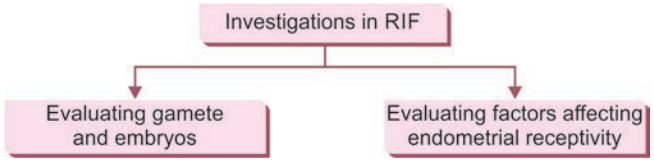
Recurrent implantation failure is not a diagnosis but a mere clinical presentation, which requires appropriate phenotyping and etiological investigations. We have various

TABLE 2: Mechanism of disrupted implantation in multifactorial effectors.

Pathology	*Anatomical*	*Physiological*	*Molecular*
Endometriosis	Impaired fertilization[26]	Altered folliculogenesis Poor oocyte quality[52]	• Reduced αvβ3 - integrin and LIF expressions in the window of implantation • Lack of IL-11 and IL-11Rα expressions in secretory phase • Absence of HOXA10 and HOXA11 peak in secretory phase • Elevated EMX2 expression • Progesterone resistance • Alteration in PR-A to PR-B ratio • Decreased HOXA10 expression due to hypermethylation of its promoter region[26]
PCOS		• Altered folliculogenesis • Defective ovulation • Inadequate progesterone action • Excessive androgen/ insulin action • Poor oocyte quality[26]	• Decreased αvβ3 - integrin, HOXA10 and IGFBP-1 during secretory phase • Overexpression of androgen receptors • Failure to downregulate estrogen receptor-α in the window of implantation • Overexpression of the steroid receptor coactivators such as nuclear receptor coactivator and transcriptional intermediary factor 2 (TIF2)[26]
Hydrosalpinx	Intermittent bathing of endometrial lining with hydrosalpinx fluid causing mechanical interference to apposition	Embryotoxic effect of the inflammatory hydrosalpinx fluid	• Reduced αvβ3 - integrin and LIF expressions • Decreased HOXA10 expression[26]

(IGFBP-1: insulin-like growth factor-binding protein 1; IL: interleukin; PCOS: polycystic ovary syndrome; PR: progesterone receptor)

Flowchart 1: Investigations in recurrent implantation failure (RIF).



tools to detect the cause of RIF, whether it is at the level of embryo, endometrium, or it is multifactorial, as depicted in **Flowchart 1**.

Evaluating Gamete and Embryo Factors

Evaluating the Oocyte

Assessment of oocyte quantity and quality is through ovarian function tests. Women with RIF should be offered basal FSH, AFC, and AMH to diagnose extremes of ovarian reserve, which is associated with poor oocyte quality.

Assessment of Sperm DNA Damage

Evidence on association between sperm DNA damage with implantation failure or pregnancy failure is conflicting. Initial studies have shown that DNA fragmentation index (DFI) value of >27% is associated with pregnancy failure in ART,[53,54] although in later studies, the predictive value of this test is questioned.[55,56] A meta-analysis in 2015, evaluating the relationship between the extent of sperm DNA damage and LBR per couple and the influence of the method of fertilization on treatment outcome showed that high sperm DNA fragmentation in couples undergoing ART is associated with lower LBR; however, further sensitivity analysis showed no statistically significant difference in LBR between low and high sperm DNA fragmentation when ICSI was used.[57] At present, DFI should be offered to couple with RIF as a part of research program. Methods to assess sperm DNA damage are depicted in **Flowchart 2**.

Parental Karyotyping

The incidence of chromosomal abnormalities in couples with RIF is approximately 2.5%, which is still higher compared to the general population.[58] This higher incidence suggests that the karyotyping testing should be considered in couple with RIF.

Evaluating the Embryo

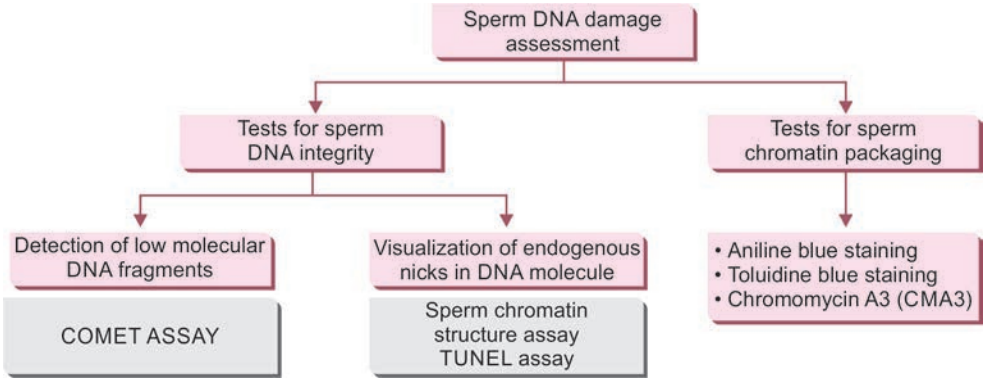
Evaluation of the embryo has been characterized in **Flowchart 3 and Table 3**.

Evaluation of Factors Affecting Endometrial Receptivity

Uterine Factors

Women with RIF should be investigated for uterine pathology (congenital/acquired), which can be a contributing cause for RIF.

Flowchart 2: Methods to assess DNA sperm damage.



(TUNEL: terminal deoxynucleotidyl transferase dUTP nick end labeling)

Flowchart 3: Evaluation of the embryo.

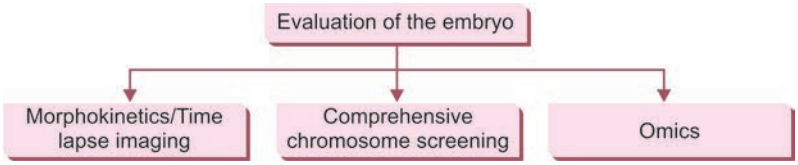


TABLE 3: Evaluation of the embryo.

Method	*Principle*	*Advantage*	*Disadvantage*	*Evidence*
Morphokinetics/ time-lapse imaging	• Analysis of embryo morphology and information about the dynamic changes in the embryo during peri-implantation period • Several studies have correlated time lapse with probability of selecting chromosomally normal embryos[59-61]	• No removal of the embryo from the incubator for evaluation, providing better culture environment • Better understanding of the poorly described concepts of embryology, such as duration of first three cell cycles[62]	• As with manual embryo morphology grading, inter- and intraobserver variability may impact time-lapse interpretation[63] • The risk of rejecting "viable embryos" based on suboptimal morphokinetic score[64]	• Can time-lapse parameters predict embryo ploidy? • A systematic review—2018 • No definitive conclusions can be drawn on the predictive value of morphokinetic evaluation for embryo aneuploidy • Time-lapse imaging cannot be used as a surrogate for preimplantation genetic screening (PGS)[65]
Comprehensive chromosome screening (CCS)	• Embryos with chromosomal abnormalities have lower implantation potential • PGS is used as a strategy to select normal embryos having higher implantation potential for transfer, thus eliminating embryos with low implantation potential from the cohort	• In poor prognosis patients such as advanced maternal age, RIF, genetic testing of the preimplantation embryo allows for selection • of chromosomally competent embryo, thus increasing the chance of conception[66-68]	• Mosaicism is an important variable to consider, especially when consistency in diagnosis has to be established[69] • Various studies have shown the frequency of mosaicism can be as low as 15.7% and as high as 32.4%[70-72] • Despite the efficacy and accuracy of CCS various studies have questioned its validity[73,74] • It is clear that not all euploid blastocysts will implant, suggesting that additional factors also determine the reproductive potential of an embryo such as "omics"	• CCS improves embryo selection: A meta-analysis (2015) • Three RCTs and eight observational studies included • PGS improves clinical implantation rates (IR) and sustained IR (beyond 20 weeks) particularly in patients with normal ovarian reserve • Results from ongoing RCTs conducted on different patient population are awaited

Method	Principle	Advantage	Disadvantage	Evidence
Omics	Analysis of "biomarkers" refers to measurement of proteins and metabolites that are associated pregnancy outcome, either positively or negatively	• Viability (ability of an embryo to implant and give rise to a healthy baby) is not just dependent on chromosome complement but with other factors such as inherent developmental potential • Embryo morphology does not alone suffice for assessment of embryo viability because morphology does not necessarily reflect physiology	• High cost involved • Very minimal sample available for analysis which affects the accuracy and sensitivity of the test • Biomarker levels are affected by various factors such as embryonic stage of development, sex of the embryo, medium composition, medium renewal frequency, • rate of ammonium accumulation, oxygen concentration, and stress[75]	Various studies have demonstrated that morphokinetics and omics are complementary approaches for the assessment of embryo viability[76-78]

(RCT: randomized controlled trial; RIF: recurrent implantation failure)

Diagnostic Modalities for Uterine Abnormalities

Hysteroscopy and laparoscopy, sonohysterography (SHG), and three-dimensional (3D) US are the most precise investigations and can be utilized as diagnostic tools. 3D-US offers the benefit of being noninvasive. SHG necessitates the introduction of fluid into the uterine cavity and this can usually be uncomfortable. Hysteroscopy and laparoscopy are both invasive procedures; however, they offer the advantage of simultaneous diagnosis and treatment. Hysteroscopy alone can identify the existence of an anomaly but cannot precisely differentiate between the different subtypes.

Two-dimensional US is the least accurate method of investigation; however, it is the most widely available and the easiest to perform. If used in combination with hysterosalpingogram (HSG), it can increase precision and aid as a valuable screening tool, especially in the absence of 3D-US, or where SHG is not practiced. Magnetic resonance imaging (MRI) seems to be more accurate than 2D-US or HSG alone, and could potentially be used for screening. However, its diagnostic accuracy remains unclear. Disadvantages are that it is more expensive than US and HSG, and is not available in the office setting.

Investigating Immunological and Thrombophilic Conditions in Implantation Failure

- *Testing TH1 and TH2 balance/imbalance:* As discussed previously, pregnancy is associated with TH2 dominance. Various studies have demonstrated an association between loss of TH2 dominance and poor pregnancy outcome.[34,35] There are several challenges to advise tests to measure TH1/TH2 balance as a routine in cases with RIF because of following reasons:
  - It is not known whether aberrations in the transition of TH2 dominance in poor pregnancy outcome is the cause or the effect.
  - In the peri-implantation interval, in fact, it is normal for a TH1 dominance.

  Therefore, no screening tests can be done in advance to predict TH1/TH2 imbalance in a future gestation.[31]
- *Testing of NK cells:* Disturbed population of uNK and/or pbNK cells has been suggested as one of the causes for implantation failure. NK cells can kill some cell lines in vitro but not decisively; but this terminology is often misleading, as it seems that these cells could harm or kill the embryos and thus associated with implantation failure.[79] A systematic review and meta-analysis failed to show any association between pbNK cell number or activity or uNK cell density and pregnancy outcome.[40] At present, routine testing of NK cell in women with RIF is not advised as there is no clear evidence of use and the potential adverse effect and cost of this therapy outweigh any benefits.[79]
- *Testing of autoantibodies:* Association between APAs and ART remains controversial. The ASRM currently recommends against the routine determination of APAs among couples undergoing ART.[45] However, there is some evidence to suggest that it is reasonable to test for thrombophilia in patients with RIF and consider treatment if a thrombophilic disorder is identified.[31]

Testing for Endometrial Receptivity

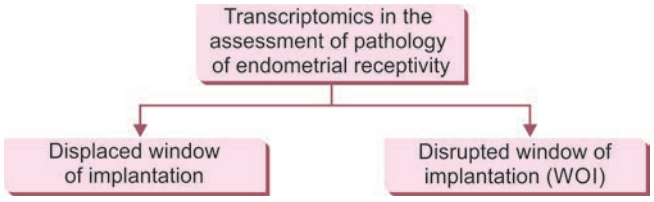
The end result is not always pregnancy, when a morphologically and/or chromosomally normal embryo is replaced into the uterus which is seemingly normal. It is the

TABLE 4: Various methods of assessing endometrial receptivity (ER).

Method	*Advantage*	*Disadvantage*
Histologic evaluation	In 1950s, in the absence of any objective means of assessing ER, Noyes criteria was widely used, but now it is obsolete	Its accuracy, reproducibility, and functional relevance as a predictor of ER has been questioned[80]
Transvaginal ultrasound	• When there are no structural abnormalities and the endometrium is thick enough with trilaminar pattern, ER is assumed • Low cost, high resolution, lack of radiation exposure, and widely used	Not sufficient to predict endometrial normalcy and implantation[81]
Hysteroscopy	• Gold standard for the diagnosis of intrauterine pathology • Minimally invasive procedure • Diagnostic as well as therapeutic at the same sitting	Not enough as it not informative about ER[82]
Transcriptomics	• For complex and multifactorial traits such as RIF and endometrial factor evaluation, genomic medicine provides a deeper understanding of diseases based on massive amounts of data generated by genomic technologies • Allows to practice more precise medicine	• Large variation in genes identified in different • studies • Variable expression of the genes • Differences in gene expression at RNA levels is not always reflected at protein levels • It is not the genes but the gene products that determine the phenotype

(RIF: recurrent implantation failure)

Flowchart 4: Transcriptomics in the assessment of pathology of endometrial receptivity.

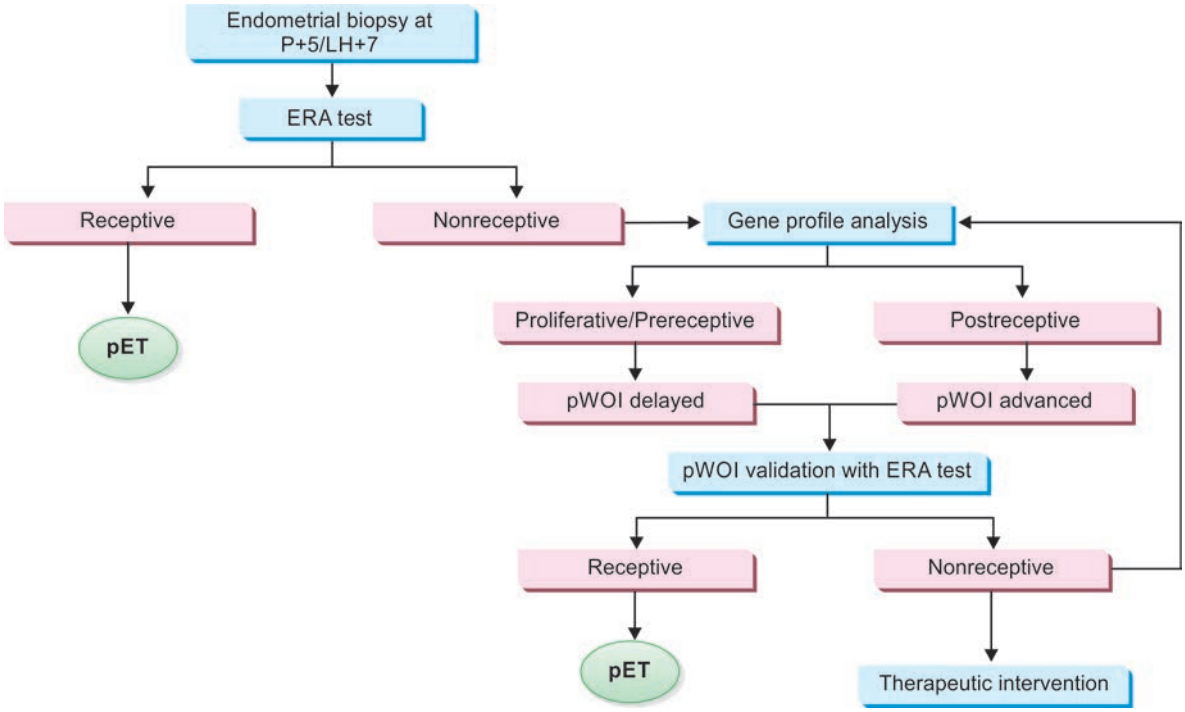


collaboration between the embryo and the endometrium, which decides success or failure. This is further dependent on the functionality and synchronization of both the partners, thus emphasizing that the embryo alone is not sufficient for successful implantation. All these point to the presence of endometrial pathology in some patients with RIF who produce seemingly normal embryos both morphologically and chromosomally. In recent years, there is a surge in interest in evaluating the role of endometrium in implantation and also the dysfunctions of endometrium that may underlie implantation failure **(Table 4 and Flowchart 4)**.

Transcriptomics to assess displaced WOI: In 1956, Hertig and Rock for the first time suggested the concept of ER and WOI.[83] Several studies following this have clearly demonstrated that the endometrium becomes receptive during 8–10 days post ovulation, with the same success during these 3 days regardless of whether it is a natural, stimulated, or hormone replacement cycle.[84-86] Díaz-Gimeno et al. (2011)[87] identified the transcriptomic signature of ER composed of 238 genes leading to the creation of the endometrial receptivity analysis (ERA). The ERA is a customized microarray now performed by NGS, coupled with a computational predictor, which enables to identify the receptivity of the endometrial sample, i.e., whether the endometrium is within the time frame of WOI or not, thus providing personalized WOI (pWOI) of a given patient facilitating personalized embryo transfer (pET). A biopsy of the endometrial tissue is taken at days luteinizing hormone (LH) +7 in the natural cycle and progesterone +5 in hormone replacement therapy (HRT) cycle. A state of nonreceptivity contemplates that the WOI is displaced. In this case, the process will be repeated according to data from the ERA predictor, which will give a new calculation of WOI (pWOI), which is depicted in **Flowchart 5**. Before beginning an ART treatment, performing an ERA can identify if the patient will need a pWOI and this could aid the clinical examination in modifying the timing of embryo transfer especially in cases of RIF. The ERA test is not sensitive to minor gene expression variations that might occur during normal reproductive life or to the effects of variability in experimental batches.

Transcriptomics to assess disrupted WOI: Endometrial gene expression has been shown to be sensitive to cyclical hormonal variation and exogenous hormone therapy.[88-91] But numerous studies have demonstrated that various factors can affect endometrial gene transcription, such as presence of endometriosis[92] and use of intrauterine device.[93] Hence, it is logical to think that although displaced WOI may be the cause in some RIF[94] patients, it may also originate as an effect of other causes and that these may include constitutive disruptions of endometrial function. The potential value of identifying a gene expression profile predictive of RIF is considerable because this would not only guide prognosis, but also could inform appropriate and effective therapeutic intervention. With regard to this hypothesis, study by Koot et al.[95] determined the transcriptomic differences between RIF patients and control subjects and demonstrated that RIF

Flowchart 5: Personalized embryo transfer (pET).



(ERA: endometrial receptivity analysis; LH: luteinizing hormone; P: progesterone; pWOI: personalized window of implantation)

may represent a pathology with a particular transcriptomic signature. Furthermore, Sebastian-Leon et al.[96] by analyzing 16 transcriptomic signatures have clearly predicted two causes of RIF: (1) a displaced WOI and (2) an on time but pathologically disrupted WOI.

Assessing endometrial microbiota: Although there are various studies regarding vaginal microbiome, there are only recent data supporting the presence of an indigenous endometrial microbiome. The endometrial cavity has long been considered to be sterile, but reports challenging this tenet support the existence of an endometrial microbiome comprising different microorganisms (specifically *Lactobacillus* spp., *Mycoplasma hominis*, *Gardnerella vaginalis*, and *Enterobacter* spp.) that affect reproductive outcomes.[97] Detection of bacteria with molecular techniques has enabled the study of low biomass microbiomes in tissues and organs. Subsequently, an abnormal endometrial microbiota has been associated with implantation failure, pregnancy loss, and other gynecological and obstetrical conditions. Further research on the reproductive tract microbiome will allow for a better realization of bacterial communities, role in physiology as well as pathophysiology, which in turn affects the ability to achieve pregnancy and maintain a healthy pregnancy.[98]

Hydrosalpinges: Hydrosalpinges as cause for RIF should be excluded, regardless of the initial infertility diagnosis. US does not always pick up hydrosalpinges; hence, HSG is preferred. Laparoscopy should be advised in women in whom HSG is inconclusive, to refute or confirm diagnosis.[11]

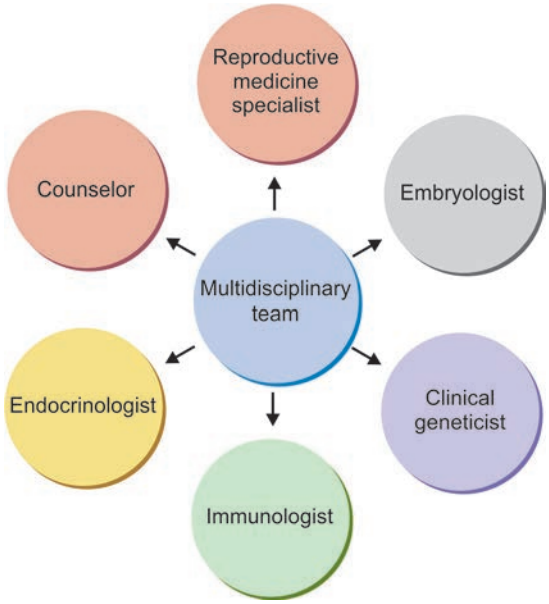


Fig. 4: Multidisciplinary team: Reproductive medicine specialist, embryologist, counselor, clinical geneticist, immunologist, and endocrinologist.

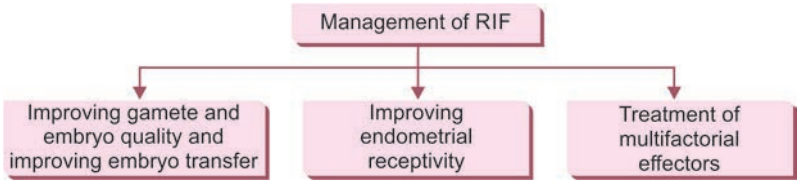
MANAGEMENT

Multidisciplinary Approach

The role of a multidisciplinary team in the management of RIF cannot be overemphasized. The multidisciplinary team should comprise reproductive medicine specialist, embryologist, counselor, clinical geneticist, immunologist, and endocrinologist **(Fig. 4)**. Couples with RIF should be

Flowchart 6: Management of recurrent implantation failure (RIF).



evaluated by this team. There should be a local protocol agreed upon by this team as to how to investigate these couples with RIF, which is based on robust evidence. During evaluation, the team should review all the details of the case that include cause of infertility, investigations done so far, treatment protocol adopted, response to ovarian stimulation, quality of oocytes and sperms, fertilization, cleavage, embryo quality, and any difficulties in embryo transfer. This consultation with the multidisciplinary team is "special" and should not be like any other routine outpatient consultation. The couple should be given ample time to discuss their problems and issues and the team should be empathetic with them. It is very important to explain in detail to the couple about the underlying cause of infertility, and also a possible explanation about why IVF did not work for them despite repeated attempts. Couple should also be explained about further plans of action and the scientific rationale behind this plan. It is very important to assess and explain the likelihood of success with further investigation and treatment. If likelihood of success is very low, they should be explained about alternative options including gamete donation, gestational surrogacy, or even adoption.

Recurrent implantation failure is a source of distress and dissatisfaction for both patients and clinicians. It is not uncommon to have the feeling of disgust with repeated failures. At times, it becomes very difficult to explain as to how the transfer of a euploid blastocyst failed to implant in a seemingly normal endometrium. In this situation, the clinicians can become illogical and begin to search for, and apply, unproven investigations and treatments based on just scientific hypotheses and anecdotal reports, with lack of robust evidence. At the same time, couples with RIF are such a vulnerable population that they are ready to do anything to achieve a pregnancy. Hence, it is very important to have this multidisciplinary approach, which can provide dedicated care and evidence-based treatment. In case such an evidence base is lacking, the patients should be counseled accordingly and, if the occasion arises, they might be invited to participate in a carefully designed clinical trial. They should not be exploited.

The role of a counselor is very crucial at this point of time. A counselor should help the couple to express their emotions, to identify the specific cause of stress, to enable coping strategies, and to facilitate decision making.

Before embarking on new investigation and treatment strategies, it should be emphasized about lifestyle modifications, which include maintaining a healthy body mass index (BMI), to quit smoking and alcohol. These lifestyle changes have shown to improve the probability of success to treatment **(Flowchart 6)**.[99-102]

Improving Gamete and Embryo Quality and Embryo Transfer

Treatment of Poor Oocyte Quality

In some patients, RIF might be because of compromised oocyte quality and this could be because of inherent problems in the oocyte quality or because of suboptimal ovarian stimulation, which is amenable for correction. As discussed previously, ovarian stimulation protocol must be reviewed as a part of RIF workup, and if previous ovarian stimulation is suboptimal in terms of number of oocytes obtained as compared to ovarian reserve, gonadotropin dosage can be increased. No particular protocol is superior to the other in this situation; however, few studies have suggested addition of LH is beneficial in hypo-responders and also in women older than 35 years.[103] In women with endometriosis, ultralong protocol with use of depot gonadotropin-releasing hormone agonists (GnRHa) 3–6 months prior to controlled ovarian stimulation is proven to increase pregnancy rate.[104] Cytoplasmic transfer as a method to improve oocyte competence has been demonstrated to be beneficial in a few studies,[105,106] but currently it is considered experimental.

Treatment of High DNA Fragmentation

Table 5 depicts the treatment of high DNA fragmentation.

Treatment of Poor Embryo Quality

Blastocyst transfer: Blastocyst transfer is superior to cleavage-stage embryos. Human embryos enter the uterine cavity 5 days after fertilization; hence, it is more physiological to transfer embryo at blastocyst stage. Although initial studies showed evidence in favor of blastocyst transfer,[112,113] meta-analysis by Glujovsky et al. (2016), which included 27 randomized controlled trials (RCTs) with 4,031 couples, concluded that blastocyst transfer is better than cleavage-stage embryo transfer; however, for LBR and CPR, the quality of evidence is low and moderate, respectively.[114]

TABLE 5: Methods to improve sperm quality.

Method	*Rationale*	*Evidence*
Oral antioxidants	Reduces oxidative stress on sperm	• Meta-analysis of 48 RCTs with a population of 4,179 subfertile men • Conclusion: Antioxidants could be considered for subfertile men; however, evidence is inconclusive[107]
Use of annexin-V columns and hyaluronic acid (HA) binding	Reduces the number of sperms with increased DNA fragmentation index (DFI)	• HA sperm selection method will likely reduce the potential genetic complications and adverse public health effects of intracytoplasmic sperm injection (ICSI)[108] • The selection of nonapoptotic sperm by magnetic cell sorting (MACS) may be used to enhance results of in vitro fertilization by increasing sperm–oocyte penetration[109]
Intracytoplasmic morphologically selected sperm injection (IMSI)	Morphologically selected sperms may improve reproductive outcome	Further trials are necessary to improve the quality of the evidence before recommending IMSI in clinical practice[110]
Testicular sperm retrieval (TSR)	Sperm DNA damage is lower in the seminiferous tubules as compared with the cauda epididymis and ejaculated spermatozoa	The use of TSR–ICSI in the absence of specific sperm DNA defects is still experimental[111]

(RCT: randomized controlled trial)

Assisted hatching (AH): Three possible mechanisms how AH could aid implantation:

- Procedures such as IVF, cell culture,[115] or cryo-preservation[116] can cause hardening of zona, which could make hatching difficult and this issue can be solved with hatching.
- Women going through controlled ovarian stimulation with gonadotropins have prematurely displaced WOI,[117] this situation can be helped with AH, which causes anticipation of implantation.[118]
- For exchange of metabolites, growth factors, opening created through AH can serve as a channel.[119]

Three meta-analyses on AH have found a significant increase in CPR, but no difference in LBR. Martins et al. (2011) found a significant difference in CPR in frozen–thawed embryos in unselected women and also in women with repeated IVF failure. Limitation of this meta-analysis was that there were too few studies looking at LBR.[120] Cochrane review by Carney et al. (2012) analyzed 31 RCTs including 1,992 clinical pregnancies in 5,728 women, concluded that CPR was significantly higher following AH, just reaching statistical significance, but there was no effect on the "take-home baby rate."[121] Li et al. (2016) looked at 36 RCTs with 6,459 women and found that AH gave a significant increase in CPR and multiple pregnancy rate, but in the 15 RCTs that looked at LBR, there was no evidence of difference between the AH and control groups.[122]

Co-culture: Scientific hypothesis behind using co-culture include secretion of embryotrophic factors such as nutrients, growth factors, and cytokines and detoxification of free radicals.[123] Spandorfer et al. studied autologous endometrial co-culture in 1,030 patients with RIF and reported 49% pregnancy rate.[124]

Preimplantation genetic screening (PGS): In 1990s, thousands of IVFs were performed after biopsying a single blastomere from day 3 cleavage-stage embryo and analyzing the normalcy of five chromosomes through fluorescent in situ hybridization (FISH). Later on, RCTs showed that PGS did not increase CPR or LBR and in some cases decreased LBR.[125,126] It is due to following reasons that PGS with day 3 embryo may not be effective:

- Limited accuracy of FISH
- Limited number of cells available for analysis
- Day 3 embryos are at a peak of chromosomal abnormality and mosaicism.

With the advent of new technologies, comprehensive chromosome screening (CCS) is possible on day 5 embryos after biopsying trophectoderm cells. With this, there is a scientific hypothesis that CCS can increase implantation rates, decrease time to pregnancy, and decrease RPL and RIF. Three RCTs on this topic have been criticized because of poor study design. The pilot RCT by Yang et al. (2012) included a small sample size of 45 young good prognosis patients.[127] RCT by Scott et al. (2013) was on 72 good prognosis patients between 21 and 42 years, but the randomization was quite late and also the study failed to account for the difference between the unit of randomization (patients) and unit of analysis (embryos).[128] RCT by Forman et al. (2013) studied 89 women comparing PGS and SET, but the same methodological flaws were noted in this study and also a wide confidence interval for pregnancy did not demonstrate a beneficial effect.[129] Currently, two large RCTs are underway and the results are expected soon. The ESTEEM study (The Eshre Study into The Evaluation of Oocyte Euploidy by Microarray Analysis) recruits patients of advanced maternal age and involves analysis of polar bodies using array comparative genomic

hybridization (CGH). The ESTEEM study has an intention to treat analysis and the outcome analysis will be of cumulative LBR. The other study is the STAR (Single Embryo TrAnsfeR of Euploid Embryo) study, which recruits all IVF patients and uses NGS on trophectoderm biopsies. The outcome analysis of STAR study is on ongoing pregnancy rate after one transfer. The results of these studies are much awaited to provide evidence of its use in various scenarios including RIF.

Mitochondrial DNA load measurement (mitoscore): It has been assessed that metaphase II oocytes contain ~10^5 mitochondrial DNA (mtDNA) copies, and it is these copies which get divided over the cleaving cells as replication of mtDNA does not occur up to blastocyst stage.[130] There are studies[131,132] reporting correlation between higher mtDNA level in blastocysts and lower implantation potential and this could be because of disturbed energy provision and higher metabolic stress in embryos with a higher mitoscore. Currently, there are no studies demonstrating lower mitoscore association with improved LBR; hence, it can only be recommended under research settings.

Time-lapse imaging and metabolomics: As mentioned previously, time-lapse imaging cannot be used as a surrogate for PGS[65] and various studies have demonstrated that morphokinetics and omics are complementary approaches for the assessment of embryo viability.[76-78]

Improving Embryo Transfer

Ultrasound-guided Embryo Transfer

Transabdominal ultrasound (TA-US)-guided embryo transfer technique is the one that is extensively studied, but its use to improve pregnancy rates has been debated.[133-136] This continuing debate could be because of bias involved in these systematic review and meta-analysis such as inclusion of meeting abstracts and observational or retrospective studies in data analysis. Moreover, the newer techniques such as transvaginal ultrasound (TV-US) guidance for embryo transfer, 3D-US, and uterine length measurement before embryo transfer (ULMbET) have not been studied. Systematic review and meta-analysis by Cozzolino et al. (2018) have addressed these issues and have concluded that there is moderate evidence to suggest TA-US embryo transfer over clinical touch in improving CPR, ongoing and LBR. No difference was found in CPR, ongoing and LBR between TV-US and TA-US. Larger RCTs are necessary to explore the possible benefits of TV-US, 3D-US, and ULMbET. Mature limitations of this analysis are: It provides only weak evidence about the ectopic pregnancy and miscarriage rates, potentially underestimating the possible beneficial effects of US application. Wide range of publication date from 1989 to 2013, and also the literature focus is mostly on day 2–3 embryo transfers, making the applicability of the results to day 5 transfers difficult.[137]

Embryo Glue and Adherence Compounds

The use of fibrin sealants to improve LBR and decrease ectopic pregnancy[138,139] was proposed in 1990s, but did not show significant improvement in clinical outcome. It is well reported that hyaluronic acid (HA) is naturally present in the female reproductive tract, and forms a viscous solution that could aid in implantation. Hence, recent studies have focused on the use of a specific embryo transfer medium enriched with HA. Cochrane review by Bontekoe et al. included 17 RCTs with 3,898 participants, demonstrating moderate-quality evidence for an improvement in CPR and LBR and an associated increase in multiple pregnancy rate.[140] RCT by Fancsovits et al. (2015) analyzed 581 cycles and did not show a benefit in implantation rate, CPR, or LBR, but found a higher birth weight in HA group.[141] In the presence of conflicting evidence, it is imperative to conduct further RCTs to evaluate the efficacy of HA as an adherence compound during embryo transfer.

Sequential Embryo Transfer

The rationale behind this strategy is to overcome the problem of embryo-endometrium asynchronicity as a potential cause of implantation failure. The possible disadvantage of this strategy is that the second insertion of the catheter can cause trauma to the endometrium or stimulate the secretion of prostaglandins, which could initiate uterine contractions. It could also cause additional microbial contamination and introduce more mucus into the uterine cavity thus affecting implantation. The possible advantage of sequential embryo transfer is that this interval embryo transfer could affect the endometrial cavity in a positive manner by inducing factors that enhance implantation. DET which happens with sequential embryo transfer can be beneficial in women with RIF. There are conflicting evidences with regard to sequential embryo transfers where a few studies support its use[142,143] and others do not.[144,145] Even though there appear preliminary evidence in favor of DET, further RCTs are required to confirm its use in women with RIF.

Freeze-all Strategy

A freeze-all strategy is a recently established methodology in which cryopreservation of all embryos after a conventional ICSI cycle is performed followed by successive fresh embryo transfer (FET) in expectations of refining the rate of implantation.[146] Currently, freeze-all strategy is adopted in hyper-responders, agonist trigger, along with PGS, etc.[147]

Magdi et al.[148] introduced RIF with FET as another indication for freeze-all strategy. It appears very likely that patients with repeated failed fresh transfers are a selected subgroup with significantly increased risk of impaired ER following ovarian stimulation, among other issues. In this study, 38.4% of patients in the freeze-all group attained

ongoing pregnancy as did 20.7% of patients in the fresh transfer group. This difference was statistically significant. Assessments of secondary measures found significant differences in pregnancy rate, implantation rate, and CPR, all supporting the freeze-all group, but no significant difference in the rate of early pregnancy loss. The rate of multiple pregnancy in the freeze-all group was significantly higher than in the fresh group, indicating that, in regular clinical practice, the number of embryos transferred should be decreased in order to compensate for the higher implantation rate (40.0 vs. 16.0%) with thawed embryos than with fresh embryos in these patients.

Another strong indication for freeze-all strategy in RIF patients is when the embryos have been subjected to PGS. The fresh blastocyst transfer approach after PGS necessitates not only availability of expanded blastocysts on the morning of day 5, but also one of these being euploid, necessitating embryo transfer. Contrary to this, in freeze-all strategy, both day 5 and day 6 embryos can be biopsied, and the whole cohort of embryos can be cryopreserved, enabling patients to have their embryo transfer at a later date. Study by Kahraman[149] at Istanbul Hospital, Turkey, analyzed a total of 1,486 cycles and found that all positive outcomes, implantation, ongoing pregnancy rate, and LBR were significantly higher in the freeze-all group. In cases with advanced maternal age (38–43 years), ongoing pregnancy rate and LBR were significantly higher in the freeze-all group and this is possibly related to ER, as it is probable that in older women, the quiet endometrium is more crucial. Furthermore, it decreases the pressure in embryology laboratory as it permits more plasticity regarding the scheduling of embryo biopsy and also having the biopsy results of the whole cohort, at the same time permits inclusion of all blastocysts.

Zygote Intrafallopian Transfer

Human tubal fluid contains several growth factors and cytokines, which aid in the development of the embryo making it competent for implantation. This scientific hypothesis drives the rationale of following zygote intrafallopian transfer (ZIFT) technique in patients with RIF. However, meta-analysis by Habana and Palter[150] has reported similar pregnancy and implantation rates in ZIFT and intrauterine transfer groups (36.5 vs. 31.4% and 15 vs. 12%, respectively). At present, with improved culture conditions in ART, intrauterine transfer remains the technique of choice in women with RIF.

Improving Endometrial Receptivity

Treatment of Uterine Abnormalities

Treatment of factors affecting ER has been represented in **Table 6**.

TABLE 6: Treatment of uterine abnormalities—congenital and acquired.

Uterine abnormality	*Intervention*	*Rationale*	*Evidence*
Uterine septum	Operative hysteroscopy (HSC) and septal resection	• Increases implantation rate • Decreases MR • Increases term delivery rates	• Tomaževič et al. (2010) performed a retrospective matched-control study in IVF/intracytoplasmic sperm injection (ICSI) patients studying 289 embryo transfer before HSC and 538 embryo transfer following HSC. A control group consisted of 1,654 embryo transfers with normal uterus. However, in spite of these impressive results in favor of surgery before IVF/ICSI, pregnancy rate and LBR remained low (15–20% and ≤3%, respectively) and MRs were high (77%) in nonoperated patients compared with other published data, and therefore these results should be interpreted with caution.[151] Others have not observed lower pregnancy rates, but have detected increased miscarriage and reduced term delivery rates in women with uncorrected septate and bicornuate uterus undergoing IVF[152,153] • According to ASRM 2016, there is limited evidence to suggest septal resection would increase LBR in women with infertility or prior pregnancy loss[154]
Polyps	Hysteroscopic polypectomy	Improvement in pregnancy rate, both spontaneous and assisted	Meta-analysis supports a benefit with the hysteroscopic removal of polyps. If 28% of women become pregnant in the control group, the evidence suggests that between 50% and 76% of women will become pregnant after the removal of the endometrial polyps[155]
Submucosal fibroids and intramural fibroids protruding into the endometrial cavity	Myomectomy	Improvement in implantation rate, CPR, and LBR Decrease in MR	The presence of a submucous fibroid in women with RIF, regardless of the size, and fibroids protruding into the endometrial cavity should be removed as it is shown in various studies that removal improves reproductive outcome[156-159]

Contd...

Contd...

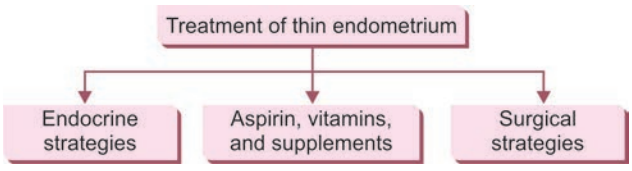
Uterine abnormality	*Intervention*	*Rationale*	*Evidence*
Intramural fibroids that do not affect the endometrial cavity	Myomectomy	Improvement in implantation rate, CPR, and LBR	Sunkara et al. (2010) published the most comprehensive systematic review and meta-analysis on this topic, including 6,087 and 11 studies, there was a statistically significant 21% relative reduction in LBR for women with non-cavity-distorting intramural fibroids compared with women without fibroids [relative risk (RR) 0.79, 95% confidence interval (CI): 0.70–0.88)]. When only studies with a prospective design were considered, the reduction in LBR was as high as 40% (RR 0.60, 95% CI: 0.41–0.87)[160]
			• Somigliana et al. (2011) studied 119 women with asymptomatic intramural or subserosal fibroids, 5 cm and compared these outcomes with 119 controls: The LBR were similar (18 vs. 13%, respectively), and the adjusted odds ratio (OR) was 1.45 (95% CI: 0.71–2.94). It was concluded that the presence of asymptomatic small fibroids did not affect ART outcomes[161] • Yan et al. (2014) included 249 women undergoing their first IVF/ICSI cycle with different types of fibroids and compared them with 249 controls without fibroids. After matching for several variables, delivery rates were 33.7% and 30.5% for controls and women with fibroids, respectively [adjusted OR 1.03 (95% CI: 0.95–1.11)]. A significant negative effect on delivery rate was noted when the largest tumor diameter was 2.85 cm[162]
Adenomyosis	Depot GnRHa alone or in combination with cytoreductive surgery	• GnRHa—regression of lesions through induction of hypogonadotropic status • Direct action on adenomyotic lesions through types I and II receptors on the endometrium • Cytoreductive surgery reduces hypertrophy and subsequently improves function by bringing the uterine layers closer together • It also enhances blood supply, thereby facilitating GnRHa action	With respect to pregnancy outcomes with GnRHa, Wang et al. (2009) retrospectively studied two groups of women. In the first group, adenomyotic tissue was surgically removed and GnRHa was given for 6 months (n = 28). A second group (n = 37) only received 6 months of GnRHa. They noted uterine regrowth after the effect of GnRHa had disappeared in the GnRHa-only group. Cumulative spontaneous pregnancy rates after 36 months were significantly higher with the combined treatment of surgery plus GnRHa[163]
Synechiae	Hysteroscopic adhesiolysis with hysteroscopic scissors	Repair the impaired lining, restoring normal uterine cavity and fertility	Adhesiolysis permits the endometrium to re-establish its anatomy and function, depending on the degree of the adhesions and the preoperative appearance of the endometrium observed with TVS. Much more than other conditions, IUAs are associated with a high recurrence rate (3.1–62.5%), which is dependent on the severity of adhesions[164]

(ART: assisted reproductive technology; ASRM: American Society for Reproductive Medicine; CPR: clinical pregnancy rate; GnRHa: gonadotropin-releasing hormone agonist; IUAs: intrauterine adhesions; IVF: in vitro fertilization; LBR: live birth rate; MR: miscarriage rate; RIF: recurrent implantation failure; TVS: transvaginal sonography)

Treatment of Thin Endometrium

Treatment of thin endometrium has been depicted in **Flowchart 7 and Tables 7 to 9**.

Flowchart 7: Treatment of thin endometrium.



Treatment of Thrombophilia and Immunological Factors

Treatment of thrombophilia and immunological factors has been explained in **Table 10**.

TABLE 7: Treatment of thin endometrium—endocrine strategy.

Strategy	*Rationale*	*Evidence*
High-dose oral E2	Estrogen helps endometrial proliferation by causing spiral artery contraction and reducing oxygen tension in the functional layer, which facilitates embryo implantation[165,166]	Different therapeutic approaches will most likely produce similar results, as exogenous estrogen administration compared with, or even combined with, endogenous estrogenic action from gonadotropin administration has not shown any superiority[11,167]
Intramuscular/ transdermal/vaginal E2	• Avoids first liver pass metabolism • Higher serum E2 concentrations • Better safety profile and longer mean t½ • Especially useful, when treating high-risk • patients, e.g., advanced maternal age	No clear benefit for one over another, and have achieved similar pregnancy rates[168]
GnRHa in luteal phase	Improved implantation and pregnancy rate, by supporting the corpus luteum	Luteal phase GnRHa (triptorelin 0.1 mg on the day of OPU, ET, and 3 days later) resulted in better pregnancy rate when compared with conventional luteal phase support. However, the quality of evidence in low[169]
Intrauterine G-CSF	G-CSF increases endometrial stromal cell decidualization mediated through cAMP by apocrine and paracrine action, and by inducing proliferation and differentiation of the human endometrium[170]	The only published RCT failed to show any impact on clinical outcome[171]
Autologous platelet-rich plasma (PRP)	Activates platelets by clotting, releases cytokines and growth factors, including VEGF, transforming growth factor, platelet-derived growth factor, and epidermal growth factor	Five patients with refractory endometrium received intrauterine PRP, along with high-dose E2 valerate. All five patients achieved endometrial thickness >7 mm, and they were all pregnant after embryo transfer (four ongoing pregnancy and one miscarriage).[172] However, no other study has validated these findings

(cAMP: cyclic adenosine monophosphate; E2: estradiol; ET: embryo transfer; G-CSF: granulocyte colony-stimulating factor; GnRHa: gonadotropin-releasing hormone agonists; OPU: oocyte pick up; RCT: randomized controlled trial; VEGF: vascular endothelial growth factor)

TABLE 8: Treatment of thin endometrium—with aspirin, vitamins, and supplements.

Strategy	*Rationale*	*Evidence*
Aspirin	• Decreasing subendometrial contractions • Inhibiting cyclo-oxygenase and prostaglandin biosynthesis • Improving uterine endometrial blood flow[173]	No beneficial effect on embryo implantation[174,175]
Nitroglycerine patches	• Nitric oxide (NO) is involved in endometrial cycle control and uterine preparation for pregnancy. Drugs that release • NO act as vasodilating agents, so they might be useful in women with thin endometrium	Ohl et al. (2002) administered nitroglycerin patches the day before embryo transfer in women with repeated implantation failure, but these authors were unable to demonstrate any effect.[176] There is no current evidence to support the use of nitroglycerin patches in women with a thin endometrium
Vitamin E ± pentoxifylline	Vitamin E—antioxidant and vasodilatory effect Pentoxifylline—inhibits phosphodiesterase by increasing intracellular cAMP—has a vasodilating effect and increases red cell membrane flexibility, while reducing blood viscosity by inhibiting red cell aggregation	Currently, only observational studies, no RCTs are available[177-179]
Sildenafil citrate	Enhances the vasodilator effect of NO by reducing cGMP degradation. It exerts its action at the endothelial smooth muscle level, and plays a relevant role in regulating vascular structure, growth and tone	Although biological plausibility exists, any evidence for the clinical benefit of sildenafil in women with a recurrent thin endometrium is weak, and very few publications[180,181] on nonrandomized studies have been found, with very few patients included
L-arginin	Arginin is an essential amino acid that plays an important role in regulating vasodilation and vascular flow. It is the main substrate for NO synthesis via NO synthase, and for ornithine and polyamines, which are key factors in placental angiogenesis and uterine flow regulation	Weak evidence to support its use in refractory endometrium,[182] solid data are still lacking to validate the usefulness of this approach

(cAMP: cyclic adenosine monophosphate; RCT: randomized controlled trial)

TABLE 9: Treatment of thin endometrium—surgical strategy.

Strategy	*Rationale*	*Evidence*
Hysteroscopy	Possible use could be to diagnose a previously unrecognized uterine pathology	Hysteroscopy in the preceding cycle has been reported to improve pregnancy outcomes in couples with three or more failed embryo transfer cycles,[183] but this evidence has recently been contradicted by a multicenter, randomized controlled trial that showed hysteroscopy to be of no value in RIF[184]
Endometrial scratch	The healing process following endometrial scratch may release cytokines and growth factors which encourages endometrial growth and facilitates implantation	• Meta-analysis including 14 trials and a total of 1,063 women concluded that moderate-quality evidence suggests that if 26% of women achieve live birth without endometrial injury, between 28% and 48% will achieve live birth with endometrial injury • A sensitivity analysis removing the studies at high risk of bias • showed no difference in effect[185]
Stem cells	Endometrial reconstruction based on the regenerative properties of the endometrium	• Three main sources of stem cells for endometrial cell reconstruction have been proposed, they are clonogenic multipotent mesenchymal stem/stromal cell, bone marrow derived stem cell, human embryonic stem cell • Till date, only one case of human endometrial regeneration • with reproductive success has been published[186]
Uterine transplantation	New therapeutic approach for women with absolute uterine factor infertility (AUFI), in whom adoption or surrogacy is not acceptable	• The first case of a healthy live birth after uterus transplantation[187] was published in 2014 in one of the nine women transplanted in Sweden[187] • Uterine transplantation as a promising clinical option for AUFI in the near future once experienced groups have settled the surgical, ethical, and social matters related to this technique

(RIF: recurrent implantation failure)

TABLE 10: Treatment of thrombophilia and immunological factors—immunomodulation.

Immunomodulator	*Rationale*	*Evidence*
Glucocorticoids	Glucocorticoids may mend the intrauterine environment by performing the action of as immunomodulation and reduce the uterine natural killer (NK) cell count and stabilize the cytokine expression profile in the endometrium and by decreasing of endometrial inflammation	14 studies (involving 1,879 couples) were included. Three studies reported LBR and these did not identify a significant difference after pooling the (preliminary) results (OR 1.21, 95% CI: 0.67–2.19). With regard to pregnancy rates, there was also no evidence that glucocorticoids improved clinical outcome (13 RCTs; OR 1.16, 95% CI: 0.94–1.44)[188]
Aspirin	Reduction of inflammation in the uterine cavity and improvement of uterine and ovarian perfusion, which might improve endometrial receptivity and ovarian responsiveness	13 trials (involving 2,653 couples) were included. There was no evidence of a difference between the aspirin group and the group receiving no treatment or placebo in rates of live birth (RR 0.91, 95% CI: 0.72–1.15, three RCTs, n = 1,053, I^2 = 15%, moderate-quality evidence). In addition, clinical pregnancy rates were also similar for the two groups (RR 1.03, 95% CI: 0.91–1.17, 10 RCTs, n = 2,142, I^2 = 27%, moderate-quality evidence). There was no evidence of a difference between groups in terms of multiple pregnancy, miscarriage, ectopic pregnancy, or vaginal bleeding. Data were lacking on other adverse effects[189]
Heparin	• The complex containing heparin-binding epidermal growth factor has been shown to enable an invasive phenotype of the trophoblast and hinder apoptosis[190] • Heparin also raises the free level of insulin-like growth factor (IGF) I and IGF II, which increase trophoblast invasion[191] • Heparin has been shown to encourage transcription of matrix metalloproteinases, which is known to control cell–cell interactions including breakdown of the decidua's basement membrane, helping trophoblast invasion	Two RCTs and one quasi-randomized trial were included in the meta-analysis. Pooled risk ratios in women with ≥3 RIF (N = 245) showed a significant improvement in the LBR (RR = 1.79, 95% CI = 1.10–2.90, p = 0.02) and a reduction in the miscarriage rate (RR = 0.22, 95% CI = 0.06–0.78, p = 0.02) with LMWH compared with controls. The IR for ≥3 RIF (N = 674) showed a nonsignificant trend toward improvement (RR = 1.73, 95% CI: 0.98–3.03, p = 0.06) with LMWH. However, the beneficial effect of LMWH was not significant when only studies with unexplained RIF were pooled. The summary analysis for the numbers needed to be treated with LMWH showed that approximately eight women would require treatment to achieve one extra live birth[192]

Immunomodulator	*Rationale*	*Evidence*
Intravenous immunoglobulin G (IVIG)	In ART, the proposed mechanism of action is by a reduction of peripheral cytotoxic NK cells,[193] enhancement of regulatory T cells, and downregulation of antibody producing B cells[194,195]	10 studies were included. The use of IVIG was significantly associated with a higher IR and RR was 2.708 (95% CI: 1.302–5.629) compared with the placebo. The clinical pregnancy rate and the LBR were significantly increased in patients randomized to IVIG; RR was 1.475 (95% CI: 1.191–1.825) for the clinical pregnancy rate and RR was 1.616 (95% CI: 1.243–2.101) for the LBR. Moreover, the miscarriage rate was significantly less in patients randomized to IVIG (0.352, 95% CI: 0.168–0.738), but the LBR per embryo transferred was not (2.893; 95% CI: 0.810–10.331) less
Anti-TNF-α	TNF-α is a cytokine produced by TH1 cells involved in the cell-mediated immune response. Anti-TNF-α interacts with and neutralizes TNF-α, thereby decreasing the inflammatory and cell-mediated immune response from TH1 lymphocytes	At present no RCTs have been reported investigating the effect of anti-TNF-α on pregnancy outcome from IVF or ICSI treatment
Intralipid	The therapeutic effect in the framework of IVF is proposed to be mediated by a decrease of peripheral blood NK cell activity and suppression of proinflammatory cytokines[196]	Only one RCT is available on this topic. No difference in chemical pregnancy was found between the two groups. The authors reported a borderline significant difference in ongoing pregnancy and live birth in favor of intralipid,[197] but the study was not sufficiently powered to enable differentiation of this from a chance observation

(ART: assisted reproductive technology; CI: confidence interval; ICSI: intracytoplasmic sperm injection; IR; implantation rate; IVF: in vitro fertilization; LBR: live birth rate; LMWH: low-molecular-weight heparin; OR: odds ratio; RCT: randomized controlled trial; RIF: recurrent implantation failure; RR: risk ratio; TNF-α: tumor necrosis factor alpha; TH: T helper)

Treatment of Multifactorial Effectors

Endometriosis

The administration of GnRHa for 3–6 months before ART in women with endometriosis significantly improves the ongoing pregnancy rate.[198] No harmful effect on ovarian response was observed. A meta-analysis of three RCTs showed that this treatment increased the odds of clinical pregnancy by fourfold.[104] Most investigators approve that there is no benefit in the removal of endometriomas before IVF,[154,155] whereas the role of laparoscopic treatment of nonovarian endometriosis in patients with failed IVF is controversial.[199,200] Furthermore, surgery might be deleterious for ovarian reserve.

Treatment of Hydrosalpinges

Treatment of hydrosalpinges has been explained in **Table 11**.

Gamete Donation and Surrogacy

Couples with RIF need help on the aptness of ensuing with further IVF attempts. If implantation fails to occur in spite of repeated treatment attempts or if the prognosis of further IVF treatment is measured to be poor, alternative treatment options should be reconnoitered. If the likely basis of the problem lies with the embryo, gamete donation should be recommended. On the other hand, if the problem lies in the uterus, e.g., multiple small fibroids or Asherman's syndrome, which has failed to react to surgical treatment, surrogacy must be discussed.

KEY POINTS

- There are a lot of controversial issues in the field of reproductive medicine, starting from the definition of infertility, which moves on to the diagnosis of unexplained infertility, which entitles the couple to an unproven treatment, IVF. And in those couples who do not conceive after three or more attempts of IVF, comes a fabricated diagnosis of RIF.
- A made up disease—infertility, refined by another refined diagnosis—unexplained infertility, and repeated failure with unproven treatment IVF, repeated failure of which leads to another new diagnosis—RIF, these are not diagnoses in themselves, but are mere clinical presentations.
- Until we understand and can accurately discern the underlying causes, the value of all proposed interventions is likely to be underestimated.
- William Watson rightly describes this as "The causes and treatment of non-disease". And JLH (Hans) Evers quotes in his prescient Editorial, "Perhaps the best course of action for a physician is to tell patients who have very little wrong with them that they do, indeed, have very little wrong with them, and then give them nothing for it".

TABLE 11: Treatment of hydrosalpinges.

Modality	*Advantage*	*Disadvantage*	*Evidence*
Salpingectomy	Improves implantation and live birth rate	May compromise ovarian response to stimulation during subsequent IVF treatment	• Strandell et al. (2005)[201] analyzed the cost-effectiveness of salpingectomy prior to IVF, for up to three IVF cycles. They found that the cost per live birth in the salpingectomy group was 22,823 Euros, which was significantly lesser than the cost per live birth in the control (no salpingectomy) group (29,517 Euros). The observation proposes that it is more cost-effective to routinely remove hydrosalpinges prior to IVF treatment • Meta-analysis159 of three RCTs involving prophylactic salpingectomy in 295 patients with hydrosalpinges, the pregnancy and live birth rates doubled following prophylactic salpingectomy
Salpingostomy	Salpingostomy not only "removes" the hydrosalpinges, but also produces the possibility of natural conception	The likely recurrence of hydrosalpinges after salpingostomy, which necessitates a further procedure to remove the tube, further delaying the treatment and suffering extra cost	• The intrauterine pregnancy rate following salpingostomy has been reported by a number of studies to be over 30%[202,203] • The results are likely to be higher if the damage to the Fallopian tubes is minimal[204]
Laparoscopic proximal tubal occlusion	Simpler operation and less likely to disturb ovarian blood supply and hence compromise ovarian response to stimulation by gonadotropins during IVF treatment	Occlusion of the proximal part of the tube leaves behind the dilated and blocked tube and increases the risk of future infection (pyosalpinx) and persistent pain, which necessitates salpingectomy in future	Meta-analysis[205] by Johnson et al. (2010) provides evidence that laparoscopic tubal occlusion is an alternative to laparoscopic salpingectomy in improving IVF pregnancy rates in women with hydrosalpinges
US-guided drainage of hydrosalpinx fluid	• Relatively simple • Less invasive • Less cost	The fluid may rapidly reaccumulate as the underlying pathology has not been altered risk of introducing infection	Studies have found no evidence of benefit for clinical pregnancy rate or live birth rate[206,207]

(IVF: in vitro fertilization; US: ultrasound)

- Couples with infertility belong to a very vulnerable group. They will do almost anything to achieve a pregnancy. They deserve our dedicated care and evidence-based treatment.
- In case such an evidence base is lacking, the patients should be counseled accordingly and, if the occasion arises, they might be invited to participate in a carefully designed clinical trial. They should not be exploited.

CHAPTER 62

Empty Follicle Syndrome

Ayesha Gupta, Kamini A Rao

INTRODUCTION

Empty follicle syndrome (EFS), a rare but frustrating complication of in vitro fertilization (IVF) leading to cycle cancellation, was first described by Coulam et al.[1] This rare event is responsible for substantial stress and anxiety to both the patients and the clinician during an assisted reproductive technology cycle.

DEFINITION

Empty follicle syndrome is a condition where no oocytes are retrieved despite repeated aspiration and flushing, after an apparently adequate ovarian response to stimulation, evidenced by serial ultrasound and adequate steroidogenesis. It was first described by Coulam et al. in 1986.[1]

INCIDENCE

Due to uncertainty of its existence and variability in the inclusion criteria across different studies, its prevalence varies over a wide range, from as low as 0.045 to 7% of IVF cycles.[2]

Also lack of the human chorionic gonadotropin (hCG) concentration threshold, to distinguish between genuine and false EFS, as well as the choice of the patient population are two key points responsible for this extreme variability in its incidence.

Considering only ovarian stimulation cycles with good ovarian response would underestimate the incidence of EFS, as in reality, the general IVF population includes at least about 30% of poor or suboptimal responders who are more likely to be affected with EFS than those with more than five well-developed follicles.

Kim and Jee (2012) in his study of 705 IVF cycles, excluding poor responders from the analysis, concentrated on the type of ovarian stimulation protocol, and demonstrated comparable EFS prevalence (2.4%) in both gonadotropin-releasing hormone (GnRH) antagonist and long GnRH agonist (GnRHa) protocols.[3]

More recently, in a study of 3,356 IVF cycles, Madani and Jahangiri (2015) reported a prevalence of 1.7%, with a slightly higher frequency with the miniflare GnRHa protocol,[4] as already known, this protocol is more often reserved for older women with a low ovarian reserve (Franco et al., 2006)[5] supporting the association of EFS with ovarian aging.

However contradicting this, Castillo et al. (2012)[6] compared 2,034 egg donor cycles (carried out among young high responders), receiving a GnRHa trigger, with 1,433 IVF cycles of women using their self-eggs (including poor responders of any age), triggered with recombinant hCG; and surprisingly, EFS prevalence was similar in both the patient populations, and higher overall than the prevalence reported in other studies (3.5% vs. 3.1%, respectively). This is the only study comparing EFS among egg donors and the general IVF patient population (women of any age and ovarian responsiveness).

In spite of being a rare phenomenon, EFS has profound implications for counseling about the future reproductive performance of the couple, especially when the chances of recurrence are high, especially in advanced age group patients. As per Velasco et al. study, it is estimated that patients with one EFS cycle have a 20% risk of recurrence in later IVF cycles.

CLASSIFICATION OF EMPTY FOLLICLE SYNDROME

Two classes of EFS can be defined as differentiated by the hormone levels on the day of the oocyte retrieval **(Table 1)**.

However, these definitions lack standardization as the threshold circulating level of hCG, in case of a hCG trigger to define a "correct trigger" is still uncertain, and a wide concentration range from 5 to 160 hCG IU/L after about 36 hours from exogenous hCG administration has been indicated by different investigators to differentiate between false (FEFS) and genuine empty follicle syndrome (GEFS).[4,7] Ndukwe et al. (1996) found a cut-off value of 10 mIU/L for

TABLE 1: Classification of empty follicle syndrome.

Genuine empty follicle syndrome	*False empty follicle syndrome*
It is defined as failure to retrieve oocytes from mature ovarian follicles, after triggering apparently normally developed follicles, in the presence of optimal beta hCG levels (in case of an hCG trigger) on the day of oocyte retrieval7 or in the presence of optimal LH levels 12 hours post agonist trigger	It is defined as failure to retrieve oocytes in the presence of low beta hCG levels, due to an error in administration or due to reduced bioavailability of the choriogonadotropin7 or inappropriately administered agonist trigger (e.g., hypogonadotropic hypogonadism group)
Rarest occurrence	Most common among EFS
Cycle cannot be rescued with a repeat trigger	Cycle can be rescued with a repeat trigger

(EFS: early follicle syndrome; hCG: human chorionic gonadotropin; LH: luteinizing hormone)

beta hCG in serum, 36 hours after an ovulatory dose of hCG, to have a 100% sensitivity and specificity for predicting EFS.

Similarly, post-agonist trigger serum luteinizing hormone (LH) and progesterone values defining an optimal trigger, to differentiate FEFS from GEFS are lacking currently. Some investigators have indicated an LH circulating level of 15 IU/L as the cutoff value,[8] but other studies have used different thresholds.[7]

In a review of EFS by Stevenson et al. (2008), incidence of GEFS and FEFS was 33% and 67%, respectively.[9]

ETIOPATHOPHYSIOLOGY

Empty follicle syndrome continues to be a rare condition of obscure etiology.

While some authors are totally skeptical about its existence,[2] various possible mechanisms have been attributed by others.

Pathophysiology of False Empty Follicle Syndrome Following hCG Trigger

Inadequate or Absent Luteinizing Hormone Surge

Throughout follicular development, the growing oocyte is surrounded by cumulus cells, and these are, in turn, linked to mural granulosa cells by cell-to-cell junctions. These junctions tightly bind the egg to the follicle wall. The physiological mid-cycle LH peak, mimicked by a bolus administration of hCG or GnRHa, brings about the rupture of these intercellular junctions and thus releases the cumulus–oocyte complex (COC) to freely float in the follicular fluid, and thereby be available for aspiration.[10]

The final triggering simulating the endogenous LH peak is a fundamental step of ovulation, and absence or any inadequacy of the LH or LH-like activity in IVF cycles, may result in failure to retrieve an oocyte (FEFS).

- *Errors in administration of the trigger:* False EFS is most likely associated with errors in the hCG administration, especially, when the patient or her partner has to self-administer the drug or, when it is administered by someone who lacks expertise. Urinary extract of hCG is available as a powder needing reconstitution before administration. Any errors in this step can deliver insufficient drug to the follicle and so FEFS can result.[11]
- *Error in timing of the injection:* Luteinizing hormone surge effect is fully displayed after 34–38 hours from injection, with a peak effect at about 36 hours.[12] Some patients may time the hCG injection incorrectly or some may refrain from informing nurses and physicians the actual hour at which they self-administered hCG.
- *Improper timing of the oocyte retrieval:* The effect of hCG may be impaired if oocyte retrieval is performed too early (before 34 hours from the injection), or too late (after 38 hours, when the largest follicles have already spontaneously ovulated).
- *Manufacturing defects and potency defects:* Such an event was described in a study showing the reduced in vivo biological activity of some batches of commercially available hCG.[13] Moreover, the manufacturers advise storing hCG medications away from direct light sources and at a temperature below 25°C; these conditions, if not met with, can alter the efficacy of the drug and hence can cause FEFS. *Poor metabolism of the bet-hCG trigger can also lead to FEFS.*
- *Low bioavailability due to variation in the absorption or clearance:* Subcutaneous administration of hCG injection in women with history of bariatric surgery may alter the absorption due to abdominal skin redundancy. In such patients intramuscular injections are preferred. In others, a very rapid clearance of hCG by the liver (desialylation of the hCG molecule subjects it to rapid clearance by the liver).[14]
- *Ovarian low bioavailability of hCG:* It may result in a unilateral EFS, as in ovarian torsion occurring between the time of trigger and follicular aspiration. Oocytes can be aspirated from the unaffected ovary.[15]
- For the above said reasons, FEFS can be rightly called—"the pharmaceutical industry syndrome".[13]

Pathophysiology of False Empty Follicle Syndrome Following GnRHa Trigger

- *Wrong trigger:* Gonadotropin-releasing hormone agonist trigger in a woman with hypogonadotropic

hypogonadism (WHO type 1 anovulation) or in an agonist protocol.
- *Inadequate response to agonist trigger:* Administering an agonist trigger in a woman with overly suppressed pituitary.

Pathophysiology of Genuine Empty Follicle Syndrome

Pathophysiology of GEFS is still poorly understood.

Recently, seven ZP1 mutations have been seen as the cause of genuine empty follicle syndrome. ZP1 encodes the ZP1 glycoproteins, these mutations are postulated to affect the secretion of zona pellucida proteins, this prevents zone pellucida formation.

Thus leading to defective oogenesis, folliculogenesis and subsequently impaired fertilization and implantation. In genuine empty follicle syndrome, the anti-ZP autoantibodies can induce GEFS.

Dysfunctional Folliculogenesis

It was observed that the granulosa cells of patients with recurrent EFS have an increased expression of some proapoptotic genes and a significant reduction in transcripts, whose products are responsible for normal follicular growth (e.g., PAPP-A, MAPK 3) than normal patients.[16] As a result, oocytes may be lost in the late folliculogenesis due to apoptosis.

- *Ovarian aging:*[17] A possible relationship exists between poor ovarian response and failure to retrieve oocytes, suggesting EFS may represent an advanced stage of ovarian aging, characterized by residual responsiveness of the granulosa cells while the oocytes fail to develop adequately.
- Faulty oocyte development and maturation[16]
- Strong attachment of the cumulus cell complexes to the follicular wall, dysfunctional signaling between the cumulus cells and the oocyte.[18]
- *Receptor polymorphism:* Novel mutation in LH/hCG receptor (LHCGR) was identified in two sisters with GEFS which is inherited as a recessive trait.[19] A mutation (p.N400S) in the gene coding for LHCGR was detected to be associated with GEFS and was inherited as a recessive trait. The mutation causes an irreversible block in the transmission pathway of LH signal, and so even repeat administration of hCG would be ineffective.[19]

A pericentric inversion in a fragile site of chromosome 2 (site 46, XX, inv(2) (p11q21) has been identified in a woman who had repeated GEFS.[20] Chromosome 2 has the genes coding for Inhibin βb, which are involved in the onset of premature ovarian insufficiency.[21] This may suggest a possible link between EFS and ovarian aging, precocious reduction of ovarian follicular reserve, or both.

Pathophysiology of EFS with Various Triggers

Physiology of EFS after triggering with hCG or a GnRHa is not the same.

Human Chorionic Gonadotropin Trigger

Human chorionic gonadotropin, when used as a surrogate for LH, as trigger, acts directly on the ovary. So, EFS in case of an hCG trigger can be said to be attributed to abnormal folliculogenesis or to the response of the ovary to the triggering stimulus or errors in administration of the trigger (dose, route, timing).

Gonadotropin-releasing Hormone Agonist Trigger

The pathology here may be the inability of the pituitary to release adequate LH sufficient to trigger ovulation or failure of the receptors on the ovary to mediate the action of LH or polymorphism of the LH β subunit gene.

Likely patients to have EFS with agonist trigger are:

- *Hypogonadotropic hypogonadism patients (WHO Type 1):* These patients are characterized by endogenous follicle-stimulating hormone (FSH) and LH <1.2 IU/L.
- The second is the possibility of EFS in a patient with borderline hypothalamic pituitary dysfunction, but with gonadotropin levels just above the hypogonadotropic hypothalamic level. The lower production of LH in these patients would allow for follicular development and initial luteinization, but would be insufficient to complete cumulus cell expansion and its loosening from the follicular wall. Hence, depending upon the degree of response of the pituitary to the agonist trigger, a GEFS or FEFS may occur.[6]
- A temporary state of hyposensitivity of the pituitary to the agonist trigger may exist in some cycles, so in such cases an hCG trigger may recover mature oocytes.
- *Patients with GnRH receptor polymorphism:* These women need a high dose of the agonist to activate the receptor.
- Women with a variant LH β gene polymorphism, especially the homozygous form, have the less bioactive LH molecule and so are at risk for a blunted response after an agonist trigger.

RISK FACTORS FOR EMPTY FOLLICLE SYNDROME

No definitive risk factors to predict the incidence of EFS before the start of controlled ovarian stimulation have been elicited.

However, the possible risk factors include:[17]

- Previous history of EFS
- Advanced age with poor ovarian reserve (37.7 ± 6 years vs. 34.2 ± 6 years, p <0.001).

- Ovarian resistance to various stimulations
- Obesity
- Longer duration of infertility (8.8 ± 10.6 years vs. 6.3 ± 8.4 years, p <0.05)
- Higher baseline FSH levels (8.7 ± 4.7 IU/L vs. 6.7 ± 2.9 IU/L, p <0.001)
- Lower estradiol levels on the day of trigger (499.9 ± 480.9 pg/mL vs. 1,516.3 ± 887.5 pg/mL, p <0.001).

DIAGNOSIS AND PREVENTION

At the time of oocyte retrieval, if no oocytes can be retrieved after aspirating a good number of follicles, EFS can be diagnosed by detecting hCG in urine or follicular fluid (using a rapid home pregnancy kit) or blood (>40 mIU/L), to exclude incorrect or inadequate trigger administration. Presence of hCG in these samples more likely suggests a GEFS and the absence or suboptimal values of hCG suggests FEFS.

For an agonist trigger, a 12-hour post-trigger LH concentration at or near 15 mIU/mL is used as a threshold between adequate and inadequate response to the GnRHa trigger.[22,23]

A 12 hour post-trigger progesterone concentration (progesterone level >3.5 ng/mL 8–12 hours after trigger) can be a complementary indicator of trigger response over LH alone.[24] Luteinization of the follicle releases progesterone. Patients with a higher number of follicles will have higher values of progesterone. An appropriately elevated post-trigger progesterone concentration associated with a borderline or even low LH concentration can still result in successful oocyte retrieval. But, conversely, low post-trigger progesterone concentration associated with LH concentration >15 mIU/mL might suggest an inadequate response.

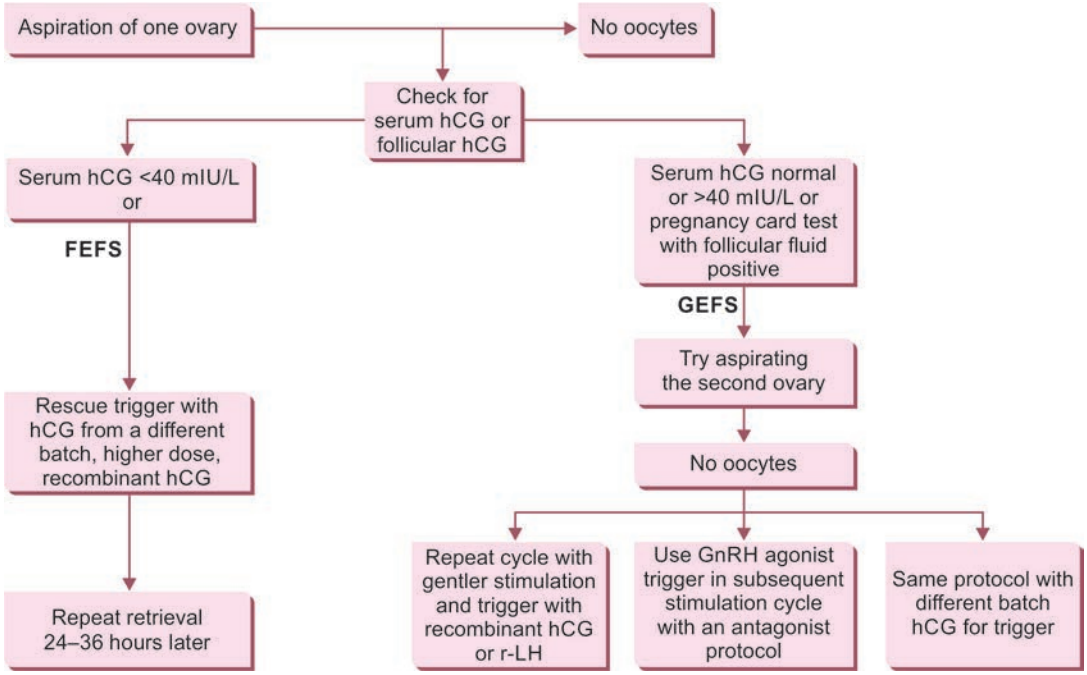
When interpreting post-trigger LH and progesterone concentrations, considering the time interval between the trigger and the post-trigger assay is crucial, especially true for LH, as peak LH levels occur 4 hours after agonist trigger followed by a rapid decline,[25] making LH highly dependent on the time of measurement, in relation to the time of trigger. Shorter time intervals (e.g., 4–8 hours) will result in higher LH values and progesterone results. Longer post-trigger intervals (e.g., 12–15 hours) will result in lower serum LH values and higher serum progesterone values.

MANAGEMENT OF EFS IN THE CURRENT CYCLE

Though EFS can be a rare event, it can be a frustrating complication of IVF, leading to cycle cancellation. So, every attempt to rescue the cycle should be made **(Flowchart 1)**.

- *Re-administering hCG and reaspiration in a case of FEFS:* A repeat, rescue dose of hCG in cases of FEFS was first proposed by Ndukwe et al. in 1997, and this has remained as the consensus solution in the literature since that time.[11,14,26-28] During the second retrieval attempt, 24–36 hours later, follicles from the previously aspirated ovary

Flowchart 1: Management of empty follicle syndrome.



(FEFS: false empty follicle syndrome; GEFS: genuine empty follicle syndrome; hCG: human chorionic gonadotropin; r-LH: recombinant-luteinizing hormone)

should be reaspirated. Mucification of the cumulus cells in response to circulating hCG allows dissociation of the cumulus–oocyte complex, and collection with a second aspiration may be possible. The rescue dose may be of a higher dose or from a different batch of urinary hCG or switched to recombinant hCG. A recent review of literature has documented that 42.8% of cycles (6 out of 14) rescued with repeat hCG resulted in a healthy live born fetus.[9]

Contrary to the above findings, Reichman et al. in his large study, presented a less optimistic picture with rescue hCG trigger. The probable theories proposed for this included a 72 hour unintended "coasting" period, thereby resulting in the post maturity of some oocytes. However, the success rates should further be investigated and the patients should be thoroughly counseled.

- *Delayed retrieval if there was an error in timing:* It may be hypothesized that cumulus expansion, which allows the oocyte to detach from the follicular wall, may also require longer time periods in certain patients.

MANAGEMENT OF SUBSEQUENT CYCLES AFTER EMPTY FOLLICLE SYNDROME

- Check for possible risk factors before the start of the stimulation.
- Triggering the next cycle with recombinant hCG or recombinant LH
- Gonadotropin-releasing hormone agonist trigger (GnRHa trigger).

Agonist trigger to induce, the more physiological LH surge, in an antagonist cycle has been proposed as one of the strategies to prevent EFS.[29-31]

PROGNOSIS

Counseling of the couples who may be at risk for EFS is very important. Though EFS may be a sporadic event with a self-limiting phenomena, it may recur in 15.8–31% of cases.[17] This recurrence increases with increasing age suggesting the association of EFS with ovarian aging.

KEY POINTS

- EFS is a condition where no oocytes are retrieved despite repeated aspiration and flushing after apparently adequate response to stimulation.
- Prevalence varies from 0.45 to 7% of IVF cycles.
- Genuine EFS is failure to retrieve oocytes from mature ovarian follicles, after triggering apparently normally developed follicles. It is a rare phenomenon, cycle cannot be rescued with a repeat trigger.
- False EFS failure to retrieve oocytes in the presence of low beta hCG levels, due to an error in administration or due to reduced bioavailability of the choriogonadotropin or inappropriately administered agonist trigger.
- Cut-off value of 10 mIU/L for beta hCG in serum, 36 hours after an ovulatory dose of hCG, is found to have a 100% sensitivity and specificity for predicting EFS. Wide range of 5–160 hCG IU/L is documented.
- FEFS causes can be attributed to errors in HCG administration, its dosage, its bioavailability, error in timing of hCG administration, improper timing of oocyte administration, manufacturing defects, its potency or ovarian low bioavailability of hcG.
- *GEFS:* Recent studies attribute ZP1 mutation leading to poor zona pellucida formation as the cause, other causes could be ovarian aging, temporary pituitary hyposensitivity to agonist trigger, faulty oocyte maturation and development, strong cumulus cell complexes attached to the follicular wall, GnRH receptor polymorphism or variant LH Beta gene polymorphism.
- EFS with GnRHa trigger can be due to inadequate release of LH by pituitary. This can be found in hypogonadotropic hypogonadism cases, with borderline hypothalamic pituitary dysfunction, GnRH receptor polymorphism or variant LH Beta gene polymorphism.
- Attempt to rescue a cycle in GEFS by readministering hCG (rescue dose) of different batch/higher dosage/recombinant hcG and attempting ovum pick up after 24–36 hours.
- For subsequent cycles check for risk factors, trigger with recombinant hcG or recombinant LH or GnRHa trigger in an antagonist cycle.
- Counsel the couple for recurrence risk in GEFS, which is 15.8–31% of cases.

CHAPTER 63

Role of Aneuploidy Screening in Preimplantation Embryos

Jwal Banker, Manish Banker, Parul Arora

INTRODUCTION

Aneuploidy is the presence of abnormal number of chromosomes, either extra or missing, in the cell nucleus. It occurs due to failure of separation of the paired chromosomes during cell division (nondisjunction).[1] It is seen commonly in human oocytes and embryos. It is believed that most embryos with aneuploidy either fail to implant, undergo developmental arrest, or miscarry. Such chromosomal defects compromise the viability of embryos and explain the low success rates of in vitro fertilization (IVF) and the low fecundity in natural conceptions. Therefore, to obtain a healthy live birth in IVF, it is important that the embryos transferred are chromosomally normal.

Traditionally, the most competent embryos used in IVF have been evaluated and selected for transfer using morphology-based grading as the primary technique. Recent advances in technologies in the fields of genomics, transcriptomics, proteomics, metabolomics, and time-lapse imaging have assisted in embryo selection. Evaluation of chromosome copy number and transfer of only euploid embryos, also known as aneuploidy screening or testing, is now gradually becoming the preferred modality to screen and select the embryos.

Aneuploidy screening or preimplantation genetic screening (PGS) has been advocated for use in conjunction with IVF. It involves identification and transfer of only euploid embryos where parents are chromosomally normal to improve the likelihood for a successful pregnancy. Preimplantation genetic diagnosis (PGD) on the other hand involves looking for a specific mutation or an unbalanced chromosomal component in the embryo for which the parents are carriers. Both the terms PGS and PGD are now replaced by the term PGT (preimplantation genetic testing) as advocated by the International Committee for Monitoring Assisted Reproductive Technologies (ICMART) glossary 2017.[2] PGT is defined as a test performed to analyze the DNA from oocytes (polar bodies) or embryos (cleavage stage or blastocyst) for aneuploidies (PGT-A), single gene disorders (PGT-M), and chromosomal structural rearrangements (PGT-SR).

ORIGIN OF ANEUPLOIDY

Aneuploidy in preimplantation embryos (whether IVF or conceived naturally) can primarily arise during three developmental stages:

1. The premeiotic divisions during gametogenesis
2. The meiotic division of gametogenesis
3. The early mitotic divisions during embryogenesis stage.

Understanding the mechanisms behind the defects in segregation of chromosomes at these stages gives insight into the role of PGT when applied in clinical practice.

Abnormal separation of chromosomes in oogenic meiosis-I and meiosis-II is the most common cause of aneuploidy in human preimplantation embryos. More than 20% of oocytes from patients with an average age under 35 years have been reported to be aneuploid in cytogenetic studies on oocytes and first polar bodies (PB1) from assisted conception cycles.[3,4] This percentage of aneuploidy increases significantly with age, to >65% of oocytes in advanced maternal age of >40 years, and 80% in the age group of 43 years and older.[5,6]

In contrast to oocytes, incidence of aneuploidy in sperms is only around 4–14%.[7,8]

As compared to meiotic, mitotic nondisjunction during embryogenesis yields two or more distinct cell lines resulting in both normal and abnormal cells in the same embryo, called as mosaic embryos. The proportions of these normal and aneuploid cells in such an embryo may vary, depending on the point at which the failed separation of chromosomes has occurred.

PROPOSED INDICATIONS FOR PGT-A

By definition, PGT-A (as compared to PGT-M) is performed in patients having no known chromosomal anomaly, mutation, or other genetic abnormalities. As such, there are no specific indications for PGT-A. It should be considered in patients in

whom the risk of having an aneuploid embryo is considered to be higher, such as:

- Advanced maternal age >35 years
- Patients with a history of recurrent early pregnancy loss
- Recurrent implantation failures
- Previous trisomic pregnancy
- Severe male factor infertility.

COUNSELING

Proper counseling is very critical because IVF patients planned for PGT-A do not have any inherent specific identifiable genetic abnormality, and PGT-A is recommended in order to detect aneuploidies so that the chances of pregnancy may be increased. The American Society for Reproductive Medicine (ASRM) Practice Committee guidelines[9] recommended certain key points that must be included at a minimum in the counseling before PGT **(Box 1)**.

TECHNIQUES AND LIMITATIONS

Biopsy for PGT is a two-step micromanipulation process that involves zona penetration and removal of one or more cells for chromosome analysis. The penetration or breaching of zona pellucida can be performed by different methods such as mechanical pipette-induced breakage, controlled acid tyrode treatment to dissolve part of zona, or by laser assistance. Various animals and humans have reported that zona breaching by the laser has no detrimental effects on embryo development, provided it is used appropriately.[10,11] Specialized micromanipulation pipettes are used to separate and remove the required cells from the embryo. Although PGT can be performed at any developmental stage starting from mature oocyte stage (metaphase II) to the blastocyst stage, generally this period has been divided into three discrete stages for clinical use: (1) Polar body (oocyte and/or zygote), (2) cleavage stage (day 3 embryo), and (3) blastocyst (day 5 or 6 embryo). Since each of these three stages is biologically different, PGT performed in each stage has different diagnostic relevance as well as limitations, both in terms of information gained and the risk to the viability of the embryo.

BOX 1: Key points that must be included in the counseling before preimplantation genetic testing (PGT).

- The risks associated with IVF
- The option of choosing not to proceed with IVF and PGT
- The risks associated with embryo biopsy and extended culture
- The possibility of a false-positive result that may lead to the discard of a normal embryo
- The possibility of a false-negative result that may lead to the transfer of an abnormal embryo
- The possibility that testing may yield inconclusive results
- The possibility that no embryos may be transferred if all appear abnormal
- Options relating to prenatal diagnostic testing and their associated risks:
  - Chorionic villus sampling
  - Amniocentesis
  - Ultrasonography with or without additional blood tests
  - No prenatal testing
- The nature and quality of the available evidence with regard to live-birth rates after IVF with PGT
- The disposition of embryos not transferred (e.g., discard, cryopreservation, research, or donation) as and when appropriate

(IVF: in vitro fertilization)
Source: ASRM Practice Committee guidelines[9]

Polar Body Biopsy

Through biopsy and analysis of the first and second polar body (PB1 and PB2), an indirect interpretation of the chromosome of the corresponding oocyte can be obtained. This helps in detecting aneuploidy of maternal origin in the embryos.[12] Removal of the polar bodies from a human oocyte does not have any deleterious effect on the development of the embryo, as these bodies have no role to play in fertilization or further embryonic growth.[13] There are two strategies for PB biopsy: (1) Biopsy of only PB1 and (2) combined biopsy of PB1 and PB2. However, isolated biopsy of PB1 has limited applicability as only metaphase-I errors can be detected in this, not including the chromatid segregation errors. Handyside et al.[14] have reported that biopsy of only PB1 can miss almost 30% of aneuploidy of maternal origin.

The other strategy of biopsy and analysis of both polar bodies can result in better detection of maternal-origin aneuploidy. This can be laborious and requires skill due to multiple micromanipulations steps which may be required—intracytoplasmic sperm injection (ICSI), PB1, PB2, and blastomere biopsy (in case of noninformative or ambiguous PB result). To minimize the multiple manipulations of sequential PB biopsy, there is a possibility of biopsying both PBs on the day of fertilization. However, there is a chance that PB1 may degenerate by that time, resulting in diagnostic failure. Another important limitation of polar body biopsy technique (either single or both) is that no information can be obtained on aneuploidies arising from paternal origin or postfertilization in the embryo.

Cleavage Stage Embryo Biopsy

Till some time back, cleavage stage embryo biopsy was the most common type of embryo biopsy performed worldwide. In a typical cleavage stage embryo biopsy, one or two blastomeres are taken from six to eight cell embryos. This is performed on day 3 following fertilization. Although the detection of aneuploidies of maternal and paternal origin as well as postzygotic origin is possible, it is not always possible to distinguish between these. The major shortcoming of cleavage stage biopsy results from the presence of the phenomenon of chromosomal mosaicism in the embryo, as discussed earlier. Mosaicism can result in both false positive

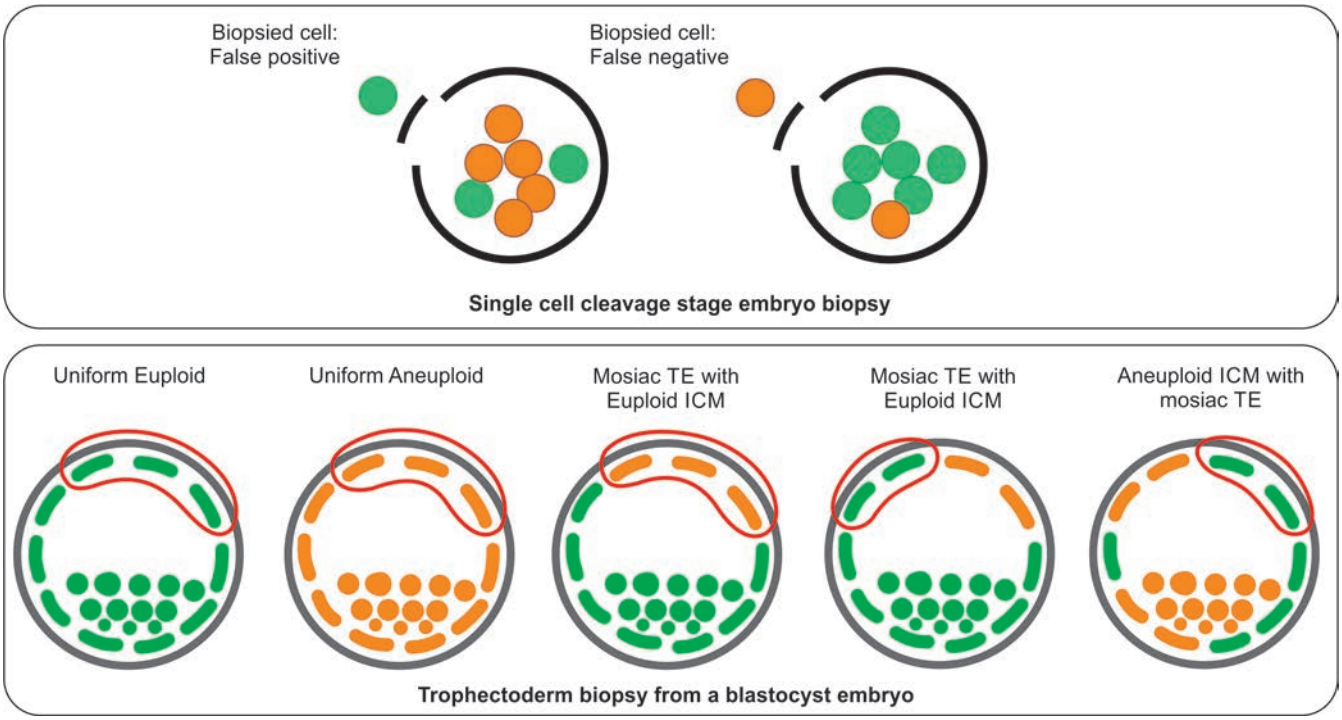

Fig. 1: Possible misdiagnosis following preimplantation genetic testing (PGT) biopsy.
(ICM: inner cell mass; TE: trophectoderm;)

and false negative results in a single cell or even two- cell biopsy **(Fig. 1)**. Further, a study by Liu et al.[15] has shown that the potential for the embryo to continue to develop and implant can be adversely affected by cleavage stage biopsy, and this deleterious effect is directly proportional to the size of the sample removed from the embryo. The cleavage stage biopsy strategy has now become less popular because of these two reasons.

Blastocyst Stage Biopsy

This is the most preferred stage for embryo biopsy, and it involves the biopsying of 6–10 trophectoderm (TE) cells from a day 5 or day 6 blastocyst. Just like cleavage stage, TE biopsy can detect aneuploidy occurring at gametogenesis stage as well as embryogenesis stage. Compared to other biopsy stages, it is highly reliable as it involves the retrieval of up to 10 cells without causing any damage to the inner cell mass (ICM) which gives rise to the fetus. The conventional method for TE biopsy involves the partial zona dissection using laser, followed by a period of culture to allow blastocyst growth. This causes herniation of cells through this laser-induced artificial breach. These cells herniating through the breach (approximately 6–10 cells) are then easily biopsied by excision or aspiration using specialized micromanipulation tools with or without the aid of a laser shot. Analysis of multiple cells decreases the chances of missing potential mosaicism and eliminates the extreme sensitivity of single cell diagnosis. The concern of nonreflection of genetic composition of ICM[16] was negated by Johnson et al.[17] suggesting 100% concordance between TE and ICM genetic makeup with exception of structural abnormalities. A major benefit of blastocyst biopsy, compatibility of embryo to grow to the blastocyst stage, is also one of its main limiting factors, as not all good quality day 3 embryos will grow to blastocyst stage. If very few blastocysts are available, biopsy cannot be used for selection purposes. Moreover, another issue faced with blastocyst biopsy is that of time constraint while awaiting the diagnosis. This leads to the need for cryopreservation of biopsied blastocysts. Hence, the subsequent effects of cryopreservation as well as thawing on the embryo viability also become an issue for concern. However, such concerns have been taken care of by improved culture methods, improved outcomes of cryopreservation and thawing, and methods of rapid molecular analysis, thus making blastocyst biopsy the preferred option.[18]

The advantages and disadvantages of biopsy for PGT at different stages are compared in **Table 1**.

DIFFERENT METHODS FOR CHROMOSOMAL ANALYSIS

Once the oocyte or embryo is biopsied and material is available for analysis, a predefined screening protocol should be used. A cytogenetic technique with very high sensitivity and specificity is required for PGT, as it involves analysis of one or only a few cells to define the karyotype and identify chromosomal abnormalities. The testing process should also be fast enough so that fresh embryo transfer (ET) can be carried out if so desired. The classic karyotyping methods cannot be used for testing as it is

TABLE 1: Advantages and disadvantages of different biopsy techniques for preimplantation genetic screening.

Technique	*Detail*	*Advantages*	*Disadvantages*
PB biopsy	• Earliest stage at which cells can be obtained for genetic testing • Based on assumption that the chromosomal make-up of PBs reflects that of the oocyte[20]	• Provides maximum time for genetic analysis in case of fresh embryo transfer • Least invasive, as PBs do not make a physical contribution to the embryo[20] and hence, no effect on fertilization rates or further embryo development[21]	• Detects aneuploidies originating only from maternal origin which in fact accounts for only 66% of embryonic aneuploidies,[22] leaving one-third of aneuploidies undetected • Not very cost-effective and labor intensive as two PBs are sampled per oocyte, and not all of them will develop into embryos
Blastomere biopsy	• Biopsied on day 3 postinsemination at the 6- to 10-cell stage • Removal of blastomeres is facilitated by incubation in Ca^{2+}/Mg^{2+}-free medium, which disrupts cellular junctions[23]	As sample is taken from embryo itself, it allows aneuploidies of both maternal and paternal origin to be detected	• Requires removal of a significant proportion of the embryo's cells, which may adversely impact embryo developmental viability and implantation rates[24] • Normal reported embryos can be mosaic and mosaicism is seen up to 29% of preimplantation embryos at cleavage stage[25,26]
Blastocyst biopsy	• Hole drilled in the zona pellucida on day 3, then cultured to blastocyst stage (days 5–6) • Some trophectoderm cells herniate through the hole in the zona pellucida which are removed, leaving the inner cell mass intact	• Randomized controlled trial evidence of no adverse impact on embryo implantation potential[27] • Allows more cells to be taken for • analysis • Greater efficiency as many cleavage stage embryos do not grow till blastocyst[28]	• The results of biopsy may not come same day, mostly necessitating vitrification of embryos and transfer in subsequent cycle[24,25] • Trophectoderm biopsy may not be • representative of the inner cell mass[18] • Mosaicism is still an issue[19]

(PB: polar body)

difficult to achieve adequate metaphase spreads with very limited number of cells.[29]

Fluorescent In Situ Hybridization

The first technique used for PGT in 1992 was fluorescent in situ hybridization (FISH) for sex selection to prevent the X-linked recessive disorders.[30] This molecular cytogenetic tool is highly sensitive and comparatively inexpensive, and it assists in determining the number of chromosome copies in the cell (ploidy) as well as structural abnormalities in metaphase chromosomes and interphase nuclei.[31] The process involves fixation of the cells to be analyzed to a glass slide followed by visual assessment after hybridization with fluorescent DNA probes specific for each chromosome. Earlier, only 2 sets with 5 chromosomes (typically for chromosomes 13, 16, 18, 21, 22 or chromosomes 13, 18, 21, X, and Y) were used in a test. Later, 12 chromosomes could be analyzed (X, Y, 2, 4, 13, 15, 16, 18, 19, 20, 21, and 22) at the cleavage stage. This allowed detection of almost 91% of blastocyst stage embryos with chromosomal abnormalities.

However, in past two decades, multiple randomized controlled trials (RCTs) have found that FISH-based PGT did not improve clinical outcomes, including live birth rates (LBRs).[32-34] This could be due to the limited number of chromosomes that can be analyzed in FISH[35] or the early stage of embryogenesis at which the biopsy is performed. Further, because of the very limited number of cells that are assessed, mosaicism may also be responsible for this.[36] There are also some technical disadvantages of FISH. For example, the signals can overlap (so that two different signals are visualized as one, or three signals as two). The signal can also "split" depending on the current cell cycle stage of the cell being analyzed, thus making a single signal visualized as two different signals.[37]

This has led to more usage of microarray-based tests using the whole genome amplification (WGA) technology.

Whole Genome Amplification

The advent of WGA technology has significantly improved the efficacy for molecular karyotyping for the complete set of chromosomes. All 23 pairs of chromosomes can be analyzed simultaneously and with greater accuracy by microarray-based tests using this technology, resulting in a lower rate of misdiagnosis.[38]

The process involves transfer of the cell(s) to a microfuge tube and cell lysis followed by genome amplification. The genome amplification can be performed either by polymerase chain reaction (PCR) or multiple displacement amplification (MDA), which can yield >20 µg of DNA from a single cell. This DNA is then used for WGA studies

TABLE 2: Technical aspects of different genetic tests used in PGT.

aCGH	• Whole-genome amplification (WGA) of DNA from the biopsied cell(s)[51] • Followed by fluorescent labeling, denaturation, and hybridization to an array platform containing thousands of DNA probes specific to each of the human chromosomes • Then subjected to fluorescent intensity scanning for each probe on the array • By comparison of these intensities with that of control sample, copy number of each chromosome in the biopsied cell is determined[52,53]
qPCR	• Preamplification of DNA from the biopsied cell/s • Followed by a high-order multiplex PCR reaction that amplifies several loci from each chromosome • Real-time qPCR quantifies each product, allowing a comparison across the genome[43]
SNP arrays	• WGA of DNA from the biopsied cell/s • Followed by fragmentation and hybridization to SNP array platform containing probes for >500,000 different SNP sites across the genome • Followed by extension and staining step • SNP sites of A/T nucleotides are labeled with a red fluorochrome, and G/C nucleotides are labeled with a green fluorochrome • With intensity measurement of red-to-green fluorescence at each SNP site on the array, it is possible to simultaneously genotype >500,000 SNPs in each sample
NGS	• WGA of DNA from the biopsied cell/s • Followed by fragmentation and tagging with a specific barcode • Barcoded DNA fragments mixed together and sequenced in parallel • Specialized computer software segregates the results according to biopsy sample by reading the tracking barcodes • Followed by comparison of each fragment against a reference human genome • Trisomy or monosomy is identified based on a corresponding increase or decrease in the number of aligned sequences

(aCGH: array comparative genomic hybridization; NGS: next-generation sequencing; PGT: preimplantation genetic testing; qPCR: quantitative polymerase chain reaction; SNP: single nucleotide polymorphism)

to establish copy number of each chromosome with high accuracy.

The following are the different techniques utilizing genome amplification that are used for PGT **(Table 2)**.

Comparative Genomic Hybridization

This method was originally developed to carry out molecular karyotyping of tumor cells.[39,40] It has now been successfully used for the analysis of PGT samples.[41] The sample DNA is first amplified and then this amplified DNA and a normal reference sample are labeled separately with different fluorescent dyes. The material is then cohybridized to an array of several thousand probes printed on a glass slide, corresponding to known regions of the genome. Quantitative image analysis is used for fluorescent intensity scanning for each of these probes, and by comparing these fluorescent intensities between the sample and the control, gain or loss of the known regions is identified.[41] Since probes from all chromosomes are included, the copy number of all chromosomes can be determined simultaneously.[42] aCGH (array-comparative genomic hybridization) is rapid (24 hours) and has an error rate of <2%.[42]

This technique has some minor technical limitations. Since it shows only the deviations from the most frequent level of the combined fluorescence signal, as a result, haploid, polyploid, and normal (diploid) embryos will appear similar and chromosomal ploidy cannot be assessed. Further, the source of the chromosomal abnormality cannot be determined. For example, meiotic errors cannot be distinguished from postzygotic errors. Despite these limitations, aCGH has established itself as the "gold standard" for PGT, and most laboratories are now using aCGH in place of FISH-based approaches.

Quantitative Polymerase Chain Reaction

Quantitative polymerase chain reaction (qPCR) has traditionally been used for PGT-M (rather than PGT), as it is very effective in detection of known single gene defects. In recent years, the technique has been adapted for use in PGT.[43] The technique utilizes a high-order real-time multiplex PCR reaction to amplify multiple loci from each chromosome along with quantification. Genome-wide comparison can be made and it can give results in just 4 hours.[43]

Single Nucleotide Polymorphism Arrays

This is another commonly used technique for PGT-A. Single nucleotide polymorphism is a variation in a single nucleotide at a specific position in the genome, occurring at an appreciable frequency within a population. They represent the most frequent form of genomic variation. Over 6 million SNPs have been found in the human genome till date.[44] SNP microarrays are used in PGT to detect the

specific alleles present in the sample cells at up to 500,000 SNP loci. Quantification of these alleles and assessment of heterozygosity enables diagnosis of aneuploidy in the cells. SNP arrays can also detect uniparental isodisomy.[45,46]

Next-generation Sequencing

The most advanced and recent technique used for PGT-A is next-generation sequencing (NGS) **(Fig. 2)**. DNA from the biopsied cell/s is amplified using WGA, fragmented, and then each fragment is tagged with a specific barcode. These small, barcoded DNA fragments (even from several samples) are mixed and sequenced parallelly. Specialized computer software is then used to read these barcoded fragments from each sample and align them against a reference human genome. Trisomy or monosomy can then be identified on the basis of increase or decrease in the number of sequences aligned against that chromosome.

The role of NGS in PGT was assessed by Yin et al.,[47] who compared SNP arrays with NGS in 38 blastocyst biopsy samples. They concluded that NGS could be used in PGT to detect chromosomal abnormality with a potentially higher accuracy and in a cost-effective manner. There have been many other retrospective[48] and prospective trials[49,50] that show that NGS for PGT is a highly accurate and cost-effective technology.

The advantages and disadvantages of these different PGT techniques are summarized in **Table 3**.

Noninvasive Preimplantation Genetic Testing

All the past and current methods of aneuploidy employ sampling of the genetic material from the oocytes/trophectoderm and require micromanipulation techniques which are invasive and not entirely without risk. In addition, they need skilled embryologists and specialized laser equipment. The discovery of DNA within the blastocele fluid of the blastocyst and in the spent culture medium (SCM) during embryo development has promoted the development of the noninvasive methods of PGT.

- *Blastocentesis:* This procedure involves aspiration the blastocele fluid with an ICI pipette by piercing through the trophectoderm, leaving the embryo in a collapsed state.[51] Loss of the fluid from blastocoel is not detrimental to the embryo, which re-expands. However, the low quantity and poor quality of DNA extracted and

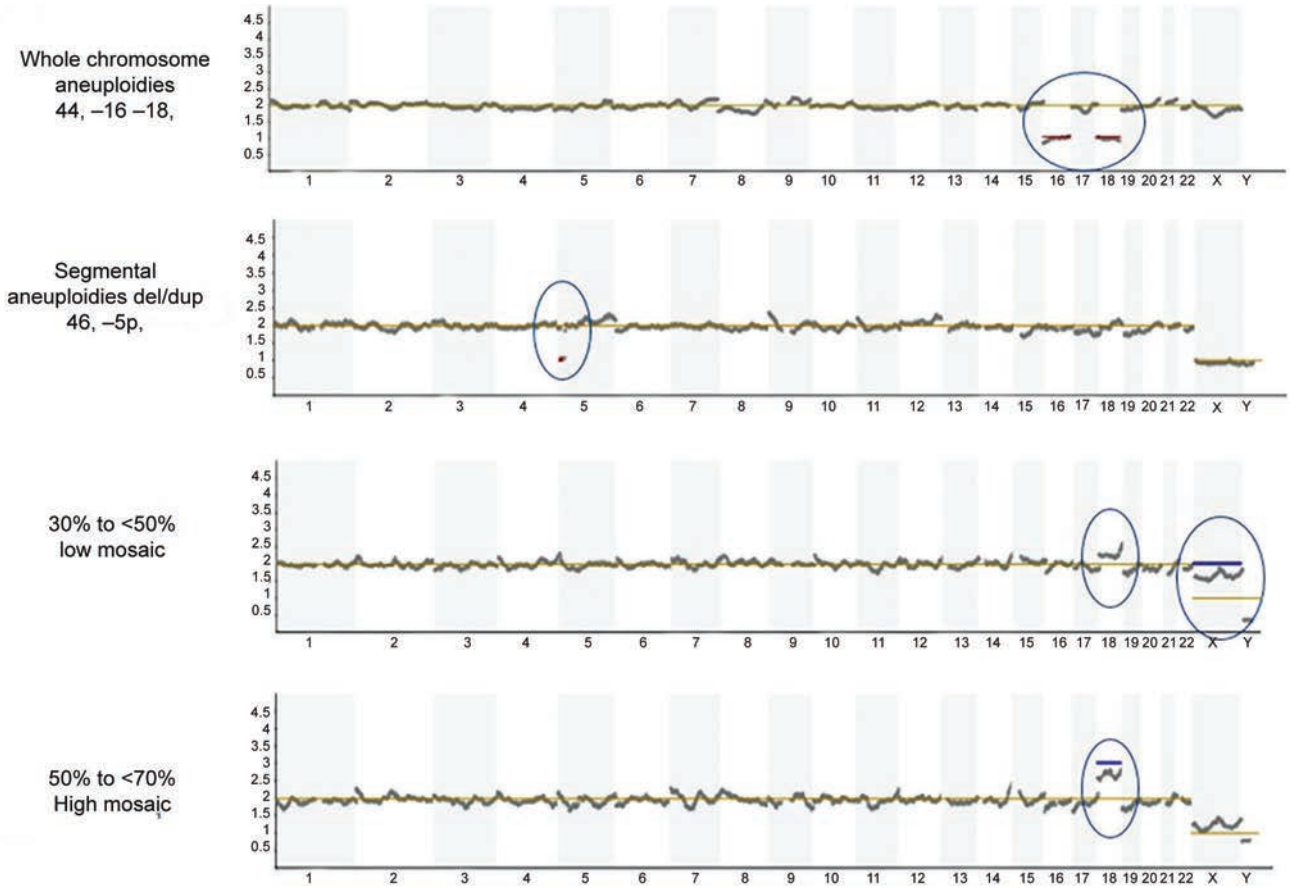

Fig. 2: Examples of next-generation sequencing (NGS) reporting. The top graph shows whole chromosome aneuploidy with deletion of chromosomes 16 and 18. Second graph shows segmental deletion at short arm of chromosome 5. Third and fourth graphs show low and high mosaic patterns.

TABLE 3: Advantages and disadvantages of different PGT techniques.

	aCGH	*SNP array*	*qPCR*	*NGS*
Advantages	Widespread clinical application	Can detect the widest range of chromosomal abnormalities	Results are ready within very short time period	Increased resolution[49] Improved detection of mosaicism[49]
Disadvantages	Limited detection of mosaics	Relatively expensive	Due to assessment of small number of loci of each chromosome, it gives significantly low resolution[43]	Expensive initial set-up

(aCGH: array comparative genomic hybridization; NGS: next-generation sequencing; PGT: preimplantation genetic testing; qPCR: quantitative polymerase chain reaction; SNP: single nucleotide polymorphism)

difficulties in amplification have not made it a popular choice for genetic analysis [51]

- *Spent culture medium:* The embryo has been found to release various metabolites such as interleukins, proteins, micro RNAs along with DNA in the culture medium during its growth which may be used for genetic analysis. Studies have shown that the amount of genetic material in the SCM increases during embryo growth and has an embryonic origin.[52] The potential of the SCM analysis for PGT-A screening has incited a huge interest due to its noninvasiveness, but is having difficulty in gaining popularity due to technical complexity and low concordance with traditional trophectoderm biopsy.

Initial studies achieved a fair degree of ploidy agreement by performing cytogenetic and molecular analysis on the spent cultures and blastocele fluid. However, the ploidy agreement efficiency is restricted by the low quality and quantity of DNA, technical limitations, maternal contamination, and embryonic mosaicism. However, future research and long-term data may validate noninvasive PGT as a less expensive technique requiring less skills for micromanipulation and lower risk to embryos. Such methods may even allow genetic analysis of embryos which are often considered unsuitable for biopsy and are discarded without biopsy.

RESULTS OF ANEUPLOIDY SCREENING IN VARIOUS PATIENT GROUPS

For Advanced Maternal Age

Fertility decreases with increasing maternal age. Data derived from IVF centers in the United States show that LBRs decline with age (41.4% in women <35 years of age, 31.6% in women between 35 and 37 years of age, 22.3% between 38 and 40 years of age, 11.7% between 41 and 42 years, 3.8% for those older than 42 years). Along with it, there is increase in aneuploidy rates as well as spontaneous miscarriage rates.[53] The miscarriage rates increase in IVF from 12.6% in those younger than 35 years to 34.8% in women older than 42 years.[54,55]

This decrease in the LBRs and increase in spontaneous miscarriage rates is, to a large extent, because of the increase in aneuploidy with age. This is supported by data from Society for Assisted Reproductive Technology (SART) registry,[56] in which, the LBR (49.3%) did not vary with the age of the recipients in the group of patients who underwent fresh transfers using eggs obtained from healthy, young donors.

Thus, theoretically, by ensuring euploidy in the transferred embryos, PGT-A should result in better pregnancy rates and LBRs. However, the results for PGT-A in advanced maternal age reported in the literature have been mixed.

The initial results of PGT-A were discouraging. In a meta-analysis performed by Mastenbroek et al.,[57] in 2011, five out of the nine RCTs, which had studied the outcomes of PGT in advanced maternal age, concluded that PGT significantly decreased the LBR after IVF in this group. The main drawback of this systematic review was that FISH had been used in all the studies, which can study only 9 out of 24 chromosomes, and all but one trials used cleavage stage biopsy wherein only 1–2 cells can be biopsied, which may not be representative of the whole embryo. Moreover, later on Scott et al., in 2013,[27] demonstrated that cleavage stage biopsy may itself be harmful to embryo leading to lower pregnancy rates. Many technical improvements have been done in PGT since then, including utilization of comprehensive chromosomal screening (CCS) and doing TE biopsy at blastocyst stage (day 5/6).

Another more recent meta-analysis was performed by Lee et al., in 2015,[58] including 13 observational studies. In this, among the subgroup of studies which included a control group of embryos selected based on morphology, improved implantation rates were consistently found in the PGT arm.[18,53,59] Another RCT noted higher delivery rates after first transfer by selecting embryos after PGT-A, with lesser mean number of ETs required per live birth (1.8 vs. 3.7) as well as less time to pregnancy (7.7 vs. 14.9 weeks) and a lower miscarriage rate.[60]

The STAR trial by Munne et al. studied the benefit of PGT-A (n = 661) versus morphology (n = 331) for selection of embryo in frozen-thawed ET in women aged 25–40 years. 661 women (33.7 ± 3.6 years) were randomized to PGT-A (n = 330) or morphology alone (n = 331). The ongoing pregnancy rate (OPR) was similar in both the groups with no significant difference per ET [50% (137/274) vs. 46% (143/313)] or per intention to treat (ITT) [41.8% (138/330) vs. 43.5% (144/331)]. Post-hoc analysis of women between

35 and 40 years showed a significant increase in OPR per ET (51 vs. 37%) but not per ITT. They concluded that PGT-A did not improve overall pregnancy outcomes in all women, analyzed per ET or per ITT. However, a significant increment in OPR per ET was noted with the use of PGT-A in the subgroup of women aged 35–40 years who had two or more biopsiable embryos, but this was not significant when analyzed by ITT.[61] Pagliardini et al. reinterpretated that data from the STAR trial and attributed incorrect diagnosis and/or biopsy-related embryo damage might underlie reduction from 82.2 to 50.0% of the LBR for competent embryos, thus reiterating the fact that PGT-A may be associated with some embryo wastage.[62]

Thus, at present, the available evidence suggests that PGT-A for aneuploidy may increase the pregnancy rate per ET, thereby reducing the time to pregnancy in advanced age, although the cumulative pregnancy rates per oocyte retrieval may not increase.

For Recurrent Pregnancy Loss

Recurrent pregnancy loss (RPL) is classically defined as loss of three or more pregnancies under 500 g (or before 20 weeks of gestation). The most common reason for RPL is aneuploid embryos.[63,64] This has also been supported by a higher rate of aneuploidy in PGT of embryos from women with RPL, independent of the maternal age.[65,66] Hence, PGT has been proposed as a solution for RPL, as it can decrease the risk of another aneuploid pregnancy.

There are no randomized studies in the literature assessing the clinical utility or efficacy of PGT in RPL. In a prospective study,[67] assessing the role of PGT in women with RPL (69 cycles in 49 patients), a high proportion of embryos were found to be aneuploid in women younger than 37 years (43.85%) as well as in women 37 years and older (66.95%). However, in their study, PGT did not improve the OPRs per cycle in younger women (26%) as compared to those generally achieved in the general IVF population. In the older group also, PGT did not improve the already poor outcomes (2.9% OPR per cycle).

Murugappan et al.[68] compared PGT-A versus expectant management in a retrospective analysis of 300 patients. In this study, 112 patients underwent PGT-A and 188 were enrolled as control in expected management group. Between PGT and expectant management, clinical pregnancy rates (44 vs. 51%), LBRs (32 vs. 34%), and clinical miscarriage rates (20 vs. 24%) were similar. However, the cycles in which PGT was planned but cancelled had a significantly higher clinical miscarriage rate (50 vs. 14%) and lower LBR (15 vs. 36%) as compared to cycles in which PGT was performed, with similar maternal ages.

Musters et al.[69] reviewed the literature on efficacy of PGT in comparison with natural conception in women with unexplained recurrent miscarriages. The authors could not find any randomized or nonrandomized studies directly comparing PGT with natural conception for patients with recurrent miscarriage. The review of 12 observational studies suggested that PGT lowers the incidence of miscarriage; however, due to lower pregnancy rates after PGT, the overall live births decrease. On the other hand, Sato et al. prospectively studied patients undergoing IVF who had RPL, with at least one case of aneuploidy ascertained through point-of-care (POC) testing and in patients who had repeated implantation failures (RIFs, at least three failed transfers).[70] They noted no difference in the LBR per patient with or without PGT-A in the RPL group and no difference in the clinical miscarriage rates per clinical pregnancy. However, they did note improvement in LBR per ET and reduced biochemical pregnancy loss per pregnancy in the RPL group.

Bhatt et al. in 2021 studied the SART data for IVF–ICSI between 2010 and 2016 and assessed the utility of PGT-A in couples with RPL. In women with RPL, the adjusted odds ratio (OR) comparing IVF with PGT-A versus without for live birth outcome was 1.31 [for age >35 years; 95% confidence interval (CI) 1.12, 1.52], 1.45 (ages 35–37 years), 1.89 (38–40 years), and 3.80 (>42 years). The ORs for spontaneous abortion were 0.95 (<35 years), 0.85 (35–37 years), 0.81 (38–40 years), and 0.58 (>42 years). They concluded that PGT-A was associated with an improvement in LBR and clinical pregnancy rate with the largest difference in women >42 years.[71]

To summarize, the available evidence currently is equivocal regarding the role of PGT in patients with recurrent pregnancy loss, and more robust evidence is needed from properly designed RCTs.

For Repeated Implantation Failure

Repeated implantation failure is defined as failure of pregnancy after three or more IVF cycles, or after transfer of 10 morphologically good embryos. Although there is still no ideal management strategy for these couples, selective elimination of aneuploidy embryos via PGT has been offered as a treatment option worldwide.

Previously, many observational studies were unable to find significant improvement in pregnancy outcomes in these patients.[72-74] A RCT by Blockeel et al. failed to show any significant benefit of PGT in RIF patients.[75] Recently, Rubio et al.[32] conducted an RCT including 91 patients (43 in PGT group and 49 control group) and reported slightly higher LBRs in PGT (47.9%) as compared to control groups (27.9%), although the difference could not achieve statistical significance. Recent studies by Sato et al.[70] and Mantravadi et al.[76] have found no benefit of PGT-A in improving the LBRs in couples with RIF; another study by Tong et al.[77] noted no significant differences in pregnancy rates (43.5 vs. 64.7%), clinical pregnancy rates (39.1 vs. 48.0%), implantation rates (39.1 vs. 51.0%), and miscarriage rates (4.3 vs. 7.8%) per ET between RIF women stratified by age (<38 and >38 years) and concluded that maternal age does not affect the implantation

potential of euploid blastocysts. Thus, the evidence so far has shown equivocal results for PGT in patients with RIF.

For Severe Male Infertility

Chromosomal abnormalities are reported in ejaculated or testicular sperms in 10–15% of azoospermic men and 5% of oligospermic men, as compared to <1% of men with semen of normal quality. A microdeletion in the Y chromosome may also be present in another 15% of infertile men having azoospermia or severe oligospermia.[78] Such high prevalence of abnormal karyotypes is expected to increase the risk of aneuploidy in the embryo, and this forms the theoretical basis for doing PGT in such patients. Initial studies focused on gene-specific testing for cystic fibrosis transmembrane conductance regulator gene mutation in cases of congenital bilateral absence of the vas deferens, Klinefelter syndrome, Y chromosome microdeletion, and known autosomal translocations and did not study PGT-A alone. Recent evidence from Asoglu et al. (2020) who studied PGT-A in cases with severe male factor undergoing IVF and noted LBRs of 55.6% in PGT-A group versus 51.1% in non-PGT-A (OR 1.19; 95% CI 0.62–1.80; p = 0.8) with similar IR and CPR. They noted that advanced maternal age was the only factor independently associated with live birth (OR 0.46; 95% CI 0.22–0.96; p = 0.04).[79]

CONCERNS WITH PREIMPLANTATION GENETIC TESTING

Testing for aneuploidy, though seems very safe and logical, is not without concerns. An important concern in PGT is chromosomal mosaicism, as discussed earlier. It results from mitotic errors occurring after fertilization. Cells obtained in TE biopsy may not represent the whole embryo, the unbiopsied TE cells, or the ICM.[80] Second, different techniques used for comprehensive screening of embryos have different sensitivity and specificity of detecting mosaicism.[81] Third and most important issue is how this mosaicism is clinically relevant, as there are mouse and now even human studies suggesting that aneuploid embryos do implant and can result in a healthy live birth.[82-84] Preimplantation Genetic Diagnosis International Society (PGDIS) is perhaps the only society which has stated its position on the use of PGT. After taking into consideration the abovementioned facts, this society has recently issued revised guidelines on PGT, including how it should be performed, how the laboratory reports should be issued, and how the clinicians should interpret these reports.[85] These guidelines are reprinted in **Boxes 2 to 5**.

BOX 2: Preimplantation Genetic Diagnosis International Society recommendations for preimplantation genetic testing (PGT) laboratories.

- For reliable detection of mosaicism, ideally five cells should be biopsied, with as little cell damage as possible. If the biopsy is facilitated using a laser, the identified contact points should be minimal and preferably at cell junctions. Overly aggressive use of the laser may result in cell damage and partial destruction of cellular DNA
- Only a validated next-generation sequencing (NGS) platform that can quantitatively measure copy number should be used for measurement of mosaicism in the biopsy sample. Ideally, a NGS methodology that can accurately and reproducibly measure 20% mosaicism in a known sample
- For reporting embryo results, the suggested cutoff point for definition of mosaicism is >20%, so lower levels should be treated as normal (euploid), >80% abnormal (aneuploid), and the remaining ones between 20 and 80% mosaic (euploid-aneuploid mosaics)

BOX 3: Preimplantation Genetic Diagnosis International Society recommendations for the clinicians.

- Patients should continue to be advised that any genetic test based on sampling one or small number of cells biopsied from preimplantation embryos cannot be 100% accurate for a combination of technical and biological factors, including chromosome mosaicism
- The patient information and consent forms for aneuploidy testing (if used) should be modified to include the possibility of mosaic aneuploid results and any potential risks in the event of transfer and implantation. This needs to be explained to patients by the clinician recommending the aneuploidy testing
- Transfer of blastocysts with a normal euploid result should always be prioritized over those with mosaic aneuploidy results
- In the event of considering the transfer of a blastocyst with only mosaic aneuploidies, the following options should be discussed with the patient:
  - A further cycle of in vitro fertilization with aneuploidy testing to increase the chance of identifying a normal euploid blastocyst for transfer
  - Transfer of a blastocyst with mosaic aneuploidies for low-risk chromosomes only, after appropriate genetic counseling if available
  - Appropriate monitoring and prenatal diagnosis of any resulting pregnancy, preferably by early amniocentesis (>14 weeks' gestation)

PREIMPLANTATION GENETIC TESTING AS UNIVERSAL SCREENING

The whole treatment of IVF is aimed at providing a singleton healthy live baby to the couple. To achieve this goal, most clinics transfer multiple embryos in order to increase the chances of a successful pregnancy in one cycle. However, transfer of multiple embryos has resulted in an increase in the incidence of multiple birth pregnancies which has its own medical and financial implications. Since the most important reason for implantation failure as well as miscarriage in IVF is embryonic aneuploidy (which increases significantly with advanced maternal age), PGT has been suggested in all IVF cycles to select a single embryo which has the maximum implantation potential.

BOX 4: Preimplantation Genetic Diagnosis International Society guidelines to prioritize mosaic embryos for transfer.

Based on our current knowledge of the reproductive outcomes of fetal and placental mosaicism from prenatal diagnosis, the following can be used as a guide by the clinician (or a genetic counselor if available) when a mosaic embryo is being considered for transfer:

- Embryos showing mosaic euploid/monosomy are preferable to euploid/trisomy, given that monosomic embryos (excepting 45, X) are not viable
- If a decision is made to transfer mosaic embryos trisomic for a single chromosome, one can prioritize selection based on the level of mosaicism and the specific chromosome involved. The preferable transfer category consists of mosaic embryos trisomic for chromosomes 1, 3, 4, 5, 6, 8, 9, 10, 11, 12, 17, 19, 20, 22, X, and Y. None of these chromosomes involve the adverse characteristics enumerated below:
  - Embryos mosaic for trisomies that are associated with potential for uniparental disomy (14 and 15) are of lesser priority
- Embryos mosaic for trisomies that are associated with intrauterine growth retardation (chromosomes 2, 7, and 16) are of lesser priority
- Embryos mosaic for trisomies capable of live born viability (chromosomes 13, 18, and 21) are of lowest priority, for obvious reasons

BOX 5: Key points for counselling regarding mosaic PGT-A results [American Society for Reproductive Medicine (ASRM), 2020].[86]

- Clinicians should understand the prevalence of mosaic PGT-A results issued by their reference laboratory
- Clinics should have a policy in place regarding the reporting and the management of mosaic PGT-A results. The policy should be known to staff and shared with patients before PGT-A testing
- Transfer of embryos deemed euploid should be prioritized before considering the transfer of embryos with mosaic results.
- If no embryos deemed euploid are available for transfer, patients should be offered, with due consideration of their clinical situation, the option of another IVF cycle, with or without PGT-A
- Patients considering the transfer of embryos with mosaic results should consult with a clinical genetics specialist, such as a board-certified genetic counselor, who has specific knowledge of perinatal and pediatric outcomes associated with chromosomal mosaicism
- Patient counseling should include a discussion of the various possible explanations for mosaic PGT-A results and potential outcomes
- A decision regarding the transfer of an embryo with mosaic result is optimally made with ample time for careful consideration of the risks, benefits, and alternatives associated with this option
- The limited outcomes reported after transfer of an embryo with mosaic results seem to be reassuring; however, current data are limited and should be interpreted with caution:
  - Lower implantation rates and higher miscarriage rates have been reported after the transfer of embryos with mosaic results compared with embryos deemed euploid; these outcomes may be due in part to biases in the patient populations studied
  - A small number of apparently healthy live births have been reported in the literature after the transfer of embryos with mosaic results
- In the prenatal and pediatric populations, cytogenetic mosaicism involving nearly every chromosome in monosomic and trisomic form has been reported in association with congenital anomalies, fetal growth restriction (also known as intrauterine growth restriction), intellectual disabilities, and/or long-term health problems. When an embryo with mosaic results successfully implants, the chance for the occurrence of such an adverse outcome is currently unknown. Nonetheless, until further data are available, patient should be counseled on these risks
- The following parameters for risk stratification of embryo with mosaic results have been proposed:
  - By percentage of mosaicism
  - By specific chromosome(s) involved
  - By monosomy versus trisomy
  - Whether full chromosome versus partial chromosome is affected
  - By the number of chromosomes involved (single vs. double vs. complex aneuploidies)
- However, no evidence-based classification system currently exists for prioritizing embryos based on these parameters. It remains to be determined whether prenatal or postnatal mosaicism data can be applied to predict outcomes for preimplantation embryos identified as mosaic
- Prenatal genetic counseling is strongly recommended for any pregnancy resulting from the transfer of embryos with mosaic results and should include a discussion of the risks, benefits, and limitations of chorionic villus sampling (CVS) and amniocentesis
- If prenatal diagnostic testing is performed, additional analyses beyond routine karyotyping should be considered depending on the specific PGT-A result. At the discretion of the ordering provider, these may include:
  - Chromosomal microarray, if a partial chromosome aneuploidy is involved
  - Uniparental disomy studies (UPD), depending on the chromosome involved
  - Additional cell counts, in an effort to identify lower level mosaicism
- Postnatal evaluation by peripheral blood karyotype and/or microarray should be considered, particularly if prenatal diagnostic testing is declined. Referral to a pediatric specialist in genetics is recommended in the event of an abnormal physical or developmental phenotype
- Large-scale outcome studies are needed to improve data available for patient counseling. Providers are encouraged to track and publish prenatal, perinatal, and pediatric outcomes following the transfer of embryo(s) with mosaic PGT-A results

A retrospective study[87] of 235 cycles of ICSI with PGT by using aCGH in Indian population, with different indications for PGT, has shown consistent implantation rates (33.3–42.9%) and pregnancy rates per transfer (31.8–54.9%) after transferring euploid embryos irrespective of indication for performing PGT and age of women.

An RCT in 2013 compared the pregnancy outcomes after transferring single euploid embryo versus two untested blastocysts.[88] The OPRs per patient after the first transfer remained similar between the two groups (60.7 vs. 65.1%), while the risk of multiple gestations was significantly reduced from 53.4% in two untested blastocysts transfer group to 0% after PGT and single euploid blastocyst transfer. The Blastocyst Euploid Selective Transfer (BEST) Trial by the same group of authors in 2015 comparing euploid elective single embryo transfer (eSET) and untested two-embryo transfer[89] found that the delivery rates were similar (69 vs. 72%) in the fresh cycle and up to one frozen transfer, with a huge and significant reduction in the incidence of multiple birth pregnancies (1.6 vs. 47%). The incidences of preterm delivery and low birthweight were also significantly lower after euploid eSET. The babies born following untested two-ET had higher chances of neonatal intensive care unit (NICU) admission and spent more than five times as many days in the NICU (479 vs. 93 days) as compared to those born after eSET.

A meta-analysis done in 2015 by Dahdouh et al.,[90] in which three RCTs with good prognosis patients were included, also concluded that PGT improved embryo selection and increased clinical and sustained implantation rates, particularly in women with normal ovarian reserve. However, few studies have concluded that the cumulative pregnancy rates per aspiration do not change with embryo selection with PGT.[91,92] Moreover, there are no studies on the cost-effectiveness of embryo selection with PGT as compared to transferring untested embryos because the intangible costs of failed implantation and spontaneous losses, variable treatment costs as well as costs due to multiple pregnancies are difficult to quantify.

After a comprehensive review, the ASRM published a practice guideline in 2018 which states "there is insufficient evidence to recommend the routine use of PGT-A for all infertile women."[88] The recent Cochrane database (2020) also concludes that "There is insufficient good-quality evidence of a difference in cumulative LBR, LBR after the first ET, or miscarriage rate between IVF with and IVF without PGT-A as currently performed."[93]

LEGAL ASPECTS AND REGULATIONS WITH PREIMPLANTATION GENETIC TESTING

While technological advancements enable new treatment modalities to patients leading to better outcomes and efficient results, legislation often lags and novel technology is often disputed. Consequently, PGT is subject to considerable regulation with variation in between countries internationally. While Western Europe has some restrictions and regulations on the use of PGT limiting use of PGT-M/SR to cases of serious hereditary disease, other countries, such as France, have a case-to-case approval by a multidisciplinary committee. In countries like the UK, specifications are in force for the conditions under which PGT can be performed and every new disease has to be approved by the Human Fertilization and Embryology Authority (HFEA). The situation in USA is quite different as no regulation exists on the application of PGT and IVF is commercially driven. These variations in legislation between countries promote reproductive tourism, that is, couples or individuals seeking treatment which is not permitted or accessible in their home country.

In India, The Assisted Reproductive Technology (Regulation) Act, 2021, has defined in Section 25 (1) "Pre-implantation genetic diagnosis" means the genetic diagnosis when one or both genetic parents has a known genetic abnormality and testing is performed on an embryo to determine if it also carries a genetic abnormality; and (2) "Preimplantation genetic testing" means a technique used to identify genetic defects in embryos created through IVF before pregnancy. It states that "Pre-implantation Genetic testing shall be used to screen the human embryo for known, pre-existing, heritable or genetic diseases only."[94]

The donation of an embryo after preimplantation genetic testing to an approved research laboratory for research purposes can be done only: (1) With the approval of the commissioning couple or woman; and (b) when the embryo suffers from pre-existing, heritable, life-threatening, or genetic diseases. In the Gazette dated June 7, 2020, the assisted reproductive technology (ART) rules have allowed PGT-A when medically indicated and have mandated clinics to ensure that no PGT shall be done for sex selection for nonmedical reasons or selection of particular traits due to personal preferences of the prospective parents or to alter or with a view to alter the genetic constitution of an embryo.

KEY POINTS

- Available evidence suggests that PGT can help in increasing both clinical and OPRs.
- The newer techniques of TE biopsy with analysis by array-based methods or better by NGS have allowed the testing of all chromosomes and hence have improved the PGT results considerably.
- By selecting the euploid embryo, PGT may decrease time to pregnancy and miscarriage rates but only in selected population which is not yet defined but can include women with advanced age.
- The cost-effectiveness of PGT needs to be evaluated before its widespread use in clinical practice.
- PGT may help in reducing the multiple gestation rate by transferring a single euploid embryo as opposed to multiple embryos.
- The concern regarding transfer of mosaic embryos needs more evidence and needs proper counseling based on the best new evidence.

- Newer technique such as the noninvasive PGT appears promising, but robust data is lacking for recommending its use in routine practice.
- One must keep updated on the latest guidelines by the regional authorities before implementing PGT in practice.
- PGT is a valuable procedure, but for the time being, it is not suitable for every patient and not for every IVF practice.

CHAPTER 64

Preimplantation Genetic Testing of Embryos

Rohit Gutgutia, Santosh Kumar Jena

INTRODUCTION

Preimplantation genetic testing can be defined as a test performed on the oocytes or the embryo to know any genetic abnormality or to know human leukocyte antigen (HLA) typing. This has replaced the previous terminologies, PGS (preimplantation genetic screening), and PGD (preimplantation genetic diagnosis).[1] PGT includes PGT-A (preimplantation genetic testing for aneuploidy), PGT-M (preimplantation genetic testing for monogenic disorders or single gene disorders), and PGT-SR (preimplantation genetic testing for structural chromosomal rearrangements). It essentially involves two steps, embryo biopsy or polar body biopsy (obtaining cells from the developing embryo or the oocyte) and genetic analysis of the cells by using different genetic platforms. PGT has evolved a lot in the last two decades, from being an experimental procedure during the 90s to a well-established procedure today. Shifting from day 3 (cleavage stage embryo biopsy) to day 5/6 (blastocyst) biopsy, from targeted genetic analysis to genome-wide analysis (all the 46 chromosomes and almost all single gene disorders) and robust vitrification program are few of the attributes to the present form of PGT (sometimes called PGT 2.0).

PREIMPLANTATION GENETIC TESTING FOR ANEUPLOIDY

Every human cell contains 46 chromosomes (22 pair of autosomes and sex chromosomes XY or XX). Aneuploidy can be defined as an extra or a missing chromosome. This can be detected in contemporary genetic testing by copy number variation. It is one of the most common causes of both early miscarriage and implantation failure. Few recent studies suggest that in an assisted reproductive technology (ART) cycle, >40% of all blastocysts across all age groups are aneuploid[2] and an unexpectedly high aneuploidy rate (>30%) even in oocyte donation cycles (donor age <36 years) as well.[3] Almost 90–99% of aneuploidy can be attributed to oocytes and the rest 1–10% due to sperm. Meiosis-I errors (nondisjunction giving rise to trisomy and early separation of sister chromatid giving rise to monosomy) during oogenesis result in aneuploidy. Meiosis-I errors and thus aneuploidy have a strong correlation with maternal age. Relation between age and aneuploidy can be very well-appreciated from one of the recent studies, which suggests when maternal age is between 22 and 28 years, percentage of euploid embryos ranges from 60 to 75% in contrast to just 10% embryos being euploid at 45 years.[4,5] To avoid such a negative outcome which has both financial and psychological impact, genetic testing of the preimplantation embryos and transferring only euploid embryos seems a noble step, although universal aneuploidy testing is severely criticized in recent times as evidence suggests it does not increase the cumulative live birth rate.[6] Advanced maternal age, recurrent miscarriage, recurrent implantation failure, and severe male factor infertility are the recommended indications for aneuploidy testing. Few recent studies suggest the role of aneuploidy testing in younger patients having good number of embryos to enhance the process of selection of embryo thus to reduce time to pregnancy (TTP) and encourage elective single embryo transfer (eSET), but in many countries, the local regulations do not allow aneuploidy testing for such indication.

A typical PGT cycle involves the following steps: (1) Pre-PGT work-up and counseling, (2) in vitro fertilization (IVF) cycle (3) embryo culture, (4) embryo biopsy (cleavage stage embryo or blastocyst), (5) genetic analysis and interpretation of results, (6) embryo transfer, and postpregnancy follow-up.

PRE-PREIMPLANTATION GENETIC TESTING FOR ANEUPLOIDY WORKUP AND COUNSELING

All patients undergoing PGT-A should ideally have a karyotyping done specifically so, if it is being done for recurrent miscarriage, implantation failure and severe male factor, as there is a high chance of structural chromosomal rearrangement in the above mentioned categories.

Counseling is the most important step in any PGT cycle. Patients should be counseled by a certified genetic counselor and all possible risks and outcomes of the test must be discussed beforehand including chances of having no embryo for transfer.

IN VITRO FERTILIZATION CYCLE

A conventional ovarian stimulation protocol (mild ovarian stimulation not preferred) is followed. Preferred method of fertilization should be intracytoplasmic sperm injection (ICSI) to avoid genetic contamination by granulosa cells and sperms [granulosa cell removal during oocyte-cumulus cell complex (OCC) denudation and use of single spermatozoa]. Embryos should ideally be cultured single again to avoid genetic contamination.

EMBRYO BIOPSY AND TUBING

Skill and experience of the embryologist performing biopsy is one of the most important factors for a successful PGT cycle, specifically as there is hardly any formal teaching and skill assessment methods in the field. In the Indian scenario, it is one of the limiting factors even in tier-I cities.

Day 3 versus Day 5 Biopsy

Few years back, the majority of embryo biopsies were performed on cleavage stage embryo (day 3), whereas presently blastocyst biopsy (day 5/6 or sometimes even on day 7) is the most favored one. Better embryo culture conditions (more confidence in growing embryos to blastocyst stage) and a robust vitrification program (nearly 100% post thaw survival rate) are primarily the factors of this recent shift from cleavage stage biopsy to blastocyst biopsy.

Advantages of blastocyst biopsy are as follows:

- More genetic material (removal of 5–10 cells from trophoectoderm) is obtained for analysis, which overcomes the problem of insufficient genetic material, frequently encountered on a day 3 embryo biopsy (removal of one or two cells).
- Percentage of cells removed from the embryo is lesser in a blastocyst (5–10 cells out of 64–128 cells) in comparison to cleavage stage embryo biopsy (1–2 cells out of 8 cells).
- It only removes cells from trophoectoderm and leaves the inner cell mass (ICM) undisturbed.
- As blastocyst is a more advanced stage in embryo selection method, so doing unnecessary biopsy of a day 3 embryo is avoided, which anyway won't survive till day 5/6.
- Chances of mosaicism are less in a blastocyst compared to cleavage stage embryos. Also, chances of errors (in mosaicism detection) are lower when more cells are analyzed.

Method of obtaining biopsy involves creating an opening in the zona (zona drilling) by either chemical or using noncontact LASER (commonly practiced method presently). This is followed by aspirating cells using embryo biopsy pipette and removing the cells from the trophoectoderm interface either by using LASER shots to favor detachment from embryo or gentle mechanical (flickering) movement. Blastocyst biopsy is only possible where there is a clear differentiation between the ICM and trophoectoderm. Throughout the biopsy procedure, the ICM should be positioned between 7 and 11 o'clock position[7] and biopsy site at 3 o'clock position to avoid any unintended injury to ICM. Each embryo should be individually tracked throughout the procedure of biopsy.

Tubing is an equally important step in embryo biopsy method. It involves transferring the genetic material with very minimal media into a container provided by the genetic laboratory. Sometimes there is a risk of losing the genetic material in the process of washing and transferring it to the tubes though it is extremely rare in experienced hands. Also, there is a chance of contamination by exogenous genetic material. Then the tubes containing cells can be transferred to the genetic laboratory for analysis following the service providers' recommendation or it can also be stored specially in cases where embryo pooling and PGT-A is planned, where collectively genetic materials from embryos obtained from different stimulation cycles are sent together. After biopsy, the embryos can be vitrified using a separate cryopreservation device for each embryo.

GENETIC ANALYSIS

The very first step in the genetic analysis is amplification of the genetic material. Multiple amplification cycles are run to obtain enough genetic material for analysis of all 24 chromosomes. The amplification can be of whole-genome amplification or even a targeted amplification, where a target area is amplified for studying specific regions. Targeted amplification increases the depth of genetic analysis in the region of interest at the cost of breadth of analysis. Postamplification the genetic analysis is carried out by using methods such as CGH (comparative genomic hybridization), array CGH, SNP (single nucleotide polymorphism), or a NGS (next-generation sequencing) based platform to detect the copy number variations. Among all, NGS-based platforms are widely followed and more popular nowadays.[8] FISH (fluorescent in situ hybridization) which was practiced in the initial days of genetic testing is almost completely replaced by these newer methods which can provide a comprehensive analysis of all 24 chromosomes with much accuracy and at the same time, less time-consuming.

COMPARATIVE GENOMIC HYBRIDIZATION

After amplification, the targeted DNA is labeled with green fluorescent dye, the same is repeated for a known reference sample (normal chromosome), which is labeled

with red fluorescent dye. Both test and reference DNA after hybridization are added to a normal metaphasic spread. The color signal is read by a computer imaging system. Any deviation of color intensity from the 1:1 ratio indicates the copy number variation of the target chromosome.

ARRAY COMPARATIVE GENOMIC HYBRIDIZATION

Principle of the test remains the same, except in place of metaphasic chromosomes microarray-based solid support is used. This eliminates the use of metaphasic spread which is nonuniform and prone for errors and thus favors automation and rapid analysis.

SINGLE NUCLEOTIDE POLYMORPHISM MICROARRAYS

Single nucleotide polymorphism represents the variations at a single base position. SNP array contains probes of thousands of unique nucleotide sequences that are distributed across the length of chromosomes. Known nucleotide sequence is used as a probe and the tested DNA is hybridized with the known sequence and the fluorescent signal is analyzed both qualitatively and quantitatively. Its advantage being single gene disorders also can be diagnosed at the same time during aneuploidy testing.

NEXT-GENERATION SEQUENCING

Postamplification the product is fragmented to produce millions of short segments of DNA. These numerous short pieces are simultaneously sequenced in parallel. This greatly reduces the cost of sequencing as multiple samples can be run in one go. The depth of analysis is typically lower in a conventional NGS method (sometimes called "low pass" or "shallow" sequencing). This "low-depth analysis" is still considered adequate for numeric chromosomal analysis[9] (aneuploidy) but the information obtained regarding individual genes is negligible although targeted sequencing is also an option for studying monogenic disorders, where a deeper sequencing is essential. There are various commercially available platforms to run NGS.

INTERPRETATION OF RESULT

Results of a PGT-A testing are no longer just a binary division. We now have situations of mosaic embryo and segmental aneuploidy apart from usual euploid and aneuploid embryos. All these need special attention as these situations demand special counseling sessions and management challenges. Although genetic testing methodology has undergone a reform in the last two decades, the lack of standardization is still a major challenge. Aneuploidy can affect a single chromosome or even multiple chromosomes called complex aneuploidy. Aneuploid embryos are not suitable for transfer.

Complex Aneuploidy

When the aneuploidy involves two or more chromosomes in the same embryo. Complex aneuploidies are incompatible with life.

MOSAIC EMBRYOS

Mosaicism is the presence of two different cell lines with different chromosomal configurations (in context of PGT-A, co-presence of both euploid and aneuploid cells) in the same embryo. It is mostly a mitotic error that results from mal-segregation of sister chromatids during the cell division. Chances of mosaicism reduce as the embryo grows. In one of the studies where embryos found to be mosaic on day 5/6 biopsy were cultured till day 12 and rebiopsy is done on day 12. Surprisingly, only 20% of those embryos, previously diagnosed as mosaic, retain mosaicism and the rest corrected.[10] This phenomenon of autocorrection of mosaicism is a well-acknowledged fact now. Autocorrection mainly depends on the fraction of cells that have been affected by mosaicism. Chances of correction are lower if the mitotic event happens early in cell division (closer to zygote stage) as more fraction of cells are affected downstream, whereas if it affects remote from zygote stage, mosaicism fragment is less and chance of autocorrection is higher. Contrary to the meiotic errors (maternal age-related aneuploidy risk), mitotic errors are not age-related and there is a uniform baseline risk throughout the reproductive years.[11] Many laboratories report mosaicism according to the percentage of mosaic cells and categorized it into different categories such as low mosaic (20–30%), medium mosaic (30–50%), high mosaic (50–70%), and aneuploid (>70% mosaic fraction).[12]

MANAGEMENT OF MOSAIC EMBRYOS

Many recent reports have been published from various groups regarding the transfer of mosaic embryos and its outcome. All these evidences indicate that mosaic embryo can result in viable pregnancy, although the chances of implantation failure and miscarriage are higher compared to euploid embryos.[13] Mosaic embryos, specifically low mosaic ones, can be considered for transfer in the absence of euploid embryos. Before proceeding with transfer of mosaic embryos, patients must be counseled thoroughly regarding the need of invasive prenatal testing such as amniocentesis or chorionic villus sampling as the data regarding the outcome of mosaic embryos is still limited.

SEGMENTAL ANEUPLOIDY

Segmental aneuploidy, also called partial aneuploidy, affects subchromosomal area and it results due to regional loss or gain of a segment of a chromosome. Presently used PGT-A testing platforms can diagnose segmental aneuploidy in a

chromosome if the segment is of 10–20 Mb or above. Many a times segmental aneuploidy of trophoectoderm biopsy does not properly represent the changes in ICM. Although presently there is no clarity regarding the management of segmental aneuploidy but very few studies suggest rebiopsy of trophoectoderm as an option. According to one such study, chances of ICM carrying the same segmental aneuploidy are just 21% if both biopsies are discordant, whereas this figure goes as high as 84% if both biopsies are concordant.[14]

LIMITATIONS OF PREIMPLANTATION GENETIC TESTING FOR ANEUPLOIDY TESTING

Current PGT-A testing has 1–2% chance of error, giving either false positive result (reported as aneuploidy when actually the embryo is euploid) or false negative result (reported as euploid when embryo is aneuploid). This is mainly due to mosaicism and the fact that trophoectoderm cells may not always be a true representation of the ICM, though there is a high concordance rate, documented from various studies. Routine prenatal screening and testing methodology should be followed in all patients undergoing PGT.

There can be other genetic or nongenetic causes of birth defects. PGT-A can detect it only if it results from chromosomal copy number variations. For example, single gene disorders can never be diagnosed in a PGT-A testing.

Preimplantation genetic testing for aneuploidy can only detect aneuploidy (either gain or loss of chromosomal copy number from euploid). It cannot detect situations involving alteration in an entire set of chromosome as in haploid (absence of a set of all 23 chromosomes) or triploid (presence of one extra set of all 23 chromosomes).

It cannot detect uniparental disomy (UPD), where both the sets of chromosomes come from a single parent only.

ADVERSE EFFECTS OF BIOPSY

One of the criticisms of doing an embryo biopsy is damage to the embryo and reduction in implantation potential due to the biopsy procedure itself although it is extremely rare in experienced hands but there can be situations of technical difficulty during biopsy procedure (sometimes due to poor embryo quality itself) resulting in damage to the embryo.

DIFFICULT SITUATIONS IN PREIMPLANTATION GENETIC TESTING

Insufficient Genetic Material

It is one of the situations which needs to be counseled with the patient properly specifically in situations of unavailability of euploid embryos. Many times it is due to compromised embryo quality itself. Rebiopsy of the embryo can be considered as an option along with transfer of the embryo without genetic analysis (benefits of PGT-A are lost).

No Transferable Embryos

This is a commonly encountered situation and needs proper counseling prior to starting the IVF cycle itself.

We have a balanced opinion about PGT-A, after analyzing our unit's PGT-A data from the last 2 years. Analysis of PGT-A result of 289 blastocysts (exclusive blastocyst biopsy) from 66 patients showed euploid rate of 40% and an implantation rate of 56.6% after the transfer of the resulting euploid embryos with maximum chance of implantation in subcategory of patient who had previous miscarriage due to aneuploid pregnancy. Success rate of euploid embryo transfer is fairly similar across all age groups. Noninformative results were obtained in 2.7% of the biopsied embryo. 11 patients (out of total 66) did not have any euploid embryo for transfer, either due to all embryos being aneuploid/mosaic or noninformative result. One such patient (out of 11) has an ongoing pregnancy that resulted from transfer of a rebiopsy-confirmed euploid embryo that had no DNA detected in the first biopsy attempt.

PREIMPLANTATION GENETIC TESTING FOR MONOGENIC DISORDERS OR SINGLE GENE DISORDERS

It is now possible to diagnose all kinds of single gene disorders using the trophectoderm biopsy and subsequent genetic analysis.

Most of the steps of PGT-M, except for the step of pre-PGT work-up and the genetic analysis, are similar to a PGT-A cycle and already discussed in this chapter.

INDICATION OF PREIMPLANTATION GENETIC TESTING FOR MONOGENIC DISORDERS OR SINGLE GENE DISORDERS

There is an extensive list of 1,380 single gene disorders approved by HFEA (Human Fertilisation and Embryology Authority), UK, which can be tested using PGT-M technique. Autosomal dominant disorders are the most common indication of PGT-M (64%), followed by autosomal recessive (21%) and X-linked disorders (15%), respectively. Ten common indications in decreasing order of prevalence (as per ESHRE PGT Consortium data)[15] are mentioned in **Table 1**.

In Indian scenario, as per our own experience, hematologic conditions are the most common indication for PGT-M followed by musculoskeletal and other indications such as cystic fibrosis and BRCA-1 mutation detection.

PRE-PREIMPLANTATION GENETIC TESTING WORK-UP

Fundamental basis of the pre-PGT-M work-up is identifying haplotype (group of alleles that are inherited together along with the gene of interest). First it is assessed whether a specific

TABLE 1: Commonest indication in decreasing order of prevalence.	
Huntington disease	9%
Cystic fibrosis	4.6%
Neurofibromatosis type 1	4.3%
Myotonic dystrophy type 1	4.3%
Breast ovarian cancer, familial susceptibility to, 1	4.3%
Beta-thalassemia	
Fragile X syndrome	
Breast ovarian cancer, familial susceptibility to, 2	
Marfan syndrome	
Muscular dystrophy, Duchenne type	

pattern is noted in affected members of the family that can be differentiated from nonaffected members. If a specific pattern can be identified, it is called high risk haplotype, then the embryo is tested for presence of the same, i.e., "the indirect method of testing." If a specific pattern cannot be identified because of either de novo mutation or absence of family members for pre-PGT work-up, then a direct method is followed to detect new mutations using different genetic markers.

First step in PGT-M work-up is a pedigree analysis by an expert geneticist to find out the inheritance in the family and the need of collecting blood samples from relevant family members apart from the couple.

After haplotype differentiation (high risk and low risk) test strategy is decided in the pre-PGT work-up itself and validation is checked.

GENETIC ANALYSIS IN CASE OF PREIMPLANTATION GENETIC TESTING FOR MONOGENIC DISORDERS OR SINGLE GENE DISORDERS

Genetic analysis that is most commonly followed in contemporary PGT-M analysis involves whole-genome amplification followed by downstream analysis either using SNP array or NGS-based methods to detect the presence of gene of interest in the embryo.

PREIMPLANTATION GENETIC TESTING FOR STRUCTURAL CHROMOSOMAL REARRANGEMENTS

Structural rearrangement is the most common indication for performing PGT-SR accounting 64% of all PGT-SR cases followed by Robertsonian translocation (22% of cases). Chromosomal inversion and deletion account for small fraction of cases of PGT-SR.[15]

Most unbalanced structural rearrangements can be diagnosed using modern-day NGS platforms for PGT-A detection, provided it is above the threshold level of detection, i.e., 10–20 Mb.

Balanced structural rearrangements, chromosomal inversion, and unbalanced translocation below the threshold level need different genetic analysis methods. In these categories of cases, there is still a role of the conventional FISH assay.

In pre-PGT-SR work-up, the karyotyping of the couple along with the exact structural change should be shared with the genetic laboratory to plan the testing strategy and validation of the same.

Analysis of single cell is preferred in few scenarios of genetic testing by the FISH method. So the genetic laboratory may suggest to do preferably a cleavage stage biopsy than a blastocyst biopsy (trophoectoderm cells are difficult to separate individually due to cohesive nature of trophoectoderm cells) in these scenarios.

HUMAN LEUKOCYTE ANTIGEN TYPING

Human leukocyte antigen typing of the embryo can also be done along with PGT-M keeping all the ethical concerns (creating a life for the purpose of helping the affected child) in mind and if permitted by local regulations.

MITOCHONDRIAL DNA QUANTIFICATION IN PREIMPLANTATION GENETIC TESTING

The basic principle behind this is mitochondrial DNA does not divide in a cell till blastocyst stage. So in slow growing embryos, the mitochondrial DNA content per cell is higher compared to a fast growing embryo. Few studies suggest the impaired implantation potential of embryo beyond certain level of mitochondrial DNA in embryos, though its application in routine practice is questionable. All euploid embryos should be considered for transfer but given situation to choose among euploid ones, embryo with lesser mitochondrial DNA score should be preferred as it has a better implantation potential.

NONINVASIVE PREIMPLANTATION GENETIC TESTING

Over the years, the genetic analysis of embryos has become very comprehensive to cover all 24 chromosomes and practically all single gene disorders. With more and more clients opting for PGT, even the cost of genetic analysis is reduced to a great extent and is no longer a limiting factor. Presently, biopsy procedure is one of the limiting steps considering the requirement of highly skilled personnel and hi-tech equipment. Added to that, invasive PGT cannot be performed in embryos having poor morphology.

BASIS OF NONINVASIVE PREIMPLANTATION GENETIC TESTING

It is based on the principle of detection of cell-free DNA in the spent culture medium (SCM) or blastocyst cavity

(blastocele). This DNA can be extracted, amplified, and downstream genetic analysis can be performed to detect aneuploidy.

LIMITATION OF NONINVASIVE PREIMPLANTATION GENETIC TESTING

Amplification failure is one of the major concerns as the DNA content is very minimal.

Contamination from other genetic material (maternal cells contamination, cell-free DNA in some of media preparation, and from laboratory personnel) is the other major issue.

Cell-free DNA may not be a correct representation of the embryo and thought to be the byproduct cell repair mechanism. During autocorrection of the embryo, the defective cells undergo apoptosis and it is released into the culture media and blastocele fluid. So rather it may erroneously have false positive results when the embryo had already undergone correction after extruding the defective cells.

CURRENT STATUS OF NONINVASIVE PREIMPLANTATION GENETIC TESTING

Noninvasive PGT is now implemented in many IVF centers as one of the options of genetic testing though results from various studies about its concordance with the invasive PGT are contradictory.

One of the recent multicenter prospective studies conducted on 1,301 embryos showed a concordance rate of trophoectoderm biopsy with cell-free DNA assay of 78.2%, ranging from 72.5 to 86.3% among different centers. Concordance rate exceeded 86% when all the defined laboratory parameters were followed to minimize contamination. In a subgroup of 81 blastocysts, where ICM biopsy was also done, the comparison of the ICM with the embryonic cell-free DNA and the trophectoderm biopsies had shown similar concordance rates, 84.4% and 87.5%, respectively,[16] though many other small studies have contradictory findings. At this point in time, we still need more evidence before completely relying on a noninvasive method of testing.

FUTURE PERSPECTIVE

Considering the invasive nature of PGT and its limitations, a truly noninvasive PGT retaining its concordance rate with the invasive one will be a revolution in genetic testing of embryos. Many other markers such as microRNA (short noncoding RNA fragments) and EV (extracellular vesicles: nanoparticles of cellular metabolism byproducts made up of lipid bilayer which can readily cross cell membrane) are also studied by various researchers, which may be possible in future.

CHAPTER 65

Epigenetics and Assisted Reproductive Technology

Mandeep Kaur, Ajitabh Shukla

INTRODUCTION

There is growing evidence that epigenetics, an erstwhile obscure branch of medicine, may be increasingly more relevant in human reproduction than previously realized. Environmental and dietary influences may surreptitiously creep into the germ line, only to reflect in future generations in the form of intractable genetic diseases.

Assisted reproductive technology (ART) contributes to 1–2% of the total live births in developed countries.[1] ART has helped achieve pregnancies for millions of couples, grappling with infertility due to various physiological and anatomical obstacles. In view of the steadily rising interest and the immense possibilities in this field, it is imperative on the part of the reproductive specialist to be aware of the emerging evidence and be able to discuss them in an informed and responsible manner with the patients, as permitted by the current data.

This chapter aims at providing an insight into the basics of epigenetics, imprinting disorders, and the latest evidence of the impact of ART procedures on genetic imprinting. Comprehending the depths of the biochemistry involved in imprinting is rather arduous, so the authors have tried to lean more toward the clinical relevance of the same in this chapter.

EPIGENETICS

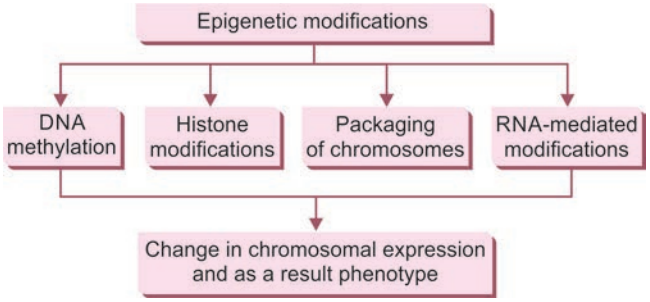
Waddington in 1942 introduced the term epigenetics.[2] It is the study of the changes in organisms caused by the modification of gene expression rather than the alteration of the genetic code. Epigenetics was later formally defined as "the study of mitotically and meiotically heritable changes in gene function that cannot be explained by changes in deoxyribonucleic acid (DNA) sequences."[3] This modification of the gene expression is heritable and can be influenced by environmental factors.[4] It may well be due to differences in chromosome packaging.[5]

Gene expression is influenced by changes in the chromatin structure **(Flowchart 1)**. Broadly stating, the genes are inactivated when the chromatin is condensed and expressed when the chromatin is open.

Methylation is the most well-studied epigenetic modification. DNA methylation is the addition of a methyl group to the DNA, which results in changed or altered gene expression, and is essential for embryonic development, genomic stability, gene silencing, and oncogenesis. Methylation usually occurs in the CpG site of the DNA ("p" in CpG stands for the phosphate group in the dinucleotide). This site is present in the promoter regions of the gene, which, according to the methylation status, activates or silences the gene.[6] Specific CpG methylation patterns are established in early development and are passed on during the process of DNA replication by DNA-methyltransferase-1 (DNMT-1).[7] Dietary deficiencies may result in low levels of folate, selenium, and methionine and this could lead to changes in DNA methylation, and as a result, clinical consequences, such as neural tube defects, cancers, and atherosclerosis.[8]

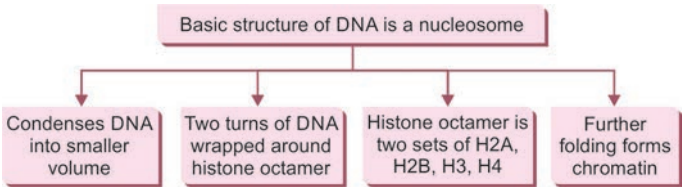
Histones are core proteins around which DNA is wound. The details of nucleosome structure are explained in **Flowchart 2**. Histone modifications can lead to

Flowchart 1: Epigenetic modifications.



(DNA: deoxyribonucleic acid; RNA: ribonucleic acid)

Flowchart 2: Nucleosome.



(DNA: deoxyribonucleic acid)

changes in gene expression (suppression or activation) depending upon the change in the amino acid sequence.[9]

GENOMIC IMPRINTING

According to Mendel's law of inheritance, genes from both parents play an equally important role in the process of development. However, genomic imprinting is an exception to this—it is a modification of the genome, selectively allowing *genes from only one parental allele to be expressed*. The underlying mechanism is mostly epigenetic, which implies a condition in which the DNA sequence is not changed, but the alleles are chosen to be expressed in a sex-specific manner.

We inherit two copies of all autosomal genes, and essentially almost all of them are expressed equally from maternally and paternally inherited alleles. However, some of the mammalian genes are expressed preferentially from either the paternal or the maternal alleles. The alleles are *stamped* by the epigenetic influences, which then continues throughout the pre and peri-implantation phases. This partial "favoritism" of some alleles is imprinting. Genomic imprinting, in other words, is the parental battle of the sexes to regulate the distribution of maternal resources to the offspring.[10] 1% of human genes are associated with imprinting.[11] Imprinting syndromes are the set of conditions that result from a disturbance in the expression of the genes that are known to be imprinted. Many of these genes are associated with the regulation of prenatal and postnatal growth.[12]

"Paternal disomy" appears to lead to retarded embryonic tissue but well-developed extraembryonic (placental) tissue development. "Maternal disomy," on the other hand, appears to be associated with poorly developed extraembryonic tissue with relatively normal or small embryos.[13] It is interesting to note that imprinting disorders are seen mainly in placental animals (summary in **Fig. 1**).

Clustering is another characteristic of imprinting, wherein the genes tend to cluster on the chromosome domains. In humans, these are seen on chromosomes 6, 7, 11, 14, 15, and 20. Clustering allows a coordinated regulation of genes in a given chromosomal region. Two imprinting clusters are well known: One on the human chromosome 11p15, which is associated with the *Beckwith–Wiedemann syndrome* (BWS), and another on 15q11-q13, related to the pathogenesis of

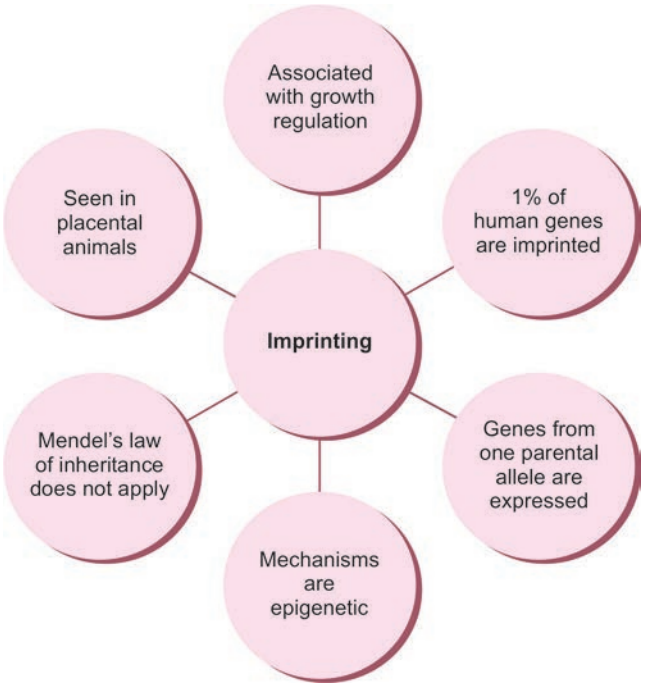


Fig. 1: Imprinting.

the *Angelman syndrome* (AS) or the Prader–Willi syndrome (PWS). These clusters are regulated by imprinting centers (IC). Microdeletions in the ICs can affect the imprinting status of the genes even kilobases away.[14] The *insulin growth factor-2* (*IGF2/H19*), IC for example, coregulates *IGF2* and *H19*, and both these genes are located in the same imprinted domain, about 90 kb apart.[15]

HUMAN PHENOTYPES ASSOCIATED WITH IMPRINTED GENES

These include:

- BWS (11p15)
- PWS (15q11-q13)
- AS (15q11-q13)
- Silver–Russell syndrome (SRS) (11p15/7p11-p13)
- Transient neonatal diabetes mellitus (6q24)
- McCune–Albright syndrome (20q13)
- Familial nonchromaffin paraganglioma (11q13)
- Maternal and paternal UPD14 syndromes (14).

These are the known human phenotypes associated with imprinting genes (chromosome numbers in brackets).[16]

EPIGENETICS IN FETAL ORIGIN OF ADULT DISEASE

Mammalian phenotype can also be changed by the influence of nutrition on the epigenetic gene regulatory mechanisms. This forms the basis for the "*fetal origin of adult disease.*" Epigenetic alterations associated with starvation of the mother in fetal life have an effect on adulthood, and thus have been known to be contributing to late-onset disorders, such as cardiovascular diseases and diabetes.[17]

BOX 1: Drawbacks of the studies showing a positive association between assisted reproductive technology and imprinting disorders.

- Small-sample size
- No correction for maternal age or diagnosis of infertility
- Statistical assumptions

TABLE 1: Mechanism of imprinting.

Event	*Timing*
Erasure	When germ cells enter the gonad
Acquisition	During oocyte and sperm maturation
Maintenance	After fertilization

In 2009, Katari et al. reported that there is a difference in some gene expression patterns between the babies who conceived naturally compared to the babies who conceived by means of in vitro fertilization (IVF). These changes were inherited by the future generations and were under epigenetic control. This mechanism could potentially place the children conceived by means of IVF at risk of certain diseases such as diabetes and obesity later in life.[18]

WHEN DID THE CONCERN START?

There is a general consensus that ART slightly increases the risk of congenital malformations in fetuses (3–4 vs. 2–3%). However, its association with epigenetic disorders is still debatable.[19]

In 2002, Cox et al. reported the association of AS with intracytoplasmic sperm injection (ICSI).[20] In 2003, the British[21] and French[22] medical registry data reported a higher incidence of BWS or the human overgrowth syndrome in ART conceptions. SRS[23] and retinoblastoma[24] were also reported to be higher in ART conceptions. It was also reported that the stimulation of the ovaries with gonadotropins causes differences in gene expression and methylation changes in the oocytes recovered from stimulated ovaries.[25]

Consequently, it was realized that these studies had a myriad of technical deficiencies. **Box 1** simplifies the drawbacks of these studies.[26] This led to a fallaciously exaggerated relative risk.

However, ensuing better-designed studies, and notably a systematic review and meta-analysis, also suggested an association of imprinting disorders with ART.[27]

WHAT IS THE MOST CRUCIAL PERIOD FOR IMPRINTING?

Germ cell development and early embryogenesis are the crucial times for erasure of the parental imprints, acquisition of the new imprints, and their maintenance during the process of embryogenesis. So, the concern with ART is valid as all these processes occur in artificial conditions, in comparison to the "in vivo" environment of spontaneous conceptions **(Table 1)**:

1. *Erasure:* When the germ cells enter the gonad, complete erasure of parental imprint occurs. Complete erasure of the entire genome of the parental imprints in the primordial germ cells occurs to serve the following three purposes:
   a. Totipotency of the gametes is restored.
   b. There is establishment of epigenetic equivalency before the establishment of new imprints during the process of gametogenesis.
   c. Any acquired epigenetic marks present in the adult somatic cells are removed.[28]
2. *Acquisition:* During the process of gametogenesis, primary imprints are established, and this occurs via the action of DNA methyltransferase enzymes.[29] The methylation programming of the sperms is complete by birth, whereas the methylation programming of the oocyte begins at puberty and is complete at the time of ovulation.
3. *Maintenance:* These primary parental imprints, established at the time of gametogenesis, are maintained during embryonic development and persist into adulthood. This maintenance occurs despite the second wave of erasure, which occurs just after fertilization. In order to ensure correct differentiation into the embryonic and extraembryonic cell lineages, methylation of the genome occurs at the blastocyst stage.

POTENTIAL RISKS IN ASSISTED REPRODUCTIVE TECHNOLOGY

Infertility, in itself, is a potential risk factor for imprinting. The additional effects of IVF, per se, further confound the issue. All the IVF-related manipulations take place almost exactly at the period when the epigenetic mechanisms too are active in the germ cells. The effect of the environment on the embryo is greater in the early stages of development. The epigenetic foci too are remodeled principally during the gametogenesis and early embryogenesis, so there is a legitimate concern with ART, wherein there is artificial manipulation of the gamete, potentially leading to increased susceptibility of the genome to epigenetic modulations.

We can divide the effects of ART on imprinting into the following categories as described here.

Male Gamete

Use of immature spermatids, surgically obtained germ cells, frozen–thawed gametes, and ICSI involving micromanipulation of both the gametes (postulations in **Box 2**) are the processes in ART where there is an apprehension of the increased susceptibility of acquisition of imprinting disorders. However, technically postulating, it is unlikely that ART involving the use of male gametes in the form of either surgically obtained immature sperms or elongated

BOX 2: How is intracytoplasmic sperm injection responsible for imprinting postulations?

- Disruption of the cytoskeleton of oocyte
- Leakage of cytoplasm
- Bypassing natural barrier/natural selection
- Paternal age/subfertility/genetic disorders
- Removal of cumulus
- Abnormal oocyte activation

sperms would interfere with the acquisition of imprinting disorders, as both erasure and the acquisition of new imprints appear to be completed by the spermatid phase of spermatogenesis. But this needs to be veritably proven with more studies.

Female Gamete

In vitro maturation, downregulation, superovulation, culturing and micromanipulation of mature oocytes, and freezing–thawing injuries are the concerns with the female gametes. Ovulation induction has been suggested to be one of the reasons for methylation errors, but it is still not clear whether ovulation induction is the root cause in itself or it is attributable to the backdrop of advanced age and underlying infertility.

Embryo Culture

Embryo culture, especially prolonged culture, manipulation, and cryopreservation, are the procedures that are thought to be related to imprinting. Preimplantation genetic screening (PGS), in fact, involves direct and invasive manipulation of the embryos. The temperature, pH, oxygen concentration, etc., in the culture media all are potential threats to the epigenetic modulation of the embryo.

The first concern of overgrowth due to culture media was the "large offspring syndrome" in cattle, characterized by high birth weight, organ overgrowth, and respiratory distress. This happened particularly when embryos were cultured with serum.[30] Weight is important as it is a marker of the growth and a harbinger of the future metabolic and cardiovascular diseases. The jury is still out on this, though with one study reporting a significant difference in the weight of the babies born after in vitro culture of embryos[31] and another refuting the same.[32] A study compiled 11 studies on media comparisons and found that while six studies showed differences, five did not. They made a note of the possibility of incomplete revelation of the culture conditions in at least some of these studies.[33] These concerns thus still await to be addressed, though it has been suggested recently that the presence of essential amino acids in culture on the first 3 days of embryo development reduces the chance of imprinting errors.[34] One impressive study reported a multitude of effects of culture media, including that on the metabolic cycles, of mouse embryos.[35]

The authors feel that in the backdrop of the above, there should, in fact, be a general shift toward disclosure of the contents, in which embryos are cultured, rather than veiling it behind a shroud of secrecy.

Ovarian Stimulation

Superovulation and pharmacological ovarian stimulation are unnatural procedures, leading to unnatural and accelerated growth of the follicles. It also leads to the atypical selection of multiple dominant follicles, bypassing the natural growth restriction mechanisms, thus potentially predisposing the eggs/embryos to epigenetic influences. A study has, in fact, incriminated ovarian stimulation with epigenetic changes at multiple loci.[36]

SPECIFIC IMPRINTING DISORDERS

- Beckwith–Wiedemann syndrome is reported to have an incidence of 1 in 14,500 live births.[37] It is a rare disorder characterized by a fetus which is large for gestational age. The placenta is large and thickened and the pregnancy may also be associated with polyhydramnios. Other characteristics include:
  - Macrosomia (newborn significantly larger than average)
  - Macroglossia (medical term for unusually large tongue)
  - Visceromegaly (enlargement of organs inside the abdomen)
  - Embryonal tumors (Wilms' tumor, hepatoblastoma, neuroblastoma, and rhabdomyosarcoma)
  - Omphalocele (a hernia in which the abdominal organs protrude in the umbilical cord)
  - Neonatal hypoglycemia
  - Ear creases or pits
  - Adrenocortical cytomegaly (presence of bizarre-looking eosinophilic cells in the adrenals)
  - Renal abnormalities.[38]

  Monochorionic twinning is also reported to be higher in BWS.[39] The disorder occurs due to "*paternal disomy and maternal deletion of chromosome 11p15.5.*" Both BWS and SRS are related to chromosome 11p15.5. SRS is a condition characterized by severe intrauterine growth retardation, poor neonatal growth, and abnormalities in the craniofacial features, such as a broad forehead and a triangular face, also accompanied by asymmetry of the body and a variety of minor malformations.[40] Hypomethylation of *H19* at chromosome 11p15.5 (40%) occurs frequently in SRS.[41]

  Maternal UPD of chromosome 7 is also known to be associated in a few cases.
- "AS and PWS" are two distinct syndromes that map to the imprinting cluster on chromosome 15q11 to q13.[42]

Each syndrome is associated with mental retardation and other problems in growth, behavior, and sexual development.[43]

- Paternal deletion and maternal disomy of 15q11 to q13 lead to PWS.
- Maternal deletion and paternal disomy of 15q11 to q13 lead to AS.

Prader–Willi syndrome presents with developmental delay, endocrinological defects, and neural tube malformations. AS presents with developmental delay, intellectual disability, and speech, movement, and sleep disorders. Excessive laughter is a typical feature of AS.[44]

- Retinoblastoma is a malignant tumor of the retina which occurs during childhood and the incidence in the general population is 1:17,000.[45] It has been reported to be higher by a relative risk of 4.9–7.2 in IVF conceptions. The association between this tumor and imprinting has been suggested because hypermethylation of the *RB1* promoter has been linked to it.[46]

GLOBAL IMPRINTING DISORDERS

Embryos that completely lack one parental genome too can have global imprinting changes. Ovarian "teratomas" have been known to occur by spontaneous oocyte activation in situ with complete absence of paternal genome.[47] Complete hydatidiform mole is well known to form by the absence of maternal genome in the embryo and exhibits excessive development of placental tissue with the risk of choriocarcinoma formation.[48] Origin of pre-eclampsia too has recently been associated with the imprinting effects on certain trophoblastic cells.[49]

WHAT IS THE EVIDENCE OF ASSOCIATION?

- The only disease with a definite association with ART is BWS with a relative risk of 5.2. Considering the population prevalence of 1:13,700, it implies that 1 in every 2,700 children born out of ART would be affected by BWS. However, it is still not clear whether this association is due to the underlying (background) high-risk factors or because of the procedure-related effects. It is important to note that routine screening for imprinting disorders is not recommended as the absolute risk is <1%.[50]
- Another disease suspected to be associated is AS. The total number of reported cases is less, but still, there is a suggestion of positive correlation with ART.
- No significant positive correlation has yet been established between the twin syndromes of SRS and PWS with ART as the incidence of these maladies is very low. Other imprinting disorders, including transient neonatal diabetes mellitus and maternal hypomethylation syndrome, have been reported, but their relationship with ART is very low or nonexistent.[51]
- After correction for infertility, the incidence of retinoblastoma has not been found to increase. However, the conclusion is that rather than the direct effect of ART on imprinting diseases, the increased risk is linked with the parental causes of infertility. However, the possible relationship will hopefully be revealed in further larger studies. Caution, as well as avoidance of undue consternations, is worthwhile at this stage.[52]
- ICSI does not cause an increased incidence of epigenetic diseases compared with a regular IVF.[53] One fact that has already been highlighted in this chapter, but needs further stressing, is that the risks of ART on imprinting disorders cannot easily be evaluated because patients who undergo ART are different from the general population in their genetics and demography. They have lower fertility rates, increased abortion rates, and are usually of advanced age. For example, sperms of men with severe semenopathies have been linked to DNA methylation defects.[54] All these factors are independently associated with fetal and neonatal abnormalities. All these confounding factors make it difficult to evaluate and estimate the direct risk of ART, per se. At present, the data obtained in humans are inconclusive and controversial. Some studies do suggest an association between ART and imprinting disorders, but this could be a "tip of the iceberg" phenomenon.[55]

However, it is noteworthy that 90–100% of the children of BWS born after ART had imprinting defects, compared to 40–50% of the naturally born children with BWS, who had genetic (not epigenetic) defects. Similarly, in reported cases of AS, 71% of the children born after ART had imprinting defects, compared to 5% of the naturally conceived ones.[56]

PREVENTION

- Elucidating the exact trigger points for imprinting disorders during ART may allow protocols to be modified, therefore minimizing the risks.
- As mentioned earlier, the presence of essential amino acids in culture on the first 3 days of embryo development may safeguard against the risk of imprinting errors.
- Strict control of the embryology laboratory environment.

However, prevention can be efficacious only once epigenetic mechanisms are clearly understood.

IMPRINTING AND ASSISTED REPRODUCTIVE TECHNOLOGY: FUTURE CONSIDERATIONS

There are certain unanswered questions in this field:

- Whether embryo culture to the blastocyst stage is linked with a higher risk of imprinting disorders
- Role of superovulation and hormone stimulation in methylation defects.

- Whether cryopreservation of gametes and embryos leads to a higher risk.
- Whether it is the underlying infertility or the ART procedure that needs to be implicated in the causation of these disorders.

More studies are still needed to answer these questions. However, as detailed earlier, there are certain methodological issues, such as lack of control and very low prevalence of these disorders, which make this a difficult task. Only a large study can be reasonably expected to resolve this conundrum. But, such a survey would require an extensive international collaboration.[26]

OTHER EPIGENETIC ISSUES

In addition to the above-mentioned imprinting disorders, some neurodevelopmental disorders are also known to be associated with imprinting. Some examples include bipolar affective disorder, autism/intellectual disabilities, epilepsy, schizophrenia, Tourette syndrome, Turner syndrome, and late-onset Alzheimer's disease.[57]

Spontaneous abortions also have been proposed to occur in ART conceptions due to aberrations in the methylation levels on the imprinted loci. This possibility is yet to be conclusively proven.[58] Oxidative stress affects gametes and the developmental capability of embryos. Environmental endocrine disruptors can increase oxidative stress and methylation errors. ART may exacerbate these defects in methylation and epigenesis. Cardiovascular abnormalities are most widely prevalent among this class of epigenetic disorders as shown in a meta-analysis.[59]

The placenta is a specialized organ that supports fetal development and growth. Placental changes can have major effects on the fetus as well as on its adaptive mechanism. IVF or ICSI-derived pregnancies are known to have increased frequency of placenta-related complications, for example, an increased incidence of hypertensive disorders of pregnancy, third-trimester vaginal bleeding, placenta previa, and abruption.[60] Whether the imprinting errors lead to a change in placental function and maternal physiology, leading to long-term consequences, needs further evaluation. Choux et al. have shown the existence of alterations in the DNA methylation patterns in placentas derived from ART pregnancies.[61]

CONCLUSION

With growing popularity of ART/IVF procedures worldwide, the significance of epigenetics cannot be disregarded anymore. Genomic imprinting, clustering etc. are the concepts all clinicians should be versed with. Moreover, awareness of these disorders would lead to more accurate reporting. This is expected to lead to better understanding of the pathogenesis of these disorders, ultimately resulting in prevention strategies.

KEY POINTS

- Epigenetics is the study of the changes in organisms caused by a selective modification of gene expression, rather than alteration of the genetic code.
- Genomic imprinting is a genome modification, allowing genes from only one parental allele to be expressed.
- The effect of the environment on the embryo is greater in the early stages of development compared to later stages and so there is a concern with ART.
- Gamete maturation and postfertilization are the most important times when methylation changes occur.
- Studies suggesting a positive association between imprinting disorders and ART are marred by the small sample sizes, lack of correction for maternal age, or parental infertility diagnoses.
- It has been suggested that the presence of essential amino acids in culture on the first 3 days of embryo development reduces the chance of imprinting errors.
- Patients undergoing ART have lower fertility rates, increased abortion rates, and are usually of higher age groups; all of these are independently associated with fetal and neonatal abnormalities.
- The only disease with a definite association with ART is BWS with a relative risk of 5.2.
- More studies are required to elucidate the effect of the composition of the culture media on birth weight.
- There is upcoming evidence indicating an association between ART and long-term sequelae, such as cardiovascular disorders.
- Routine screening for imprinting disorders is not recommended as the absolute risk is <1%.

Complications in ART

CHAPTER 66

Ovarian Hyperstimulation Syndrome

Surbhi Gupta, Divyashree PS

INTRODUCTION

Ovarian hyperstimulation syndrome (OHSS) is an iatrogenic complication of ovulation induction and ovarian stimulation for assisted reproductive technology (ART) and is characterized by cystic enlargement of the ovaries and rapid fluid shifts from the intravascular compartment to the third space. It is the most feared complication, potentially life threatening in its severe form, resulting in hospitalization in 1.9% cases,[1] and human chorionic gonadotropin (hCG), either exogenous or endogenous, is the triggering factor of the syndrome. The incidence of clinically significant OHSS is 2–3%; however, milder forms of OHSS develop in about 20–30% of in vitro fertilization (IVF) patients.[2] The mortality risk is estimated to be 1 in 450,000–500,000 cases.[3] It is second only to multiple gestations as the most common complication of ART. Young women, who wish to get pregnant, may face a potentially life-threatening condition. Therefore, every effort should be made to achieve an OHSS-free clinic.

CLASSIFICATION

Classification Schemes by Disease Severity

Over the past 25 years, several classification systems have evolved for categorizing OHSS so as to formulate uniform guidelines for prevention and treatment. Six major severity-based classifications, which have developed over a period of time, are as follows **(Table 1)**:

1. Rabau et al. (1967)—first classification combined both clinical and laboratory findings.
2. Scheneker and Weinstein (1978)—modified the classification and included three categories of mild, moderate, and severe as well as six grades of severity.
3. Golan et al. (1989)—made further changes including four major modifications to the earlier system: (1) Urinary assays of hormones were not taken into account, (2) the diagnosis of ovarian enlargement and the detection of ascites were ultrasound-based, (3) nausea, vomiting and diarrhea, and abdominal distension were classified into mild OHSS and not moderate (grade 2) OHSS, and (4) the detection of ascites on ultrasonography-classified OHSS to be moderate (grade 3).
4. Navot et al. (1992)—further contributed to the classification, based on clinical criteria and by reviewing and comparing the risk factors and previous treatment strategies. Mild OHSS was not included since it lacked clinical significance.
5. Rizk and Aboulghar (1999)—include specific laboratory values, and the major areas of the classification rely on qualitative clinical findings.
6. Royal College of Obstetricians and Gynaecologists (RCOG) Classification (2016)

Classification by Disease Onset

Ovarian hyperstimulation syndrome can be early or late based on the source of hCG **(Table 2)**.

ETIOLOGY AND PATHOPHYSIOLOGY

Ovarian hyperstimulation syndrome manifests systemically as a result of vasoactive mediators being released from hyperstimulated ovaries causing extravasation of protein-rich fluid into the third space. This leads to intravascular hypovolemia causing hypoalbuminemia, hemoconcentration, electrolyte imbalance, decreased renal perfusion and oliguria, ascites, and pleural/pericardial effusions, which may precipitate significant morbidity and mortality from thrombosis, renal, liver, and respiratory failure. Ovarian enlargement is also a risk factor for torsion and cyst rupture. Hemoconcentration can lead to complications such as hypercoagulability and reduction in organ perfusion **(Flowchart 1)**.

The exact etiology for the pathogenesis of OHSS is still unknown, but the syndrome is known to be dependent on hCG. The ovaries which are primed with gonadotropins and are subsequently exposed to hCG lead to pathophysiology of increased vascular permeability.[7]

TABLE 1: Classification of ovarian hyperstimulation syndrome (OHSS).[4]

Study	*Mild*	*Moderate*	*Severe*	
Rabau et al. (1967)	*Grade 1:* Estrogen >150 mg and pregnanediol >10 mg/24 h *Grade 2*: Grade 1 + enlarged ovaries and possibly palpable cysts. Grades 1 and 2 were not included under the title of mild OHSS	*Grade 3:* Grade 2 + confirmed palpable cysts and distended abdomen *Grade 4*: Grade 3 + vomiting and possibly diarrhea	*Grade 5:* Grade 4 + ascites and possibly hydrothorax	*Grade 6:* Grade 5 + changes in blood volume, viscosity, and coagulation time
Scheneker and Weinstein (1978)	*Grade 1*: Estrogen >150 mg/24 h and pregnanediol >10 mg/24 h *Grade 2*: Grade 1 + enlarged ovaries, sometimes small cysts	*Grade 3*: Grade 2 + abdominal distension *Grade 4*: Grade 3 + nausea, vomiting, and/or diarrhea	*Grade 5*: Grade 4 + large ovarian cysts, ascites, and/or hydrothorax	*Grade 6*: Marked hemoconcentration + increased blood viscosity and possibly coagulation abnormalities
Golan et al. (1989)	*Grade 1*: Abdominal distension and discomfort *Grade 2*: Grade 1 + nausea, vomiting and/or diarrhea, enlarged ovaries 5–12 cm	*Grade 3:* Grade 2 + ultrasound evidence of ascites	*Grade 4:* Grade 3 + clinical evidence of ascites and/or hydrothorax and breathing difficulties	*Grade 5*: Grade 4 + hemoconcentration, increased blood viscosity, coagulation abnormality, and diminished renal perfusion
Navot et al. (1992)			*Severe OHSS*: Variable enlarged ovary; massive ascites ± hydrothorax; Hct >45%; WBC >15,000; oliguria; creatinine 1.0–1.5; creatinine clearance >50 mL/min; liver dysfunction; anasarca	*Critical OHSS*: Variable enlarged ovary; tense ascites 6 hydrothorax; Hct >55%; WBC >25,000; oliguria; creatinine >1.6; creatinine clearance <50 mL/min; renal failure; thromboembolic phenomena; ARDS
Rizk and Aboulghar (1999)		Discomfort, pain, nausea, distension, ultrasonic evidence of ascites and enlarged ovaries, normal hematological and biological profiles	*Grade A*: Dyspnea, oliguria, nausea, vomiting, diarrhea, abdominal pain, clinical evidence of ascites, marked distension of abdomen or hydrothorax, US showing large ovaries and marked ascites, normal biochemical profile *Grade B*: Grade A + massive tension ascites, markedly enlarged ovaries, severe dyspnea and marked oliguria, increased hematocrit, elevated serum creatinine, and liver dysfunction *Grade C*: Complications as respiratory distress syndrome, renal shutdown, or venous thrombosis	
RCOG Green-top Guidelines (2016)	Abdominal bloating, mild abdominal pain, ovarian size usually <8 cm^2	Moderate abdominal pain, nausea, vomiting, ultrasound evidence of ascites, ovarian size usually 8–12 cm^2	Clinical ascites (±hydrothorax), oliguria (<300 mL/day or <30 mL/h), hematocrit >0.45, hyponatremia (sodium <135 mmol/L), hypo-osmolality (osmolality <282 mOsm/kg), hyperkalemia (potassium >5 mmol/L), hypoproteinemia (serum albumin <35 g/L), ovarian size usually >12 cm^2	Tense ascites or large hydrothorax, hematocrit >0.55, white cell count >25,000/mL, oliguria/anuria, thromboembolism, acute respiratory distress syndrome

(ARDS: acute respiratory distress syndrome; Hct: hematocrit; US: ultrasound; WBC: white blood cells)

Any molecule with an important role in pathophysiology of OHSS should fulfill the following prerequisites:[8]

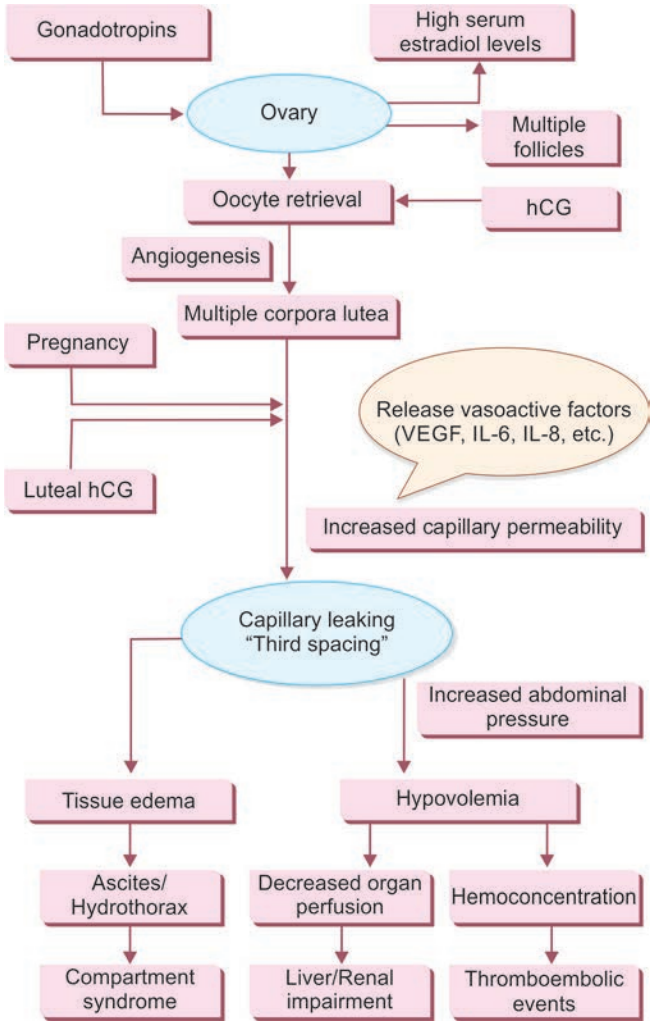
- Its expression should be increased by hCG and should be higher in cases of OHSS.
- It should have a clear and strong effect on vascular permeability.
- Inhibition of such effect should ameliorate the clinical manifestations of OHSS.

TABLE 2: Classification on the basis of disease onset.[2,5,6]

	Early OHSS	*Late OHSS*
hCG	Exogenous	Endogenous
Time of onset	3–7 days after hCG trigger	>10 days after hCG trigger
Occurrence	Occurs in a stimulated cycle	Occurs in setting of a pregnancy
Associated with	Higher peak E2 levels, greater gonadotropin doses	Singleton or multiple pregnancy

(E2: estradiol; hCG: human chorionic gonadotropin; OHSS: ovarian hyperstimulation syndrome)

Flowchart 1: Pathophysiology of ovarian hyperstimulation syndrome (OHSS).



(hCG: human chorionic gonadotropin; IL: interleukin; VEGF: vascular endothelial growth factor)

Vascular endothelial growth factor (VEGF) has been found to be crucial for the development of OHSS, fulfilling all the aforementioned prerequisites. Cytokines and growth factors have been implicated in the inflammatory process associated with follicular maturation, ovulation, corpus luteum function, and embryo implantation. Renin–angiotensin–aldosterone system, prostaglandins, inhibin, endothelin-1, tumor necrosis factor α, and inflammatory mediators have all been implicated in the etiopathogenesis of OHSS.[9]

Factors implicated in the past in the pathogenesis of OHSS:[10]

- *Histamine and OHSS*: It was demonstrated that OHSS could be blocked in rabbits by the administration of antihistamine preparations.[11] It also caused a more rapid regression of the hyperstimulated ovaries. But later, no difference was demonstrated in histamine levels between rabbits in whom OHSS was induced and controls. Also, using two different H1 receptor blockers, the role of serotonin was not found in the pathogenesis of OHSS. The role of chlorpheniramine maleate, an H-1 receptor blocker, was also studied in OHSS.[12] This effectively blocked the ascites formation but did not prevent the ovarian enlargement and augmentation of the intraovarian prostaglandin F content.
- *Estrogen (E2) and OHSS:* Serum E2 has also been implicated in the pathogenesis of OHSS, but the exact role is still not clear. Although it is a known risk factor for OHSS, it is neither necessary nor sufficient for the development of the disease. High E2 levels are found in OHSS patients;[13] but no matter how high E2 levels may be, OHSS does not occur unless hCG is administered.[14] Also, OHSS can occur in patients with low E2 levels due to desmolase gene mutation[15] and those with hypogonadotropic hypogonadism.[16] Also, in experimental animals, OHSS was not prevented by extraperitonealization of ovaries.[17] E2 does not have a direct effect on vascular permeability[18] and high E2 is a mere marker of granulosa-lutein cell activity. Thus, increased capillary permeability in OHSS is caused by excess concentrations of the immediate metabolites secreted by the ovary after gonadotropin-hCG stimulation and not high E2 levels per se.
- *Prostaglandins and OHSS*: Experiments have been performed to determine whether prostaglandins are involved actively in the development of OHSS. Excessive E2 produced by the large number of developing follicles may lead to increased production of prostaglandins, which in turn may be responsible for the increased capillary permeability observed in OHSS. Indomethacin, a prostaglandin inhibitor, has not shown to improve ascites in cases of OHSS,[19] nor it has shown to improve the pathological process in the patients with severe OHSS.[20] Thus, the role of prostaglandins in triggering OHSS has not been proven.

The lead players currently implicated in the pathogenesis of OHSS are as follows:

- *hCG*: Human chorionic gonadotropin has a pivotal role in the development of OHSS, and this is based on

the observation that OHSS rarely occurs when hCG is withheld as an ovulatory trigger during controlled ovarian stimulation (COS).[14] hCG has been used as a luteinizing hormone (LH) surrogate from the inception of COS. Its prolonged half-life and avid affinity to LH/hCG receptor results in prolonged ovarian stimulation and changes in periovarian vasculature in the postovulatory period. It also exerts follicle stimulation hormone (FSH)-like action in stimulating the ovaries.

In patients undergoing ART, hCG, apart from its role in ovulation triggering, adversely affects OHSS in a number of ways:

- hCG supplementation during the luteal phase makes OHSS worse.
- Pregnancy and, therefore, rising levels of hCG make OHSS much worse.
- Multiple-gestation pregnancy produces even higher levels of hCG, which is associated with more severe OHSS. Those cases, which constitute an early form followed by pregnancy, are serious and long lasting.[21]

Human chorionic gonadotropin is also implicated in the development of some cases of spontaneous OHSS, an extremely rare, noniatrogenic condition, unrelated to exogenous hormones and is usually seen to complicate both singleton and multiple pregnancy. Spontaneous OHSS is a rare but important differential diagnosis for abdominal distension in early pregnancy.[22,23]

High levels of glycoprotein hormones such as β-hCG, thyroid stimulating hormone (TSH), LH, and FSH with/without FSH receptor (FSHR) mutation are seen as the trigger for most cases of spontaneous OHSS.[24] These hormones are believed to release unknown mediators and vasoactive substances such as histamine, serotonin, prostaglandins, interleukins (ILs), E2, prolactin, the ovarian renin–angiotensin system (RAS), and VEGF leading to increased vascular permeability, extravascular fluid accumulation, hemoconcentration, deep vein thrombosis, and other complications observed in OHSS.

De Leener et al. classified spontaneous OHSS into four types **(Table 3)**. In both type I and type II, development of OHSS is hCG mediated. Mutations in FSHR may cause increased sensitivity to hCG. Type III is associated with hypothyroidism and type IV is caused by ectopic FSH-secreting neuroendocrine tumors.

TABLE 3: Modified De Leener's classification of spontaneous ovarian hyperstimulation syndrome.

Modified De Leener's classification	*Primary abnormality*	*Underlying trigger*
I	Mutated FSHR	Pregnancy
II	Elevated β-hCG	• Multiple pregnancies • Gestational trophoblastic disease (GTD) • β-hCG-secreting tumor
III	Elevated TSH	Hypothyroidism
IV	Elevated FSH/LH	• FSH/LH-secreting pituitary adenomas • Ectopic FSH-secreting tumors

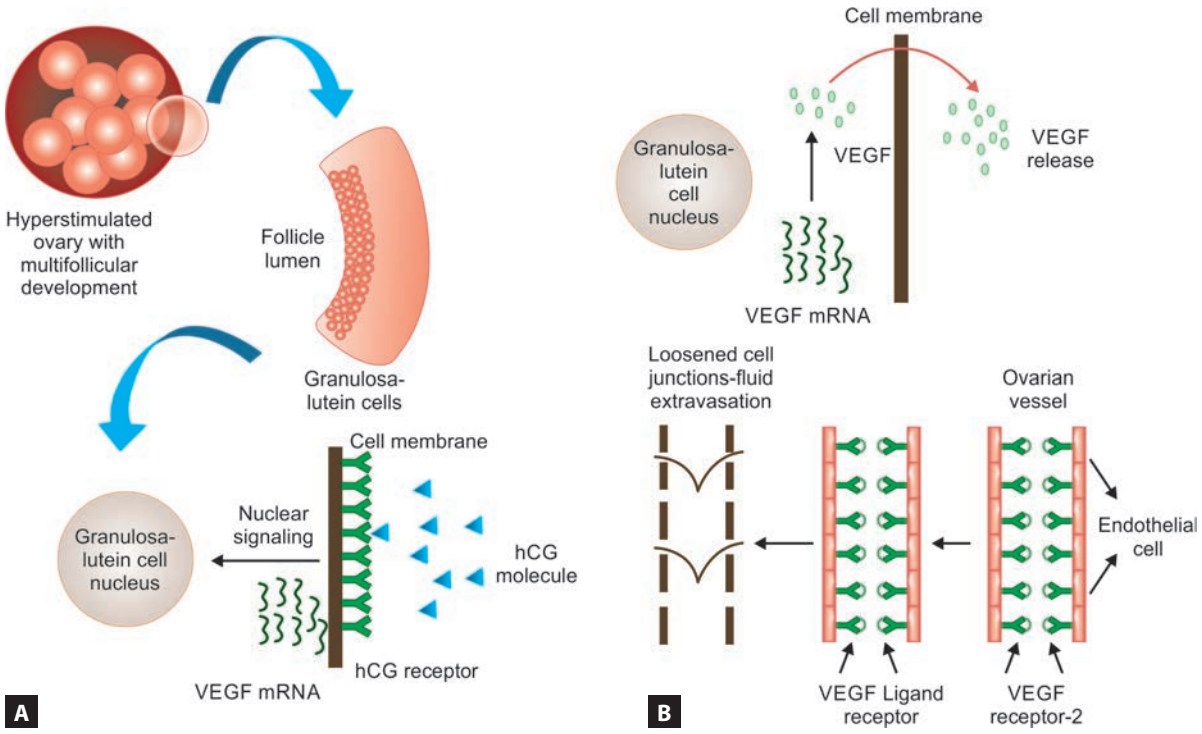
(FSHR: follicle-stimulating hormone receptor; FSH: follicle stimulation hormone; hCG: human chorionic gonadotropin; LH: luteinizing hormone; TSH: thyroid-stimulating hormone)

- *VEGF:* Vascular endothelial growth factor is the key player in the pathophysiology of OHSS.

  In humans, there are five VEGF messenger ribonucleic acid (mRNAs), encoding $VEGF_{121}$, $VEGF_{145}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$.[25] The isoforms $VEGF_{121}$ and $VEGF_{165}$, also known as VEGF A, are normal products of the ovary.[26] Two specific endothelial cell receptors for VEGF belonging to tyrosine kinase receptor family are known: VEGF receptor-1 (VEGFR-1) and VEGFR-2.[27] VEGFR-1 is also produced as a soluble receptor (sVEGFR-1) which modulates the bioactivity of VEGF.[28-30] These receptors are present not only in the endothelium but also in the ovarian follicles.[31] The binding of VEGF to VEGF-2 receptor determines the phosphorylation of intracellular domains and is critical for downstream signaling **(Figs. 1A and B)**, which is responsible for endothelial reorganization, membrane ruffling, and chemotactic contraction.[27] Expression of VEGF mRNA has been shown to be induced by hCG in a dose- and time-dependent fashion.

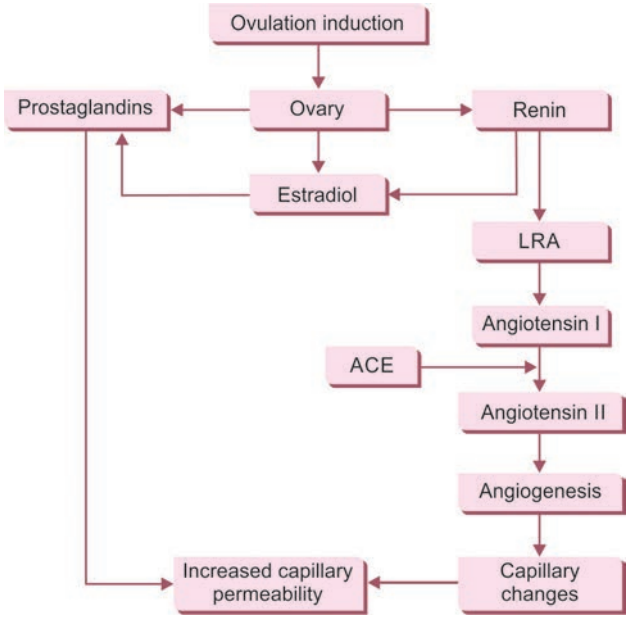
  Vascular endothelial growth factor has a very strong angiogenic effect in the ovary. hCG administration increases VEGF expression in granulosa-lutein cells, especially in patients at risk for OHSS. It has also been demonstrated that endothelium contains hCG receptors and responds to gonadotropin stimulation by releasing VEGF and increasing the amount of VEGF-2 receptor in the cell surface, recommending the role of endothelial cells as VEGF producers in the pathogenesis of OHSS.[32] Not only the ovarian vessels, but other endothelial cells of the body might also be the target for VEGF, explaining general circulatory disturbances in some patients.[33] The principal pathophysiologic events of typical OHSS are attributed to the gonads, and the ovary is the main source of VEGF and other cytokines responsible for increased capillary permeability and ascites.[34]
- *RAS*
  - *Local ovarian RAS*

    The RAS of the ovary also plays a causative role in the pathogenesis of OHSS and functions independently of the renal RAS **(Flowchart 2)**. It leads to the conversion of the avascular preovulatory follicle into a richly vascularized corpus luteum.



Figs. 1A and B: The pathogenesis of ovarian hyperstimulation syndrome (OHSS). (A) Human chorionic gonadotropin (hCG) stimulates a high number of granulosa-lutein cells leading to the increased production of vascular endothelial growth factor (VEGF) messenger ribonucleic acid (mRNA) (A); (B) VEGF receptor-2 (VEGFR-2) mRNA production in the granulosa-lutein and endothelial cells is also increased in response to hCG. High amounts of VEGF are produced and released from the granulosa-lutein cells and bind to VEGFR-2 on the endothelial cell membranes. Downstream signaling augments vascular permeability.

Flowchart 2: Suggested role of angiotensin–renin system and prostaglandins in the pathogenesis of ovarian hyperstimulation syndrome.



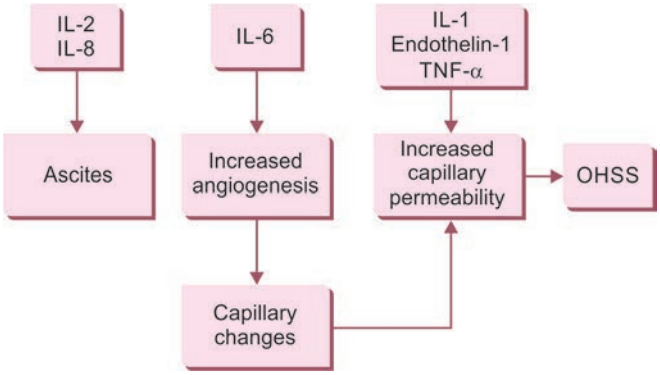
(ACE: angiotensin converting enzyme; LRA: luteal phase renin activity)

Ovarian follicles contain rennin in an inactive form, prorenin, which is activated at mid cycle, causing conversion of angiotensinogen to angiotensin I which in turn is converted to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II promotes angiogenesis, increased vascular permeability, and stimulates release of prostaglandins. hCG is a strong stimulant of RAS activity as high renin activity is observed in the follicular fluid and plasma of women with OHSS. Thus, ovarian RAS, in the same way as VEGF, brings about new vessel formation and increased capillary permeability leading to ovarian enlargement and extracellular fluid sequestration, characteristic of OHSS.[35] Overstimulation of the RAS cascade along with increasing VGEF levels can synergistically potentiate OHSS.

- *Systemic RAS*

In the development of OHSS, another pathway thought to be is the arterial dilatation. This leads to underfilling of the arterial vascular component, arterial hypotension, and a compensatory increase in heart rate and cardiac output (CO).[36,37] If circulatory dysfunction occurs only as a result of extravascular fluid shift, then there will be a reduction in CO and increase in peripheral vascular resistance and atrial natriuretic peptide. On the contrary, there is an increase in CO and atrial natriuretic and a marked reduction in peripheral vascular resistance. This increase in CO is thought to be due to the activation of neurohormonal vasoconstrictor pathways including RAS.

Flowchart 3: Suggested role of cytokines and other factors in ovarian hyperstimulation syndrome.



(IL: interleukin; OHSS: ovarian hyperstimulation syndrome; TNF: tumor necrosis factor)

- *Immune factors*: The immune system and the reproductive system have been found to be linked through cytokines and their receptors which in turn lead to the local and systemic effects of immune response.[38,39] Proinflammatory cytokines: IL-1β, IL-2, IL-6, IL-8, endothelin-1, and tumor necrosis factor α have been implicated to mediate the acute phase response, which leads to capillary leakage and the third space loss in OHSS **(Flowchart 3)**. Elevated serum levels of these cytokines have been found in OHSS.

RISK FACTORS FOR OVARIAN HYPERSTIMULATION SYNDROME

Identifying at-risk patients is critical in prevention of OHSS as it assists the clinician in making changes in the ovarian stimulation protocols or taking other preventive measures. Risk factors can be primary or secondary **(Table 4)**.

Primary risk factors are patient-related and confer an increased risk of OHSS to the patients. They include young age, low body mass index (BMI), previous history of OHSS, polycystic ovary syndrome (PCOS), high basal anti-müllerian hormone (AMH), and antral follicle count (AFC). AMH is expressed in granulosa cells from preantral and small antral follicles and is a measure of ovarian reserve. It predicts ovarian response independent of age and PCOS.[45] AMH ≥ 3.36 ng/mL has a sensitivity of 90.5% and specificity of 81.3% in predicting OHSS.[44] Another primary risk factor is high AFC, that is, ≥12 follicles of 2–8 mm in each ovary, typically located in the periphery of the ovary, "necklace sign" or "string of pearls" appearance predicts OHSS with a sensitivity of 82% and specificity of 89%.[46] Only one study has evaluated black race as a predictor of OHSS, utilizing data from the Society for Assisted Reproductive Technology (SART) database.[43] Activating mutations in the *FSHR* gene have also shown to confer a higher response to FSH and, therefore, FSHR genotype may predispose women to OHSS.[47]

TABLE 4: Risk factors for ovarian hyperstimulation syndrome (OHSS).

Risk factor	***Increased risk***
Primary risk factors (patient related)	
Young age	<33 years predicts OHSS[38]
High-basal AMH	>3.36 ng/mL independently predicts OHSS[38]
High AFC	>14 may predict hyperresponse[38]
Previous OHSS	Moderate or severe cases especially those with hospitalization
PCOS/isolated PCOS characteristics	≥24 antral follicles in both ovaries combined[40]
BMI	Lower BMI predicts OHSS[41-43]
Race	Black race predicts OHSS[43]
Secondary risk factors (ovarian response related)	
Number of follicles on the day of hCG	>14 follicles of 11 mm^2; >11 follicles of 10 mm[38]
High and rapidly rising E2 levels and high number of follicles	E2 5,000 ng/mL and/or ≥18 follicles predictive of severe OHSS[39]
VEGF levels	Not applicable
Elevated inhibin-B levels	Elevated levels on day 5 of gonadotropin stimulation, at oocyte retrieval, and 3 days before oocyte retrieval appear to correlate with development of OHSS
hCG administration for LPS	Not applicable
Pregnancy (increase in endogenous hCG)	Not applicable

(AFC: antral follicle count; AMH: anti-müllerian hormone; BMI: body mass index; E2: estradiol; hCG: human chorionic gonadotropin; LPS: luteal phase support; OHHS: ovarian hyperstimulation syndrome; PCOS: polycystic ovarian syndrome)

Secondary risk factors are related to ovarian response and become apparent during ovarian stimulation when patients with no predisposing factors develop an excessive response. The number of follicles on the day of trigger, E2 levels, number of oocytes retrieved, serum inhibin-B, and VEGF levels predict the risk of OHSS. But none of these has shown to independently predict the risk of OHSS. The data regarding measuring inhibin B levels and VEGF levels for the prediction of OHSS is still conflicting.

CLINICAL FEATURES

The clinical manifestations of OHSS are a cascade of pathophysiologic events resulting from increased vascular permeability. Symptoms of OHSS may begin as early as 24 hours after hCG administration and increase in severity over the next 7–10 days due to endogenous hCG rise resulting from early pregnancy.

- *Abdominal pain, nausea, and vomiting:* Ovarian hyperstimulation syndrome is marked by massive bilateral cystic ovarian enlargement. The ovaries show remarkable stromal edema, interspersed with multiple hemorrhagic follicular and theca-lutein cysts, areas of cortical necrosis, and neovascularization. This enlargement of the ovaries causes abdominal pain, nausea, and vomiting.
- *Third space fluid collection*: There is a generalized increase of vascular permeability, which results in decreased colloid oncotic pressure.[48] This causes fluid shift from intravascular to extravascular or "third" space resulting in ascites, pleural and pericardial effusion, and dependent edema. Dyspnea results due to mechanical impingement of diaphragm as a result of ascites. There can be rapid shift of fluid in the peritoneal cavity leading to ascites, increased intra-abdominal pressure (>20–25 mm Hg), and organ dysfunction. This is known as abdominal compartment syndrome (ACS). It is a triad consisting of:[49]
  - Respiratory compromise as a result of elevation of the diaphragm, thus affecting respiration resulting in dyspnea and pleural effusion[50]
  - Decreased venous return due to increased pressure compressing the inferior vena cava (IVC) and thus impeding blood return to heart
  - Intestinal obstruction because of compression of viscera, which can lead to decreased appetite and then nausea/vomiting[51-53]
- *Hypotension and hypovolemia*: The fluid shift into the third space depletes the intravascular volume, thus causing hypovolemia. Cardiac preload falls due to hypovolemia as well as compression of IVC due to increased intra-abdominal pressure leading to decreased CO. There is arterial vasodilatation leading to decreased peripheral resistance which in turn leads to decreased renal perfusion.[36,37]
- *Renal manifestations*: Decreased renal perfusion leads to increased proximal tubular reabsorption of salt and water and thus decreased sodium urinary excretion and oliguria.

  There is also impairment of sodium–hydrogen/potassium exchange in the distal tubule, leading to hyperkalemic acidosis.

  Decreased renal perfusion also decreases the glomerular filtration rate, which can result in oliguria or anuria and acute renal failure.
- *Hypercoagulable state and thromboembolic episodes*: A combination of hemoconcentration, high levels of ovarian steroids, and changes in liver perfusion and, thus, decreased hepatic protein synthesis and depletion of antithrombotic factors[54] results in a hypercoagulable state. Thromboses are mostly venous (67–75%) involving the upper limbs and neck and then arterial (25–33%), which are mainly cerebrovascular events usually occurring concurrently with the onset of OHSS.

TABLE 5: Classification of ovarian hyperstimulation syndrome (OHSS) symptoms.[52]

OHSS stage	*Clinical feature*	*Laboratory feature*
Mild	• Abdominal distension or discomfort • Mild nausea or vomiting • Mild dyspnea • Enlarged ovaries	No important alterations
Moderate	• Mild features • Ultrasonographic evidence of ascites	• Hemoconcentration (Hct >41%) • Elevated WBC (>15,000)
Severe	• Mild and moderate features • Clinical evidence of ascites • Hydrothorax • Severe dyspnea • Oliguria or anuria • Intractable nausea or vomiting	• Severe hemoconcentration (Hct >55%) • WBC >25,000/mL • CrCl <50 mL/min • Cr >1.6 mg/dL • Na^+ <135 mEq/L • K^+ >5 mEq/L • Elevated liver enzymes
Critical	• Low blood or central venous pressure • Pleural effusion • Rapid weight gain (>1 kg in 24 h) • Syncope • Severe abdominal pain • Venous thrombosis • Anuria or acute renal failure • Arrhythmia • Thromboembolism • Pericardial effusion • Massive hydrothorax • Arterial thrombosis • Adult respiratory distress syndrome • Sepsis	Worsening of findings

(Cr: creatinine; CrCl: creatinine clearance; Hct: hematocrit; K^+: potassium; Na^+: sodium; ; WBC: white blood cell)

OHSS is classified into mild, moderate, severe, and critical based on symptoms and laboratory features **(Table 5)**.

Humaidan et al. proposed a more objective classification system[55] incorporating vaginal ultrasound and laboratory parameters **(Table 6)**.

PREVENTION

Preventive strategies[56] for OHSS include

- Identifying "at risk" women and thus classifying the risk factors as primary or secondary **(Table 7)**

TABLE 6: Proposed new clinical grading system for ovarian hyperstimulation syndrome.

	Mild	*Moderate*	*Severe*
Objective criteria:

- Risk stratification into high, normal, or low risk and thus following preventive strategies. Prevention is either primary or secondary.
  Primary prevention: It involves classifying a person on the basis of their risk factors and then accordingly individualizing treatment regimens.
  Secondary prevention: It focuses on methods used in patients who have displayed an excessive response to ovarian stimulation during a cycle and aims to prevent progression to OHSS.

Primary Prevention

- *Reducing exposure to gonadotropins*: Gonadotropins have the capacity to enhance follicular recruitment and serum E2 concentrations, thus increasing the risk for OHSS. The exposure to gonadotropins can be minimized by reducing both dose and duration of administration of gonadotropins. The concept of individualized controlled ovarian stimulation (iCOS) should be followed for ovarian stimulation in patients at risk for OHSS.[57]
  Polycystic ovary syndrome is one of the major risk factors for the development of OHSS and, thus, this subgroup of women should be targeted for monofollicular ovulation. Thus, the protocols which stimulate the ovaries without exceeding FSH threshold and facilitate the development of a single dominant follicle are employed. Hence, either a chronic low-dose step-up or a step-down protocol regimen is favored. It is associated with a lower risk of OHSS and cycle cancellation and favors monofollicular development.[58,59] The duration of gonadotropin exposure can be reduced by mild stimulation protocols which delay the administration of FSH till the mid or late follicular phase.[55,60] In addition to reducing the risk of OHSS, mild stimulation protocols are also cost-effective as compared to standard agonist or antagonist protocols.
  In a Cochrane review published in 2018, it was highlighted that lower doses of FSH seemed to reduce the overall incidence of moderate and severe OHSS.[57]
- *Use of follitropin delta (follitropin δ)*: Follitropin δ is a new recombinant FSH derived from the cell line of human fetal retinal origin. The sialic acid of this FSH molecule is higher as compared to α and β subunits. It has a longer elimination half-life (30 vs. 24 hours) and induces a higher ovarian response when administered at equal doses of biological activity.
  The individualized dose for follitropin δ was determined on the basis of body weight and serum AMH levels. In Phase III ESTHER (Evidence-based Stimulation Trial With Human rFSH in Europe and Rest of World) trial,[61] its noninferiority to follitropin α was established. Also, the use of follitropin δ leads to decreased risk of moderate/severe OHSS as well as OHSS preventive interventions.[61,62]
- *Avoiding adjunct gonadotropin-releasing hormone agonist (GnRHa) utilization*: GnRH agonist protocol is employed to downregulate the endogenous pituitary secretion of LH to prevent premature luteinization. GnRHa plays a paradoxical role by causing profound ovarian suppression. The FSH rise in the late luteal phase is prevented. This process ends up in requiring increased doses of gonadotropins, more follicles attaining maturity with consequent rise in serum estradiol values and hence increased risk of OHSS.[55] It is also hypothesized that pituitary downregulation interferes with natural cohort selection and prevents smaller atretic follicles from becoming atretic.[63]
  Moreover, GnRHa cannot be utilized to trigger final oocyte maturation.
  It also adds to the cost of treatment without an increase in pregnancy rate. A Cochrane review by Nugent et al. demonstrated an increased risk of hyperstimulation with the use of GnRHa [odds ratio (OR) 3.15; 95% confidence interval (CI) 1.48–6.70].[64]
- *GnRH antagonist protocol*: GnRH antagonists are associated with a decreased risk of OHSS. The mechanism is thought to be related to reduction in circulating estradiol levels with GnRH antagonists.[65]

TABLE 7: Preventive measures for ovarian hyperstimulation syndrome (OHSS).

Preventive measures	***Rationale***	***Level of evidence***
Primary prevention		
Reducing gonadotropin exposure(both dose and duration)	Increased gonadotropins enhance both follicular recruitment and serum E2 concentrations with increased risk of OHSS	Grade A
Use of follitropin delta	Newer FSH with a long half-life and higher response with decreased incidence of OHSS	Grade B
Avoiding adjunct GnRH agonist (GnRHa) utilization	Pituitary downregulation prevents FSH rise in the luteofollicular transition; so, no atresia of follicles; hence cohort of follicles recruited for stimulation is more. More gonadotropin requirement, more E2 levels	Grade A
GnRH antagonist protocol	More physiological follicular selection, recruitment of smaller number of follicles, less gonadotropin requirement, less E2, and hence reduced risk of OHSS	Grade A
Avoidance of hCG for luteal phase support	• hCG increases the risk for OHSS • Progesterone significantly reduces the risk of OHSS without affecting pregnancy rates	Grade B
Insulin sensitizing agents (metformin)	By improving hyperinsulinemia and intraovarian hyperandrogenism, reduces number of nonperiovulatory follicles and hence estradiol secretion	Grade A
Secondary prevention		
Alternative agents for triggering ovulation [GnRha or recombinant LH (rLH)]	• GnRHa triggers cause massive luteolysis and thus less E2 levels in luteal phase • hCG itself is a risk factor for OHSS	Grade A
Reduced dose of hCG for triggering ovulation	Appears to decrease the risk of severe OHSS	Grade C
Cryopreservation of all embryos	Avoids endogenous hCG rise in fresh transfer cycles which can exacerbate late onset OHSS	Grade B
Cycle cancellation	Cycle cancellation and withholding hCG is definitive method for preventing OHSS	Grade C
Coasting	Withholding gonadotropins and delaying hCG reduces the risk of OHSS. Also alters the capacity of granulosa cells to produce VEGF	Grade C
Dopamine agonists	Prevents phosphorylation of VEGF receptor-2 and thus reduces the release of vasoactive angiogenic agents	Grade A
Calcium infusion	Inhibition of cAMP dependent renin secretion leading to decreased angiotensin-II production and thus VEGF synthesis	Grade B
Aspirin	Inhibits platelet activation thus inhibiting release of substances that can potentiate OHSS	Grade A
Glucocorticoids	Inhibitory effect on VEGF gene expression	Grade C
Colloid (albumin and hydroxyethyl starch) infusion	Increases plasma oncotic pressure and counteracting the permeability effect of angiotensin II	Grade C
Aromatase inhibitors	Inhibits aromatase enzyme and prevents excessive synthesis of estrogen	Grade C
Follicular aspiration		Grade C
Experimental		
In vitro maturation (IVM)	Aspiration of immature oocytes helps in preventing OHSS	
VEGF antagonists	Blocks action of VEGF	
Kisspeptin trigger for oocyte maturation	Stimulates GnRH release and in turn FSH and LH release	
Vasopressin V1a receptor antagonist	Inhibits vasopressin-induced VEGF secretion	

(cAMP: cyclic adenosine monophosphate; E2: estradiol; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; hCG: human chorionic gonadotropin; LH: luteinizing hormone; VEGF: vascular endothelial growth factor)

The action of GnRH antagonists mimics the normal physiology in selection of follicles as a smaller number of follicles are recruited, thus requiring less dose of gonadotropins and decreased risk of OHSS. Also, they constitute a more rational way of inhibiting premature LH surge as compared to GnRHa. The differential action of GnRH antagonists at both pituitary and ovarian receptors is also thought to be responsible for reduced risk of OHSS.[55]

A Cochrane review compiled 29 randomized controlled trials (RCTs) and demonstrated statistically significant lower incidence of OHSS in the GnRH antagonist group (OR –0.43, 95% CI 0.33–0.57) as compared to GnRHa group with no difference in live birth rates.[66]

The advantages of using GnRH antagonists are lack of flare effect, absence of menopausal symptoms, no refractory period, reduced risk of ovarian cyst formation, shorter treatment cycle, and reduced gonadotropin dose requirement. Most importantly, because of lack of desensitization, GnRHa can be employed to trigger ovulation. It is mandatory to give full progesterone (P) support during luteal phase while using GnRHa to trigger ovulation.

- *Avoiding hCG for luteal phase support (LPS)*: The supraphysiological levels of E2 and progesterone due to COS result in low endogenous LH levels and, thus, defective luteal phase and impaired endometrial receptivity. Hence, LPS is crucial to improve these parameters.[67-69] hCG has been used for LPS, but it also increases the risk for OHSS. Use of P halves the risk of OHSS without affecting pregnancy rates.[70]

  As an alternative to P, GnRHa as repeated intranasal administration can be used for LPS, but more studies are required to support this.[71] It is recommended that in high-risk cases, LPS should be given in the form of P and not hCG.
- *Insulin sensitizing agents (metformin):* Metformin is an insulin-sensitizing agent widely used in PCOS patients. The concept of "androgen priming" states that androgens increase the ovarian response to gonadotropin stimulation. By improving intraovarian hyperandrogenism, metformin affects the ovarian response by reducing the number of nonperiovulatory follicles and hence estradiol secretion. Metformin is also hypothesized to inhibit the secretion of vasoactive molecules such as VEGF and thereby modulating vascular permeability and preventing OHSS.[72] A recent meta-analysis analyzing 12 studies and 1,516 participants showed that the use of metformin significantly reduced the risk of OHSS in PCOS patients.[73]

  In a recent Cochrane review based upon eight RCTs with 798 women, it was noted that there was a decreased risk of OHSS with metformin use (OR 0.29, 95% CI 0.18–0.49).[74]

Secondary Prevention

- *Alternative agents for triggering ovulation*: Utilizing exogenous hCG to mimic endogenous preovulatory LH surge and trigger ovulation has been in use for decades. However, due to its longer half-life, hCG results in prolonged luteotropic effect. This results in stimulation of LH receptors on multiple post-retrieval corpora lutea and raised E2 and P levels throughout the luteal phase and thus increasing the risk of OHSS. Therefore, alternative agents for triggering final oocyte maturation have been investigated so as to prevent OHSS.
  - *GnRHa trigger*: GnRHa, when administered as a bolus, results in a flare of gonadotropins (LH and FSH) released by the pituitary, mimicking the natural mid-cycle surge and triggering final oocyte maturation.[55] Moreover, it produces a more moderated and shorter gonadotropin surge in contrast to hCG, thus virtually eliminating the risk of OHSS.[75-77] However, it causes a profound luteal phase insufficiency due to massive luteolysis and hence, LPS in the form of E2 and P is required in patients receiving GnRHa trigger.

    A Cochrane review published in 2014 found that GnRHa as compared to hCG triggers results in lower incidence of OHSS in fresh autologous as well as donor–recipient cycles. It was also associated with lower live birth rate in fresh autologous cycles.[78]

    Although GnRHa is said to virtually eliminate the risk of OHSS, there have been case reports demonstrating OHSS even with OHSS trigger.[79-81] This was attributed to massive luteinization of the follicles after exaggerated stimulation and OHSS occurred independently of the ovulation triggering agent. Also, it cannot be used as a trigger in GnRHa cycles where the risk of OHSS is higher as compared to antagonist cycles.
  - *Recombinant LH (rLH)*: Recombinant LH closely mimics natural LH surge and a single peak of rLH is sufficient to induce final oocyte maturation. One preliminary comparison of rLH and recombinant hCG (rhCG) has demonstrated a lower incidence of moderate to severe OHSS with a single dose of rLH.[82] However, because of poor cost–benefit ratio, its use as a trigger is limited in routine clinical practice.
- *Reducing dose of hCG for triggering ovulation*: Human chorionic gonadotrophin is a known risk factor for OHSS; thus, different doses of hCG for triggering ovulation have been assessed. There has been no difference in the clinical outcome between 5,000 and 10,000 IU of hCG.[83,84] Low-dose hCG does not eliminate the risk of OHSS in high-risk patients. However, further studies are required before very low doses of hCG can be recommended.
- *Cryopreservation of all embryos*: During cryopreservation, COS and oocyte retrieval are performed, followed by

cryopreservation of all the embryos and their subsequent transfer in nonstimulated cycles. This prevents endogenous hCG rise in fresh-transfer cycles, which can exacerbate late-onset OHSS.

The routine use of elective cryopreservation has not been validated because, with routine culture of embryos to blastocyst stage, the degree of OHSS can be accurately assessed prior to embryo transfer as blastocyst transfer takes place on the 7th day after hCG and in the absence of moderate degree OHSS, fresh transfer can be safely done.[85,86] Cryopreservation also increases the cost of the treatment.

Another concern which was previously associated with cryopreservation was lower pregnancy rates owing to slow freezing methods; however, with the advent of vitrification, pregnancy rates with cryopreserved embryos exceed fresh embryo transfer.[87-90]

A Cochrane review analyzed two RCTs and concluded that there was insufficient evidence to recommend routine cryopreservation.[86]

A recent meta-analysis by Roque et al. supports the use of elective FET in hyper-responders as it increases live birth rate and significantly decreases the risk of moderate and severe OHSS.[91] Also, the evidence supports the use of GnRHa trigger followed by cryopreservation for "OHSS-free clinic" which is discussed subsequently.[92]

- *Cycle cancellation*: Withholding hCG and cycle cancellation guarantees prevention of early OHSS.[93] However, natural LH surge resulting in ovulation and natural conception may still occur in some cases, with a possibility of late OHSS.

  Although cycle cancellation is effective in preventing OHSS, it is not recommended because of the financial burden and psychological distress it causes to the patient.[55,94]
- *Coasting*: It is a preventive strategy of withholding gonadotropins at the end of COS for up to 4 days when a certain E2 concentration and/or a critical number of follicles are reached. hCG trigger is subsequently delayed until E2 levels significantly decrease or plateau.[94] Initial studies showed that coasting is associated with a lower risk of OHSS without compromising the pregnancy rate.[95,96] However, a Cochrane review in 2017 analyzed 8 RCTs and 702 women and concluded that there was insufficient evidence to suggest that coasting reduced moderate and severe OHSS. Also, there was no evidence to suggest that coasting was more beneficial than other interventions.[97] As a routine, coasting is not recommended for the prevention of OHSS.
- *Dopamine agonists*: As discussed previously, the pathophysiology of OHSS is mainly attributed to an increased vascular permeability of ovarian and peritoneal capillaries caused by ovarian hypersecretion of VEGF.

  Cabergoline is a dopamine receptor-2 agonist and inhibits the phosphorylation of VEGFR-2.[98] This results in reduction of VEGF production and subsequently decreased risk of OHSS.

  It has also been demonstrated that tyrosine hydroxylase enzyme, rate-limiting enzyme for dopamine synthesis, was downregulated in overstimulated ovaries.[99] High VEGF expression and activity in OHSS were associated with reduced dopamine production. Hence, it was postulated that dopamine could be used as an anti-angiogenic factor in ovary.[100] Also, with cabergoline, there was a dopaminergic control of LH release and thus a better clinical control of ovarian response and consequently reduced risk of OHSS.[101] Cabergoline in low doses does not produce any anti-angiogenic activity; states of high-level VEGFR-2-dependent vascular activity such as corpus luteum physiology or pregnancy development are not affected.[8,102-104]

  A daily administration of 0.5 mg/day for 8 days starting from the day of hCG administration has shown to reduce the incidence of moderate OHSS by 50%.[105] A Cochrane review in 2016 by Tang H et al., including 16 RCTs and 2,091 women, concluded that dopamine agonists reduce the incidence of moderate and severe OHSS in high-risk women and do not affect the pregnancy outcome in fresh embryo transfer cycles.[106]

  Therefore, use of cabergoline in a dose of 0.5 mg/day for 8 days commencing on the day of hCG trigger is recommended.
- *Calcium infusion*: As discussed previously, the ovarian renin–angiotensin system is involved in the etiopathogenesis of OHSS. Calcium infusion inhibits cyclic adenosine monophosphate (cAMP) synthesis and cAMP-dependent renin secretion from juxtaglomerular cells in the kidneys.[107,108] Decreased renin secretion leads to decreased angiotensin II production and consequently decreased angiotensin II-mediated stimulation of VEGF synthesis.[65] Intravenous infusion of 10 mL of 10% calcium gluconate in 200 mL normal saline on the day of oocyte retrieval and 3 days thereafter decreases the risk of mild and severe OHSS.[109,110] This preventive strategy has a potential benefit but further studies are required for routine recommendation.
- *Aspirin*: Increased VEGF levels lead to increased platelet activation, which causes release of substances such as histamine, serotonin, platelet-derived growth factor, or lysophosphatidic acid, further potentiating the physiologic cascade of OHSS. Aspirin is associated with reduced incidence of OHSS with no effect on pregnancy outcome and is routinely recommended.[65,111]
- *Glucocorticoids*: Glucocorticoids and their synthetic derivatives have an inhibitory effect on *VEGF* gene expression in vascular smooth muscle cells.[112]

By inhibiting vasodilatation and preventing increase in vascular permeability, they ameliorate the inflammatory response and prevent edema formation, thus helping in treating early signs of developing OHSS.[55,113] One randomized trial has demonstrated a beneficial role of corticosteroids in conjunction with aspirin in preventing OHSS; the treatment begins on the day of starting COS.[114] However, there is insufficient evidence to recommend the use of glucocorticoids in preventing OHSS.[115,116]

- *Colloids (albumin and hydroxyethyl starch)*: As third spacing and intravascular volume depletion due to increased capillary leakage are hallmarks of OHSS, use of intravenous infusion of colloidal agents (albumin and hydroxyethyl starch) for prevention of OHSS has been investigated.[117-119] Albumin has a low molecular weight and an average half-life of 20 days. It increases plasma oncotic pressure, counteracting the permeability effect of angiotensin II and thus attenuates the effects of hypovolemia, hemoconcentration, and ascites. It also binds to vasoactive substances such as VEGF and factors related to RAS.

  In a Cochrane review analyzing nine RCTs, albumin infusion administered on the day of oocyte retrieval reduce rates of moderate and severe OHSS in high risk women, but at the same time it is associated with reduced pregnancy rates.[120] The data on hydroxyethyl starch is limited. Moreover, as albumin is a blood-derived product, it leads to allergic reactions and transmission of viruses and prions. The benefits of colloidal agents still remain unclear and further studies are required to recommend their use as preventive strategies.
- *Aromatase inhibitors*: The aromatase enzyme catalyzes the rate-limiting step in E2 synthesis. Aromatase inhibitors, therefore, help to reduce excessive E2 and reduces the risk of OHSS. The antiestrogenic effects of these agents are promising, but further studies are required for their routine use in prevention of OHSS in a clinical setting.[55,121]
- *Follicular aspiration*: It means aspiration of granulosa cells from one ovary 10–12 hours post hCG injection or at the time of oocyte retrieval as a means of inducing intraovarian bleeding and limiting the production of OHSS mediators while allowing continued contralateral ovarian development.[122]

  There is insufficient data to prove its role in preventing OHSS. Moreover, it leads to increased cost, discomfort, and invasive procedures requiring anesthesia. Hence, this approach is not recommended.
- *Miscellaneous treatments*: There is insufficient data to make recommendations regarding the use of luteal antagonist administration, intramuscular P, or ketoconazole to reduce the risk of OHSS.[65]

EXPERIMENTAL METHODS

- *In vitro maturation (IVM)*: In patients having high risk of OHSS, IVM helps in OHSS prevention.[55] It is the process of aspirating antral follicles of unstimulated or minimally stimulated ovaries and thus retrieving immature oocytes. Although the clinical outcome has improved in the recent years,[123] it is not widely used. It is still in the experimental stages and further trials are needed to use it in clinical practice.
- *VEGF antagonists*: A compound SU4516 blocks the intracellular phosphorylation of VEGFR-2 and acts as a VEGF antagonist and helps in preventing OHSS.[35] Similarly, FMS-like tyrosine kinase, which binds to VEGF and decreases its concentration, is available for endothelial cells.[124] However, it has side effects such as thromboembolism, severe vomiting, and teratogenicity; hence, it has not been used in clinical practice.
- *Kisspeptin trigger for oocyte maturation*: A group of peptides in the hypothalamus encoded by *KISS1* gene plays an important role in the reproductive pathway. Through a G protein-coupled receptor, it increases the secretion of GnRH and in turn FSH and LH. Kisspeptin-54, 54-amino acid peptide trigger, acts as a trigger for final oocyte maturation without causing OHSS or affecting implantation rates. It can also be utilized to control LH pulsatility and, thereby, secretion of sex hormones. It is still in the experimental stages and holds a high potential in prevention of OHSS.[125,126]
- *Vasopressin V1a receptor antagonist*: Relcovaptan is a vasopressin V1a receptor antagonist and blocks vasopressin-induced VEGF secretion. It alters vasoconstriction and proliferation of vascular smooth muscles.[56] During experiments, it has been found that relcovaptan decreases the number of corpora lutea, and the increase in the weight of ovaries is also less. However, further studies are required before it is brought into clinical practice.[127]

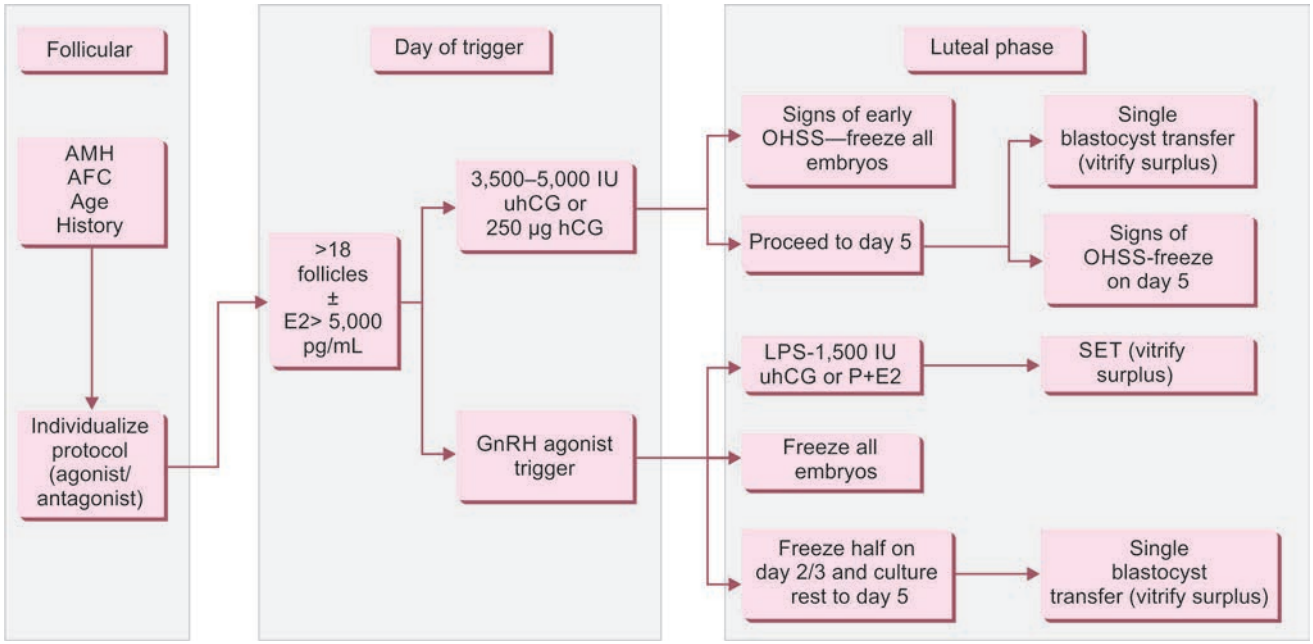
Thus, we have seen that there are many methods to prevent OHSS. The following flowchart is an example of how we can use the above-mentioned measures for the prevention and treatment of OHSS **(Flowchart 4)**.

Hence, in the present day, we should aim to achieve an "OHSS fee clinic," a concept given by Paul Devroey,[128] by incorporating a segmentation approach for IVF treatment **(Flowchart 5)**.

MANAGEMENT

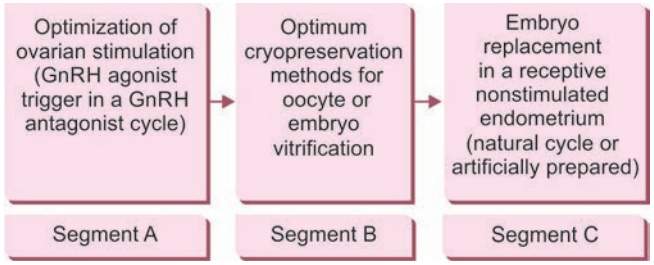
The management depends on the severity of OHSS and guides the clinician on whether it should be done on an outpatient basis or admission is required. The initial assessment[129] of the patient with suspected OHSS is done on the following basis:

Flowchart 4: Prevention and treatment of ovarian hyperstimulation syndrome (OHSS).



(AMH: anti-müllerian hormone; AFC: antral follicle count; E2: estradiol; LPS: luteal phase support; SET: single embryo transfer; uhCG: urinary human chorionic gonadotropin)

Flowchart 5: Segmentation approach for obtaining ovarian hyperstimulation syndrome-free clinic.



(GnRH: gonadotropin-releasing hormone)

- *History:*
  - Presence of high-risk factors for OHSS
  - Time of onset of symptoms from the time of trigger
  - Trigger used (hCG or GnRHa)
  - Number and size of follicles on the day of trigger
  - E2 levels
  - Fresh embryo transfer done or not
  - Presentation of the patient: Abdominal pain, discomfort, nausea, vomiting, difficulty in breathing, decreased urine output, swelling in legs or vulva, or any other co-morbidities.
- *Examination:*
  - General examination:
    - Assess for dehydration
    - Weight
    - Heart rate
    - Blood pressure
    - Respiratory rate
    - Saturation
  - Abdominal examination: Girth, ascites, any palpable mass, guarding, rigidity
  - Respiratory examination: Signs of pulmonary edema or pleural effusion
- *Investigations:*
  - Complete blood count
  - Hematocrit
  - Liver function tests
  - Renal function tests
  - Electrolytes (sodium and potassium)
  - Coagulation profile
  - Serum E2 (if required)
  - Ultrasound (ovarian size, ascites, pleural effusion; Doppler in cases of suspected torsion).

Other tests which might be indicated in critical cases are:

- C-reactive protein (CRP)
- Arterial blood gases
- D-dimers
- Electrocardiogram (ECG)/echocardiogram
- Chest X-ray.

Based on this, the severity and hence management of OHSS are decided **(Table 8)**.

Outpatient Management

Patients who are managed on an outpatient basis **(Table 9)** should be counseled in detail about symptoms such as abdominal pain, bloating, breathing difficulty, and decreased urinary output. The seriousness of the condition should be explained to the patients. Strict instructions should be given to take oral fluids abundantly as it is more

TABLE 8: Indications for outpatient and inpatient management.

Outpatient management	*Inpatient management*
• Mild ovarian hyperstimulation syndrome (OHSS) • Moderate OHSS	• Severe or critical OHSS • Worsening signs of OHSS in cases of outpatient management • Inadequate fluid intake due to nausea • Nonsatisfactory pain control • Noncompliance of the patient

TABLE 9: Management of ovarian hyperstimulation syndrome on an inpatient basis.

Medical management	*Paracentesis*	*Surgical management*
• Daily assessment of body weight, abdominal girth, input–output, full blood count, hematocrit, electrolytes, creatinine, and liver function tests • Analgesia and antiemetics (avoid nonsteroidal anti-inflammatory drugs) • Fluid replacement (mainly orally) • Intravenous crystalloids if inadequate oral intake • Intravenous colloids in cases of persistent hemoconcentration or oliguria • Diuretics only in cases of tense ascites with oliguria despite adequate hemodilution • Anticoagulants (low-molecular-weight heparin)	• Tense ascites • Oliguria • Increasing serum creatinine or falling creatinine clearance • Hemoconcentration nonresponsive to medical treatment • Need for symptomatic relief • Shortness of breath and respiratory compromise due to increased intra-abdominal pressure	• Adnexal torsion • Ovarian rupture • Ectopic pregnancy • Hemorrhage

BOX 1: Management on an outpatient basis.

Outpatient management:
- Counsel about symptoms
- Avoid intense exercises, sexual intercourse
- Fluid intake guided by thirst
- Weight, abdominal girth measurement
- Input–output chart
- *Analgesics:* Paracetamol or opioids; avoid nonsteroidal anti-inflammatory drugs
- Monitor every 2–3 days till symptoms resolve or onset of menses

BOX 2: Parameters to indicate worsening of ovarian hyperstimulation syndrome.

Clinical findings:
- Weight gain: ≥2 lbs (0.91 kg)/day for 2 days
- Heart rate: >100 beats/min
- Respiratory rate: >20 breaths/min at rest
- Oliguria: <0.5 mL/kg/h for >6 hours or a 24-hour negative fluid balance of 500 mL
- Ascites:
  - Grade 1: Visible only on ultrasound
  - Grade 2: Detectable with flank bulging or shifting dullness
  - Grade 3: Marked distension

Laboratory findings:
- Hematocrit: >45%
- Liver function tests: >2 times normal range
- Electrolytes:
  - Sodium: <132 mEq/L
  - Potassium: >5 mEq/L
- Renal function:
  - Serum creatinine increases to ≥0.3 mg/dL or increases to ≥150% above initial baseline levels

physiological. Oral fluids, especially isotonic electrolyte solutions and sports drinks, help in optimum rehydration. Patients should be instructed to keep a diary of their daily weight, abdominal girth, urine output, fluid intake, and symptoms including abdominal discomfort, shortness of breath, and gastrointestinal complaints **(Box 1)**. They should report to the hospital immediately if any of the symptoms worsen. Nonsteroidal anti-inflammatory agents (NSAIDs) can be toxic to the kidney and hence should be avoided. Instructions should be given to avoid intense physical exercises and sexual intercourse so as to prevent injury/torsion of hyperstimulated ovaries. Women managed on an outpatient basis should be reviewed urgently if they develop signs and symptoms of worsening OHSS. If the signs do not worsen, patients can be reviewed every 2–3 days till resolution of symptoms or until menstrual bleeding ensues. OHSS is usually a self-limiting condition; however, it can worsen in case pregnancy occurs. Women with moderate OHSS should be evaluated for predisposing risk factors for thrombosis and prescribed either anti-embolism stockings or low-molecular-weight heparin (LMWH).

The deterioration of the following parameters **(Box 2)** indicates the worsening of OHSS,[130] and inpatient management may be indicated:

Baseline laboratory investigations should be repeated if severity of OHSS is thought to be worsening. Hematocrit is a useful guide to the degree of intravascular volume depletion.

Inpatient Management

Women admitted with OHSS should be assessed at least once daily. Assessment should be done more frequently for those with critical OHSS and with complications.

Severe and critical OHSS should be managed on an inpatient basis and may also require admission to the intensive care unit. It is usually managed medically, but surgical intervention in the form of paracentesis, laparoscopy, or laparotomy **(Table 9)** might be required. A multidisciplinary approach should be used for the management of critical OHSS.

Strict monitoring of inpatients should be done. Body weight, abdominal girth, input–output, complete blood count with hematocrit, electrolytes, and liver and renal function tests should be monitored on a daily basis. CRP also helps in monitoring severity.[131] As OHSS resolves, diuresis ensues along with reduction in hematocrit, abdominal girth, and body weight.[65,132] Supportive treatment should be given in the form of analgesics and antiemetics for the relief of pain and nausea. NSAIDs should be avoided because of their toxic effects on the kidneys. Intravenous fluid therapy forms an important part of treatment when oral fluid intake is inadequate or if the patient is unable to take it orally because of severe nausea. Isotonic crystalloids should be given though they might not restore the balance because of increased capillary permeability and massive protein loss. Intravenous colloids are given if there is markedly decreased urine output or persistent hemoconcentration.

If oliguria persists despite adequate fluid replacement and drainage of ascites, diuretics can be used but with caution. Intravenous furosemide is given in a dose of 10–20 mg when adequate fluid replacement has been done, but still the urine output is markedly decreased.

Ovarian hyperstimulation syndrome is a hypercoagulable state, and anticoagulation therapy should be instituted prophylactically in the form of LMWH. The dose and duration of LMWH are given depending on the patient's risk factors.

Tense ascites with oliguria, respiratory compromise, or deteriorating renal function require paracentesis. It is tapping of the ascetic fluid and should be done under ultrasound guidance using all aseptic precautions. It can be done transabdominally or transvaginally. Up to 4 L of fluid can be drained by gravity or by using negative pressure.[133] Paracentesis should not be done in the presence of hemoperitoneum or if the patient is not stable hemodynamically. Another novel technique under research for the management of severe OHSS is perito-neovenous shunting.[134]

The chances of ovarian torsion or rupture are increased in OHSS. Usually, laparoscopy is employed for untwisting of ovaries in case of torsion. Ectopic pregnancy should always be kept as a differential diagnosis in cases of severe pain and if fresh embryo transfer has been done.[135] Rarely, late-onset critical OHSS might require termination of pregnancy.[135] In addition to the usual symptoms and signs of venous thromboembolism (VTE), thromboembolism should be suspected in women with OHSS who present with unusual neurological symptoms, even if they appear several weeks after improvement of OHSS. Clinicians should be aware and the patients be informed that pregnancies complicated by OHSS might be at an increased risk of preterm delivery and preeclampsia.

CONCLUSION

Ovarian hyperstimulation syndrome is a threat to every patient undergoing ovulation induction. It is important to understand the pathophysiology of OHSS and take appropriate measures for its prevention. All efforts should be made to make ART clinics OHSS-free clinics and prevent the fatal complications of this iatrogenic condition.

KEY POINTS

- OHSS is a threat to every patient undergoing ovulation induction.
- It is life threatening in its severe form resulting in hospitalization in 1.9% cases.
- It has been classified in various ways but the most commonly being practiced is the RCOG classification classifying it into mild, moderate, severe, and critical. It is also classified on the basis of onset, whether early or late onset.
- It is important to understand the pathophysiology of OHSS and take appropriate measures for its prevention. The most important factors implicated in its pathogenesis are hCG, VEGF, renin–angiotensin system, and certain immune factors.
- The primary risk factors include young, thin women with high basal AMH and AFC, having PCOS with history of OHSS.
- Prevention should be at both primary and secondary levels. Primary prevention involves using iCOS and GnRH antagonist protocol and avoiding GnRHa trigger.
- The most important secondary preventive measure is segmentation of the cycle with cryopreservation of embryos.
- The clinical features of OHSS should be recognized as early as possible and appropriately managed.
- All efforts should be made to make ART clinics OHSS-free clinics and prevent the fatal complications of this iatrogenic condition.

CHAPTER 67

Ectopic Pregnancy

Rishma Dhillon Pai, Hrishikesh Pai, Nidhi Shah Gandhi, Navina Singh

INTRODUCTION

For pregnancy to occur, the egg has to enter the fallopian tube, where it survives for 24 hours. If it gets fertilized with a sperm, the embryo stays in the fallopian tube for 3 days or 4 days before it reaches the uterus. There it attaches to the endometrium and continues to grow until a baby is born.

DEFINITION

An ectopic pregnancy (EP) occurs when the embryo is implanted anywhere other than the cavity of the uterus. It could get implanted within the fallopian tube, ovary, abdomen, etc.

HETEROTOPIC PREGNANCY

A heterotopic pregnancy is a combination of two pregnancies occurring simultaneously at two different implantation sites. The most frequent combination is an intrauterine and an extrauterine pregnancy. The most common extrauterine site is the fallopian tube (90%); however, an EP can also be seen in the cervix, ovary, abdomen, or even a previous cesarean scar.

HISTORY OF ECTOPIC PREGNANCY

Abulcasis was the first to describe an EP as early as the 10th century AD. The first known surgical procedure for EP was performed in France in 1714. In the late 19th century, Robert Lawson Tait, a British surgeon performed laparotomy and salpingectomy for ruptured tubal EP. The first ever in vitro fertilization (IVF) conception was also known to be an EP.

INCIDENCE

Among the general population, EP is known to occur in 19/1,000 pregnancies. The incidence is higher—4% in women undergoing assisted reproductive techniques for conception.

Ectopic pregnancy is considered the number one cause for maternal deaths during the first trimester of pregnancy, accounting for approximately 10% of the total deaths.[1]

COMMON SITES FOR ECTOPIC PREGNANCY

Approximately 93–97% of all ectopic pregnancies occur within the fallopian tube.[2] The other lesser frequently involved sites include the ovary, cervix, abdomen, and a previous cesarean scar **(Table 1)**.

RISK FACTORS

The blastocyst travels along the fallopian tube as a result of smooth muscle contractions and ciliary beating.[3]

Any condition that interferes with this tubal transport mechanism or damages the tubes may predispose to EP.[4-6]

Abnormality of the tubes can occur as a result of any of the following:

- Pelvic inflammatory disease (PID)
- History of a previous EP
- Infertility ≥2 years
- Pelvic/abdominal surgery resulting in adhesions and interference with the normal anatomical structure
- Endometriosis
- Sexually transmitted infections such as *Chlamydia* and gonorrhea
- Previously failed tubal surgery such as tubal sterilization or a tubal ligation reversal procedure.

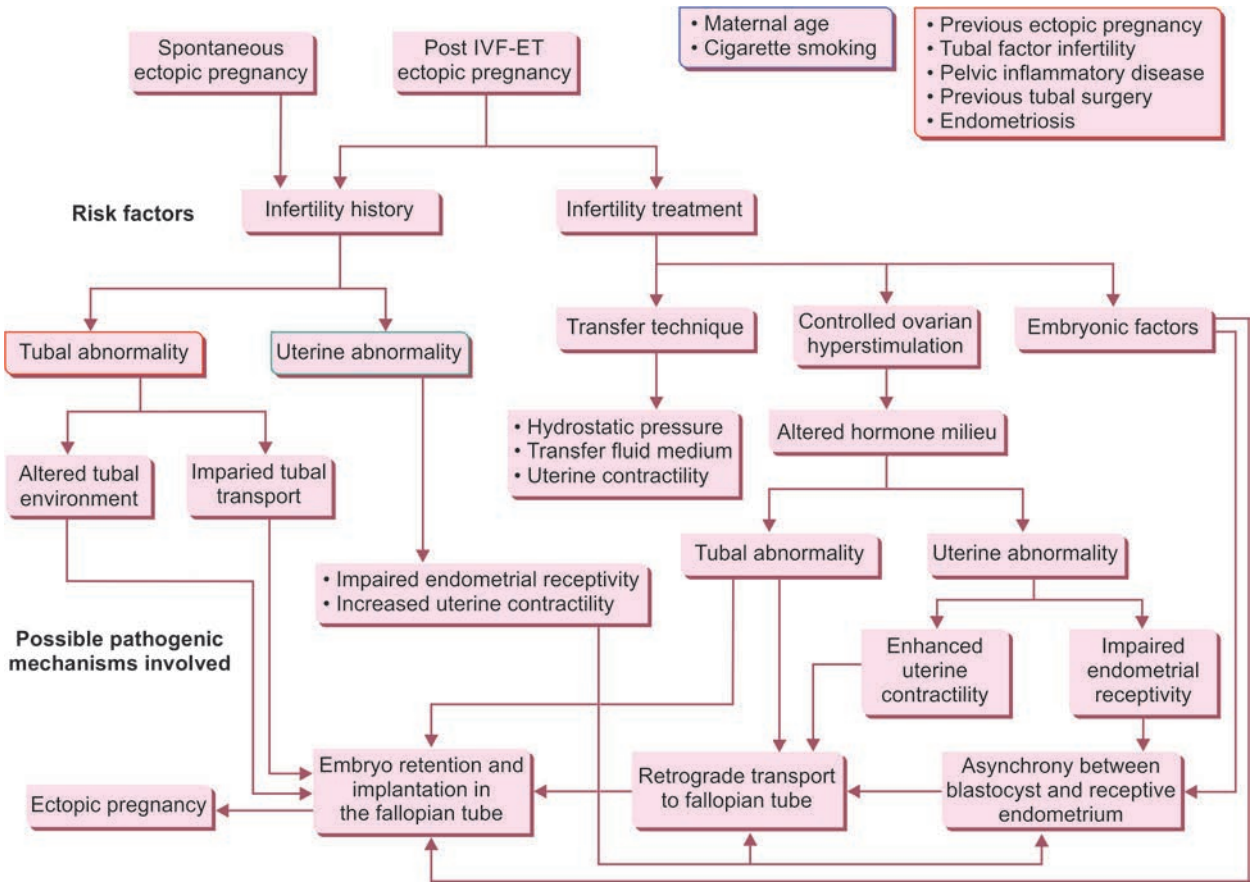
Relative risk (RR) factors **(Flowchart 1)** include the following:

- Cigarette smoking increases the risk by twofold.
- Increased maternal age.

TABLE 1: Common sites for ectopic pregnancy.

Fallopian tubes	93%
Ampulla	70%
Isthmus	12%
Fimbria	11%
Ovarian	3.2%
Cornual/interstitial	2.4%
Abdominal	1.3%
Cervical	<1%

Flowchart 1: Risk factors for an ectopic pregnancy.



(ET: embryo transfer; IVF: in vitro fertilization)

- Multiple sexual partners probably due to increased risk of exposure to sexually transmitted diseases (STDs).
- Intrauterine exposure to diethylstilbestrol increases the risk by twofold.
- Pregnancy with an intrauterine device (IUD) in situ.
- IVF/assisted reproductive technology (ART) increases the risk by twofold.

CLINICAL FEATURES

Ectopic pregnancy can manifest differently in different individuals. Patients may be symptom-free or may present with more than or equal to one of the following symptoms:

- *Amenorrhea*—generally of 5–6 weeks
- *Abnormal vaginal bleeding:* Any bleeding that manifests at times other than your normal menstrual period is called abnormal vaginal bleeding. It could be either scanty in the form of spotting or heavy with passage of clots/tissues.
- *Lower abdominal pain:* It may be unilateral/bilateral. The pain may arise acutely as a sudden sharp ache or it may occur gradually over several days. The pain generally does not respond to painkillers and is not relieved on rest.
- *Shoulder pain if it is a ruptured tubal pregnancy*. Accumulated blood within the peritoneal cavity irritates the diaphragm and causes shoulder ache.
- *Weakness, lightheadedness, or syncope* because of sudden, excessive blood loss from a ruptured EP.

Currently, we seldom come across such advanced cases with vast majority of women presenting with either low-grade pain or vaginal spotting, and fortunately, they are promptly identified using highly sensitive and specific methods available.

DIAGNOSIS

History

When a woman of the reproductive age presents with the classical triad of amenorrhea, abnormal vaginal bleeding, and abdominal pain, one should think "ectopic."

Hence, the clinician should carefully evaluate the period of amenorrhea/gestational age, the onset, and severity of the symptoms.

The clinician must try to look for any possible risk factors for an EP.

Note: The woman may be unaware of her pregnancy. Hence, any fertile woman presenting with pelvic pain or abnormal

vaginal bleeding should undergo a pregnancy test as part of the initial evaluation.

Physical and Pelvic Examination

On General Examination

Look for pulse rate and volume, blood pressure, pallor, and peritoneal signs, such as guarding, rigidity, and rebound tenderness which indicate the possibility of hemoperitoneum.

On Pelvic Examination

Per speculum examination: This is done to visualize the cervix and look for positive signs of pregnancy. Rule out a local cause for the abnormal bleeding.

Bleeding arising from the cervical os with visualization of the gestational products in the vagina will confirm the diagnosis of spontaneous abortion and rule out an EP.

Per vaginal examination: This is done to assess the uterine size, feel for an adnexal mass and look for cervical motion tenderness.

Urine Pregnancy Test

This test is done to confirm the pregnancy.

Biochemical Investigations

β-human Chorionic Gonadotropin

β-human chorionic gonadotropin (β-hCG) is secreted by the syncytiotrophoblast and becomes detectable in maternal serum as early as 8–10 days postovulation in normal conception cycles.

Modern assays for the β-subunit of hCG are highly sensitive and specific, with detection limits below 5 IU/L.

Serial β-hCG levels: Serum β-hCG concentrations rise predictably, at an exponential pace, during the early weeks of normal intrauterine pregnancy. After 7 weeks, the titer doubles every 3.5 days and the β-hCG levels peak between 50,000 and 100,000 IU/L at 8–10 weeks of gestation.[2]

Compared to the pattern observed in women with viable intrauterine pregnancies, serum β-hCG levels increase at a slower rate in most of the women with an ectopic or nonviable intrauterine pregnancy.

β-hCG discriminatory level: It is the value (1,500 IU/L) beyond which an intrauterine pregnancy should be visualized on transvaginal ultrasonography. Failure to do so is highly suggestive of an EP.

Combined use of history, clinical symptoms, and early first quantitative hCG drawn approximately 15 days after oocyte retrieval is an effective means to predict EP after IVF.[7]

There is a misconception that EP is unlikely in cases with serum β-hCG levels >1,000 IU/L.

Meta-analysis indicates that an isolated titer of serum β-hCG cannot predict an EP.[8]

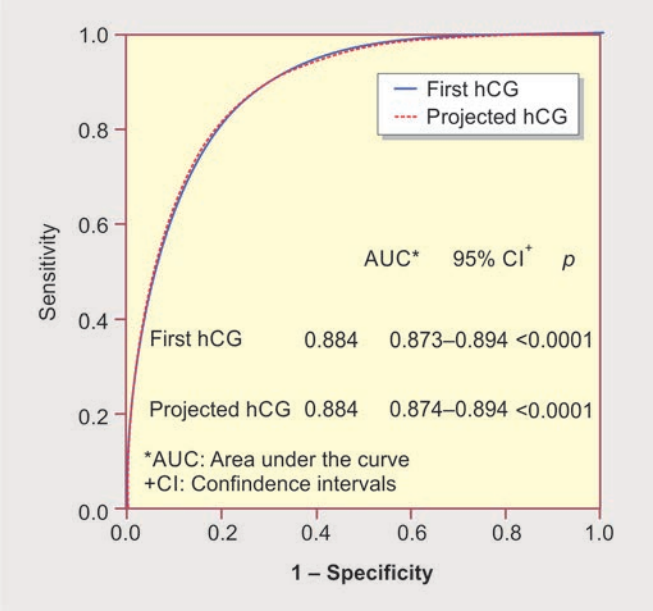


Fig. 1: Receiver operating characteristic (ROC) curves of first and projected human chorionic gonadotropin (hCG) levels to predict ectopic pregnancy.

Serum β-hCG levels are used in the management of an EP.

The key prognostic indicator for successful conservative management of ultrasound-visualized tubal ectopic pregnancies is initial serum β-hCG levels.

The receiver operating characteristic (ROC) curves of first and projected hCG levels to predict EP have been shown in **Figure 1**.

Serum Progesterone Levels

Serum progesterone levels are not useful (grade C evidence) in predicting ectopic pregnancies.

Different biomarkers for determination of tubal EP are enlisted in **Table 2**.

Blood Group and Rhesus Typing

Blood grouping with rhesus (Rh) typing should be done on all women with suspected EP. As per the Royal College of Obstetricians and Gynecologists (RCOG) guidelines 2016, anti-D prophylaxis should be offered to all RhD-negative women with the following:

- Has undergone surgical removal
- Has recurrent, heavy bleeding
- Has pain in lower abdomen to protect them against the development of Rh alloimmunization.

Imaging Techniques

Transvaginal sonography is the primary diagnostic tool in patients suspected of having an EP. It is superior to the abdominal route because of its close proximity to the adnexa allowing direct visualization of an ectopic mass.[9]

TABLE 2: Biomarkers of tubal ectopic pregnancy.

Related to embryo			*Related to implantation milieu*	
Abnormal trophoblast function	***Abnormal corpus luteal function***	***Angiogenesis***	***Normal uterine implantation***	***Abnormal tubal implantation***
• β-hCG • Hyperglycosylated hCG • Activin • Follistatin • PAPP-A • Pregnancy specific β-glycoprotein-1 • Human placental lactogen • Disintegrin and metalloproteinase-12 • Placental micro-RNA • AFP • Cell-free fetal DNA	• Progesterone • Estradiol • Inhibin A • Relaxin and rennin	• VEGF • Placental-like growth factor • Angiopoietins	• Leukemia inhibitory factor • Glycodelin • Mucin-1 • Adrenomedullin • Activin B	• Markers of compromised tubal musculature—creatine kinase, smooth muscle heavy chain myosin, and myoglobin • Markers of inflammation and peritoneal irritation—cytokines, CA-125, and antibodies to C1q

(AFP: alpha-fetoprotein; hCG: human chorionic gonadotropin; CA: cancer antigen; DNA: deoxyribonucleic acid; PAPP-A: pregnancy-associated plasma protein A; RNA: ribonucleic acid; VEGF: vascular endothelial growth factor)

By 5.5–6 gestational weeks, an intrauterine pregnancy is generally seen in the form of a gestational sac with a yolk sac ± fetal pole ± cardiac activity.[10] Visualizing these structures inside the uterine cavity effectively rules out an EP since we know that only about 1 in every 4,000 spontaneous conceptions results in a heterotopic pregnancy.[11]

The "intradecidual sac sign" is a useful feature in identifying an early intrauterine pregnancy as early as 25 days of gestation. As per this sign, the site of implantation is seen as a collection of fluid or as an echogenic area in an excessively thickened decidua on one side of the uterine cavity.

The "double decidual sac sign" is another useful finding to confirm an early intrauterine pregnancy. It involves the decidua parietalis and the decidua capsularis and is seen as two concentric rings surrounding an anechoic gestational sac.

A tiny collection of anechoic fluid in the cul-de-sac is seen in both intrauterine and EP.

TUBAL PREGNANCY

A transvaginal sonography showing an adnexal mass that moves separately from the ovary along with an empty uterine cavity is highly suggestive of an EP with a sensitivity of 87–99% and a specificity of 94–99%.

The initial sonographic findings may be as follows:

- 50–60% of patients present with a nonhomogeneous/noncystic adnexal mass.
- 20–40% of patients present with an empty gestational sac.
- 15–20% of patients show an extrauterine gestational sac + yolk sac ± fetal pole ± cardiac activity.
- 10% of patients may present with a "pseudosac"—blood collected within the uterine cavity and may be erroneously diagnosed as having a small intrauterine gestational sac.
- 28–56% of patients present with free fluid in the pelvis secondary to tubal rupture with leakage from the fimbrial end of the fallopian tube.

Fig. 2: Ring of fire appearance of tubal ectopic pregnancy in color Doppler view.

The color and pulsed Doppler sonography can improve the diagnostic accuracy as follows:

- The blood flow in the arteries of the fallopian tube harboring the EP is 20–40% greater than that seen in the contralateral tube.
- Similarly, the adnexa will show numerous tiny vessels with increased velocity and low impedance signals. This is known as ring of fire appearance as depicted in **Figure 2**.
- Visualizing the ipsilateral corpus luteum blood flow is an important diagnostic feature of tubal pregnancy.[12]

Note: Some pregnancies are too early to be visualized on initial scans and are termed "pregnancy of unknown location (PUL)."

NONTUBAL ECTOPIC PREGNANCY

Cervical Pregnancy

Cervical pregnancy is rare and seen in <1% of all ectopic pregnancies.

Rubin's ultrasonographic criteria for the diagnosis of cervical pregnancy include:

1. The presence of cervical glands opposite to the site of attachment of the placenta.
2. The placenta and the cervix should be intimately attached with each other.
3. The placenta should be implanted below the level of peritoneal reflection on the uterine surfaces.
4. The uterine cavity should be devoid of any fetal elements.

Other ultrasonography features consist of:

- An empty uterus.
- Presence of a barrel-shaped cervix.
- A gestational sac presents below the level of the internal os of the cervix.
- Absent "sliding sign." When the gestational sac slides over the endocervical canal on applying pressure on the cervix, the diagnosis goes in favor of an ongoing miscarriage rather than a cervical pregnancy.
- Doppler studies to analyze the blood flow around gestational sac.

In the 20th century, Paalman and McElin proposed additional *clinical criteria* for the diagnosis of cervical pregnancy. They believed that one should think of an EP in cases of:

- Painless uterine bleeding following a period of amenorrhea.
- A soft and enlarged cervix equal to or bigger than the size of a uterine fundus.
- Endocervical confinement and attachment of the gestational products.
- A closed internal cervical os with a partially open external cervical os.

CESAREAN SCAR PREGNANCY

Cesarean scar pregnancy is defined as the implantation of the products of conception in a myometrial defect seen at the level of a previous uterine incision.

It is seen in 1 in 2,000 pregnancies and can present in the form of a potentially ongoing viable pregnancy or as a miscarriage within the scar.

However, its true prevalence is much higher than estimated as some cases are misdiagnosed as cervical pregnancies or end as miscarriages and thus go unreported.

There are two types of cesarean scar pregnancies. In the first type, the products of conception grow into the uterine cavity and can reach a viable age. However, the implantation site may bleed heavily. In the second type, the pregnancy grows toward the serosal surface. This can result in an early uterine rupture with massive hemorrhage.[13]

A transvaginal sonography along with a transabdominal approach is the first choice of diagnosis. Magnetic resonance imaging (MRI) may be helpful in equivocal cases.

Jurkovic's diagnostic criteria on transvaginal ultrasound include:

- An empty uterus and endocervical canal
- Gestational sac lies anteriorly at the level of the internal os
- The presence of a thin layer/absence of myometrium between the gestational sac and the bladder
- Evidence of placental/trophoblastic circulation on color and pulsed Doppler.

There is no role in measuring serum β-hCG level in diagnosing a cesarean scar pregnancy.

INTERSTITIAL PREGNANCY

In interstitial pregnancy, the products of conception implant within the interstitial part of the fallopian tube. It occurs in 1–6.3% of all ectopic pregnancies and has an increased risk of rupture resulting in hemorrhagic shock and maternal death. This is due to the high vascularity seen in this area.

The following *ultrasonographic criteria* may be used for the diagnosis of interstitial pregnancy:

- An empty uterus
- The gestational sac is located laterally within the intramural portion of the tube and is surrounded by <5 mm of myometrial thickness in all imaging planes.
- The presence of the "interstitial line sign"—it is a thin echogenic line that extends from the uterine cavity echo in the center to the periphery of the interstitial sac.

Three-dimensional (3D) ultrasonography can be used to differentiate a pregnancy implanted into the lateral angles of the uterus from an interstitial pregnancy. In a 3D coronal view, we can see the connection between the endometrial cavity and the interstitial part of the tube. These findings can be corroborated with those of an MRI.

On MRI, the cornu lies medial to the gestational sac, which is surrounded by myometrium. The diagnosis is confirmed by visualizing an intact endomyometrial junction between the uterine cavity and the gestational sac.

Two β-hCG levels, 48 hours apart, are useful in the decision of management.

CORNUAL PREGNANCY

Cornual pregnancy is an extremely rare type seen in 1/76,000 pregnancies.

The *ultrasonographic criteria* for the diagnosis of a cornual pregnancy are as follows:

- A single interstitial portion of the fallopian tube is seen within the uterine body.
- The visualization of a gestational sac surrounded on all sides by the myometrium and seen separated from the uterus.
- Doppler studies show that the gestational sac is joined to the unicornuate uterus by a vascular pedicle.

Serial serum β-hCG levels are useful for further management.

OVARIAN PREGNANCY

Ovarian pregnancy is seen in 3% of patients presenting with an ectopic.

Spiegelberg's ultrasonographic criteria for its diagnosis are as follows:

- The gestational sac is seen and lies within the ovary.
- The ovarian ligament connects the gestational sac to the uterus.
- Histopathologic evidence of ovarian tissue from the products retrieved
- The ovary along with the gestational sac is seen separate from the ipsilateral tube.

  Note: A corpus luteum and an ovarian pregnancy can be mistaken for each other and should always be differentiated.
- Color Doppler will confirm the presence of a fetal heartbeat within the ovary.

Negative sliding organ sign—the pregnancy cannot be felt separately from the ovary on deep palpation.

Any complex adnexal mass with free fluid in the pelvis—suspect a ruptured ovarian pregnancy.

Diagnosis is generally confirmed at surgery and made histologically as ovarian pregnancies are difficult to differentiate from hemorrhagic corpus luteal cysts, germ-cell tumors, and other ovarian pathologies.

Serial serum β-hCG levels are used for further management.

ABDOMINAL PREGNANCY

Abdominal pregnancy is the implantation of the products of conception in the peritoneal cavity, excluding the tubes, ovaries, or intraligamentary structures.

Implantation may occur anywhere within the omentum, pelvic sidewalls, broad ligament, pouch of Douglas, liver, spleen, bowel, diaphragm, and uterine serosa.

It is a rare obstetric complication seen in 1/10,000 pregnancies with a high maternal and perinatal mortality.

There are two types of abdominal pregnancies:

1. The primary type where the pregnancy is implanted in the peritoneal cavity from the beginning
2. The secondary type is more common. Here, the pregnancy continues its development within the abdominal cavity after expulsion from its primary organ of implantation.

Studdiford criteria for the diagnosis of primary peritoneal pregnancies are as follows:

- Both the fallopian tubes and ovaries are normal with no history of a recent/past pregnancy.
- The absence of a uteroperitoneal fistula.
- Visualization of a pregnancy attached exclusively to the peritoneal surface with elimination of a secondary implantation following a primary implantation elsewhere.

Another classification important from the point of view of management is early peritoneal pregnancy when the products of conception are ≤20 weeks and an advanced abdominal pregnancy for ≥20 weeks.

The *ultrasonographic criteria* by Gerli et al.[14] for diagnosing an early abdominal pregnancy are:

- An empty uterine cavity.
- The absence of a complex adnexal mass and a dilated fallopian tube.
- The presence of a gestational sac surrounded by bowel loops but separated by peritoneum.
- A wide range of mobility that occurs as a result of pressure with a probe toward the pouch of Douglas similar to that of a fluctuating sac.

Diagnosis is at laparoscopy performed for persistently raised serum β-hCG levels.

Advanced abdominal pregnancies account for 1 in 25,000 pregnancies. It is a life-threatening condition with risk of massive hemorrhage leading to shock and very poor fetal outcome.

Prompt management with preoperative arterial embolization along with methotrexate (MTX) administration will minimize the volume of blood lost during surgery and aid in the maximal removal of placental tissue.

Magnetic resonance imaging is useful in confirming the diagnosis and identifying the sites of placental attachment.

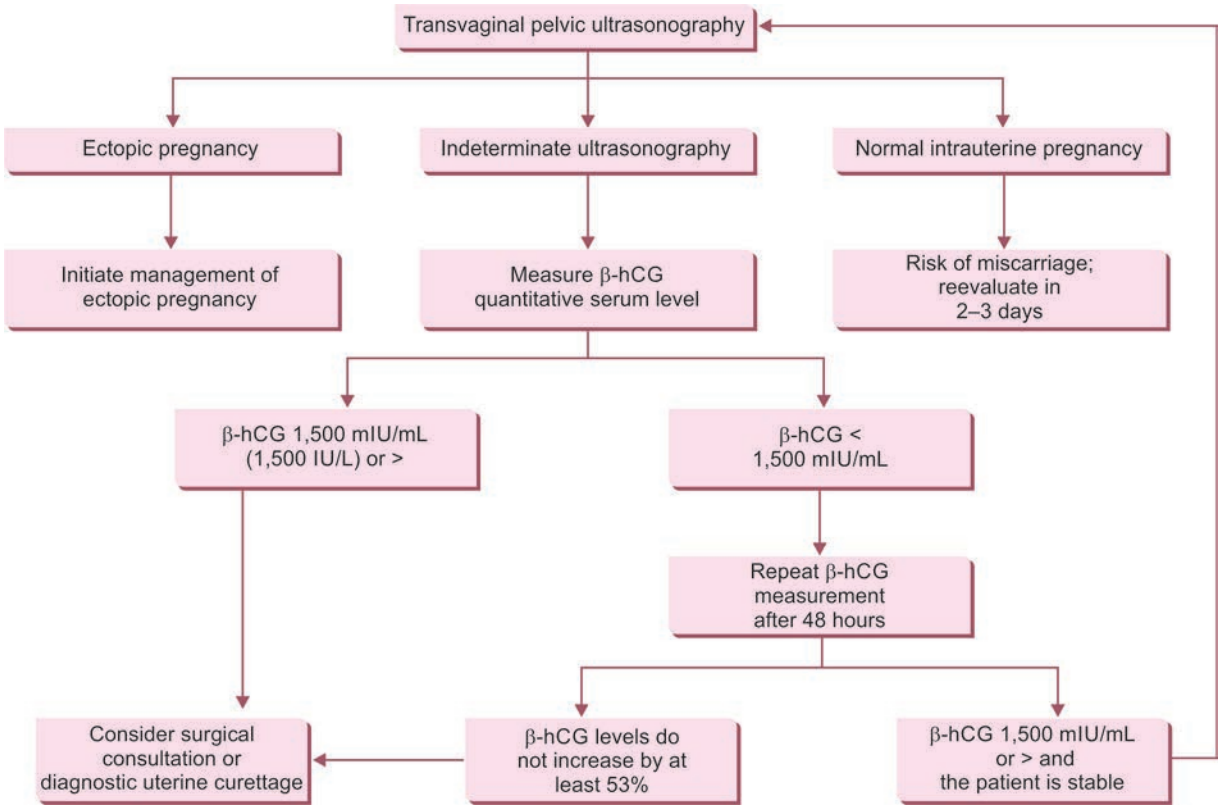
HETEROTOPIC PREGNANCY

The incidence of heterotopic pregnancy is increased substantially due to increasing use of exogenous gonadotropins and artificial reproductive techniques. It is seen in 1/3,900 pregnancies.

Heterotopic pregnancies are often missed initially because both the serum β-hCG and ultrasonography can be misleading.

The clinician should suspect a heterotopic pregnancy when a patient complains of persistent pelvic pain along with an intrauterine pregnancy and when a woman presents with persistent high levels of serum β-hCG following a miscarriage or a medical termination of pregnancy **(Flowchart 2)**.

Flowchart 2: Representing initial diagnostic intervention.



(hCG: human chorionic gonadotropin)

An ultrasound showing a coexisting intrauterine and extrauterine pregnancy confirms the diagnosis.

Differential diagnosis with partial or complete mole should be made.

LAPAROSCOPY

The pregnancy should be located within 7–10 days with the help of blood tests and ultrasonographies provided there is no major risk to the patient.

A diagnostic laparoscopy should be considered if there is uncertainty in the diagnosis.

However, in a woman with a previous history of an ectopic or in the presence of other high-risk factors, a diagnostic laparoscopy may be considered earlier. During laparoscopy, tubal ectopic is seen as dilated bluish discoloration with hemoperitoneum as shown in **Figure 3**.

Earlier, laparoscopy was the gold standard for the diagnosis of an EP, but as high as 3–4.5% of cases of false-negative laparoscopies were reported when they were performed too early.

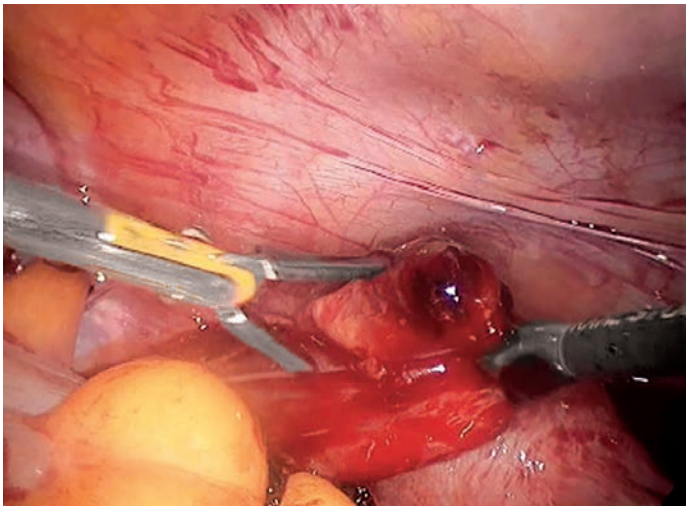


Fig. 3: Tubal ectopic pregnancy during laparoscopy.

PRIMORDIAL AND PRIMARY PREVENTION OF ECTOPIC PREGNANCY DURING IN VITRO FERTILIZATION

The lowest risk of EP is associated with a single blastocyst transfer in a frozen embryo transfer cycle. This approach leads to better perinatal outcomes and overall increase in pregnancy and birth outcomes.[15]

Approximately 2–5% of all clinical pregnancies following an IVF–embryo transfer are ectopic in nature.

Following IVF, tubal pregnancies occur as a result of:

- Injecting the transfer medium directly into the fallopian tubes
- Reflux expulsion of the embryos into the tubes secondary to uterine contractions

The junctional activity of the uterine musculature, especially that of stratum subvasculare, decreases with increasing time interval from oocyte retrieval. Thus, there is a lower risk of EP with day 3 transfer as opposed to day 2 transfer secondary to reduced uterine contractions toward the luteal phase.[16]

The incidence of EP is lower following blastocyst transfer as opposed to cleavage stage transfer due to the following:

- Reduced retrograde uterine contractions from the cervix to the fundus on day 7 following an hCG injection as compared to the first 4 days.
- A bigger diameter and integrin expression resulting in the resting stage of the blastocyst.

MANAGEMENT OF TUBAL PREGNANCY (FLOWCHARTS 3 TO 5)

Expectant Management

Expectant management is defined as watchful waiting or close monitoring of the clinical symptoms, the serum β-hCG levels, and transvaginal sonographies instead of any immediate intervention.

Indications of expectant management:

- Low (1,500 IU/L) or decreasing serum β-hCG levels
- Clinically and hemodynamically stable women
- Patient has minimal pain.
- An ultrasonography showing a small, unruptured, nonviable (absent heartbeat) EP.

When opting for expectant management, the patient should be counseled about the need for continuous, close monitoring and the possibility of tubal rupture.

Serial β-hCG levels, initially every 48 hours until the blood levels begin to drop and then weekly thereafter, should be checked until the levels become normal (<5 IU/L).

Immediate termination of expectant management—if the patient complains of increasing abdominal pain or if there is an increase in the serum β-hCG levels.

Approximately 25% of women initially managed expectantly go on to need medical or surgical treatment.

Medical Management

Before the 1980s, the management of EP was only surgical. Evolving knowledge and experience with MTX has revolutionized the treatment of ectopic pregnancies.

The advantages of medical management over surgical management are:

- It eliminates the morbidity arising out of anesthesia and surgery.
- Comparatively, there is lesser tubal damage.
- It is more cost-effective.

Methotrexate is a folate antagonist that causes acute deficiency of a folate coenzyme, tetrahydrofolate, essential for the synthesis of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) in rapidly multiplying cells.

Methotrexate is structurally similar to norethindrone with five times higher affinity for the progesterone receptors.

It competitively binds to the progesterone receptors in the decidua and results in degeneration of villi tissue, atrophy, and necrosis of decidual tissue, eventually leading to embryo death.[19, 20]

It selectively kills the cytotrophoblasts, which are then gradually reabsorbed by the body leaving an intact fallopian tube.

As per the National Institute for Health and Care Excellence (NICE) guidelines, MTX should be the first-line management if the following criteria are fulfilled:

- A hemodynamically stable patient with no evidence of rupture
- A serum β-hCG level between 1,500 and 5,000 IU/L
- Minimal pain
- No visible intrauterine pregnancy on sonography
- Ultrasound showing absent fetal cardiac activity
- An adnexal mass <3.5 cm size
- Hemoperitoneum <100 mL
- Women should be capable and willing for regular follow-ups.

The mean resolution time is 32 days following a single dose and 58 days following repeated doses of MTX.

Mechanism of Action

Methotrexate acts as an antifolic acid.

Dosage

Single-dose regimen: Administer a single dose of MTX intramuscularly, 1.0 mg/kg or 50 mg/m^2 on day 1 and follow it with serum β-hCG level measurements on days 4 and 7. If the serum β-hCG level drops by >15%, then repeat β-hCG levels every week until it reaches the normal range (<5 IU/L).

If the level does not drop by 15%, then a repeat ultrasonography should be done to rule out the presence of an ectopic fetal heartbeat and significant hemoperitoneum.

A second dose of intramuscular MTX 50 mg/m^2 can be given in such cases.

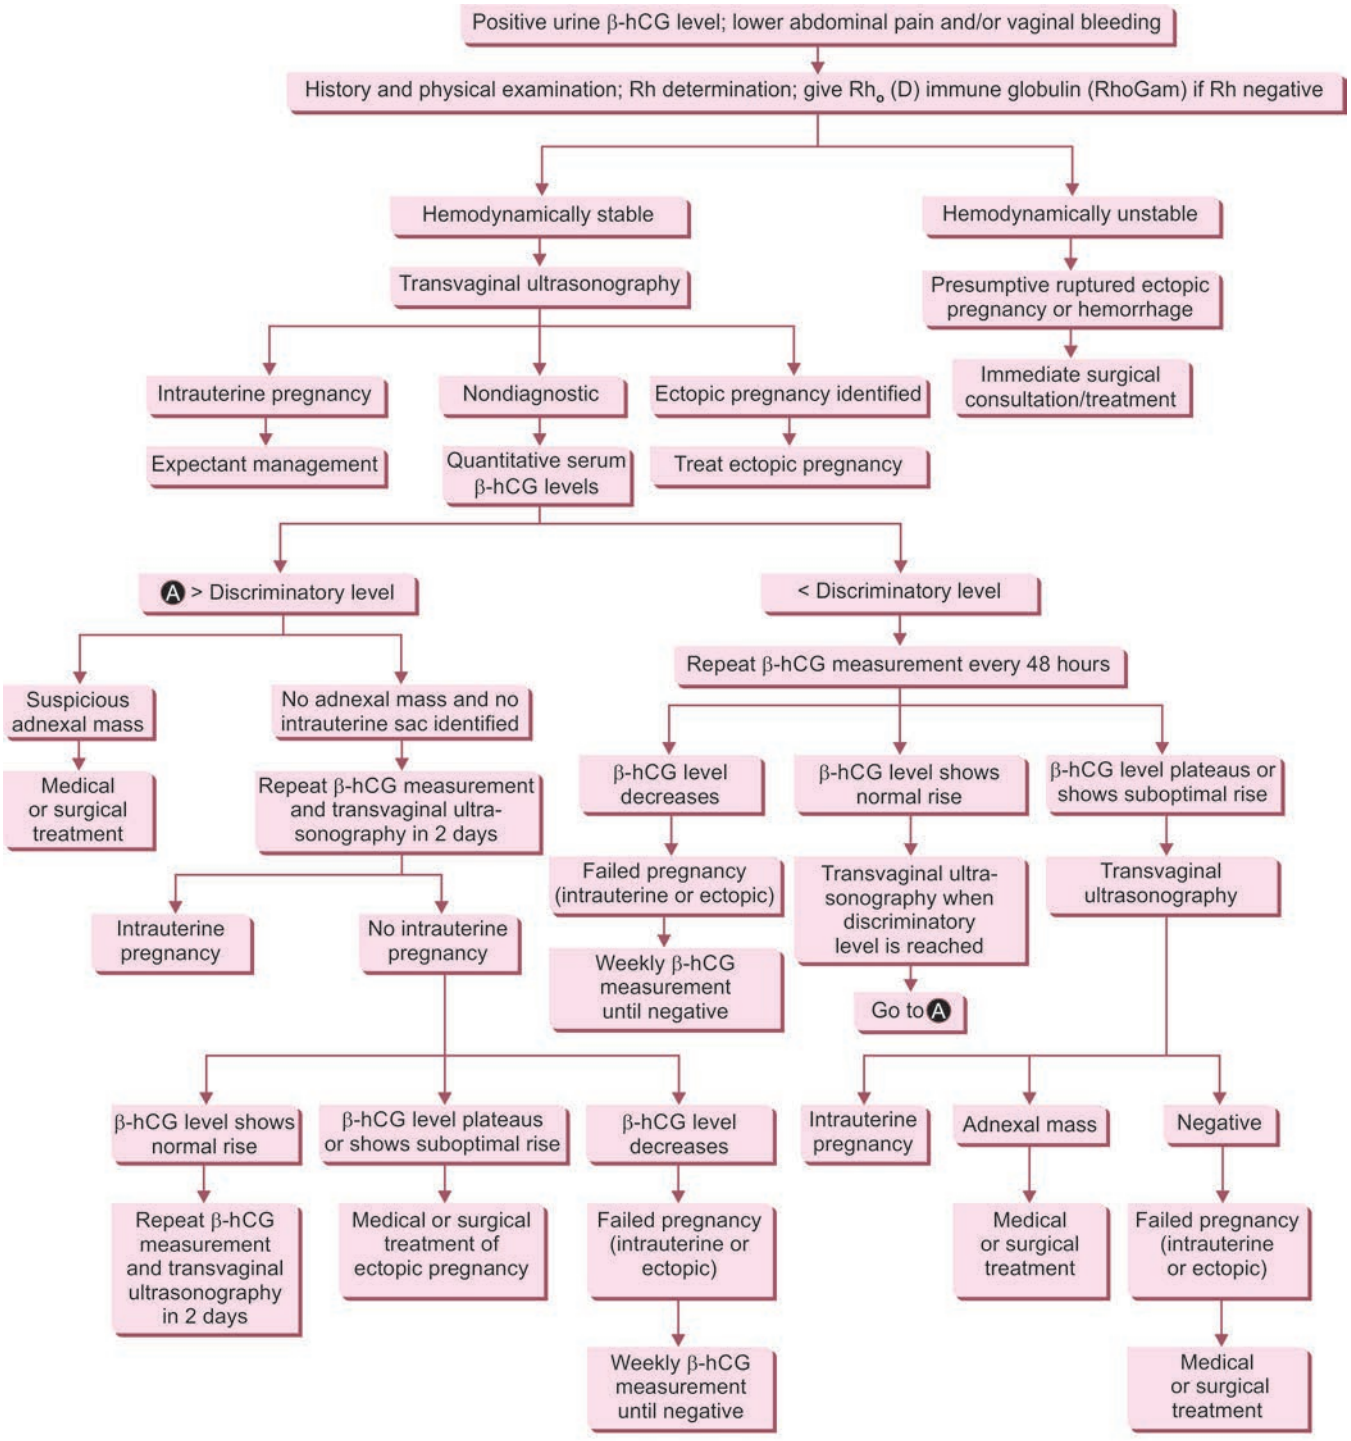
The success rate of a single dose of MTX ranges from 65 to 95%, with 3–27% of women requiring a second dose.[21]

Multiple-dose regimen: MTX 1.0 mg/kg intramuscularly on 0, 2, 4, and 6 days alternated with folinic acid 0.1 mg/kg orally on days 1, 3, 5, and 7.

If the serum β-hCG level drops by >15% on 2nd day, measure β-hCG levels weekly until it reaches <5 IU/L.

If the level does not reduce by 15%, repeat intramuscular MTX 1 mg/kg on day 2 and leucovorin (folinic acid) 0.1 mg/kg orally on day 3.

Flowchart 3: Algorithm for the management of a suspected ectopic pregnancy.[1,17,18]



(hCG: human chorionic gonadotropin; Rh: rhesus)

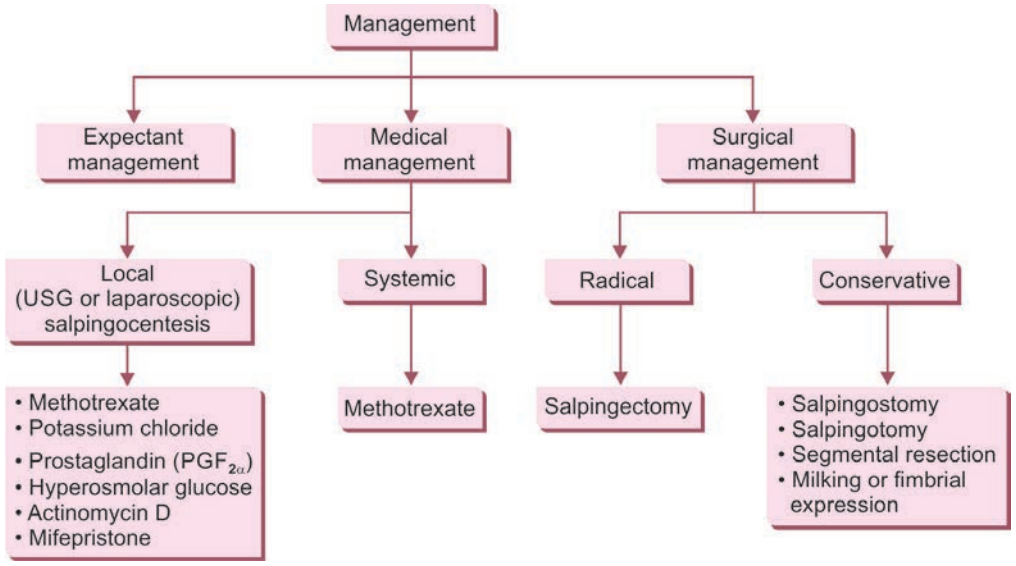
Women presenting with pain following MTX administration should be thoroughly evaluated before assuming the treatment has failed and rushing into surgical intervention.

Regardless of the regimen selected pretreatment evaluation consisting of complete blood count, kidney, and liver function tests, and blood grouping with Rh factor typing should be done in all patients on day 1 prior to MTX administration.

Adverse Effects

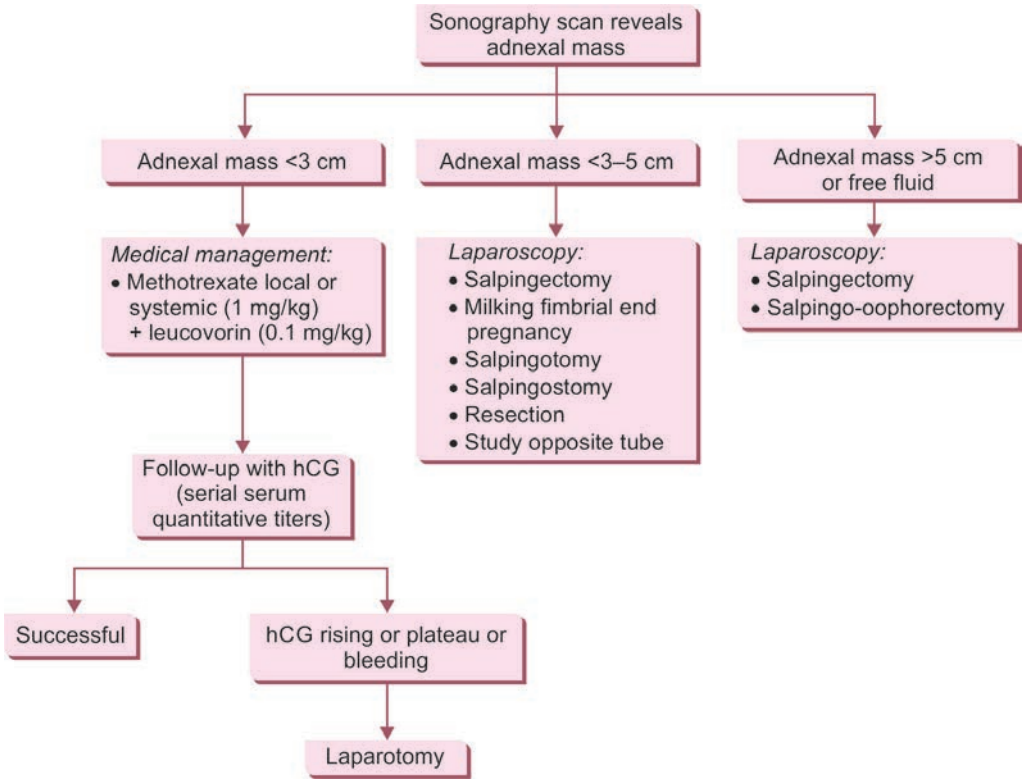
- Side effects of MTX are relatively common but usually minor and transient; their prevalence is somewhat

Flowchart 4: Management of ectopic tubal pregnancy.



(USG: ultrasonography)

Flowchart 5: Management according to the size of adnexal mass.



(hCG: human chorionic gonadotrophin)

higher with multidose regimen as compared to single-dose therapy.

- Gastrointestinal effects such as gastric pain, nausea, vomiting, and stomatitis are the most common side effects seen with MTX.
- Other rare adverse effects include bone marrow depression with severe neutropenia, elevated liver enzymes, reversible alopecia, dermatitis, and pneumonitis.[22]

Contraindications to Methotrexate Treatment

- Hemodynamically unstable patient
- Presence of an intrauterine pregnancy
- Breastfeeding
- Noncompliance for follow-up
- Known sensitivity to MTX
- Chronic liver disease

- Preexisting blood dyscrasia such as severe anemia, leukopenia, and thrombocytopenia
- Active pulmonary disease
- Immunodeficiency conditions
- Active peptic ulcer disease
- Renal dysfunction.

Lower abdominal pain is usually seen 3–7 days after the initiation of treatment. This pain occurs due to dilatation of the fallopian tubes secondary to tubal abortion or hematoma formation.[23] Generally, the pain is mild and lasts for 4–12 hours in a hemodynamically stable patient. Immediate surgery should be considered for tubal rupture as indicated by hemodynamic instability, dropping hemoglobin levels, or visualization on ultrasonography.[1]
