Foreword

Infertility today is an international health problem. It concerns all social classes and races. Advances in assisted reproductive technologies over the years, have provided greater possibilities for successful infertility treatment. Generally, however, over the past forty years or so, emphasis has been mainly on how to "improve" results of infertility treatment, not on how to strike a balance between success, risks and costs. The time has now come to shift focus and trade off the efficacy of treatment against its quality and safety. The essence of infertility treatment in general is to provide infertile couples with a single healthy baby, with a minimum of complications at a reasonable cost. The end of treatment does not come with a positive pregnancy test, but with a liveborn healthy child who has a potential to grow up as a healthy adult. It is the duty of the infertility specialist to guide patients not only through the procedure, but also about the risks associated with it.

Over 44 years since the birth of the first IVF baby, reproductive medicine has expanded much. A noble attempt to keep ourselves updated about the advances in this specialty and passing on the light to those who seek knowledge is the need of the hour. Dr Kamini Rao and her team have managed to put out a very comprehensive book which can be considered one of the greatest works in reproductive medicine of all times. The beauty of this book is that it covers all the aspects of infertility starting from basics to the most recent advances in this field. It is a unique compilation where each topic is written by experts who have relevant experience in that field. Hence in each chapter the reader will not only get a bird's eye view on the topic, but also opportunities for a deep dive into the same. Approaching the most relevant topics in a very practical manner is a highlight of this book.

The previous 2 editions of "the principles and practice of assisted reproductive technology" speak for themselves. They are widely read and cherished. The third edition has not only managed to keep up with the high standards of the previous editions, but also brings a fresh perspective to many socially relevant topics like addressing the fertility issues with gender transformation, fertility options in the LGBTQ community and the like. The book stays at the top of the game by having new chapters on every new advance in reproductive medicine like rejuvenation therapy. It is indeed very thoughtful of the team to include a chapter on the COVID-19 pandemic as well. At the time of the release of this book there are major shifts happening in the field of assisted reproduction in India through new rules and regulations. It is quite commendable that they have managed to put together the latest information on these regulations.

This gigantic work should be a must read and a companion to any professional who is associated with fertility medicine including gynecologists, reproductive medicine specialists, embryologists and medical students. It will remain treasured by students of reproductive medicine for years to come. Such a gigantic, yet comprehensive treasury is a valuable asset to the entire fraternity of reproductive medicine specialists and each one of us will proudly own, nourish and cherish this noble work.

Reproductive Medicine Services
St George's Hospital
London, United Kingdom

Preface to the Third Edition

"If hope is what keeps us alive, I owe my life to all those wonderful humans who kept their hopes alive!"

Reproduction is the basic instinct of all living forms and not being able to have a progeny is perceived as an irreplaceable loss. Human reproduction is on the decline. 10 to 15 percent of the population across the globe finds it difficult to conceive. Reproductive medicine is a field which is evolving at a rapid pace. It has been 44 years since the first IVF baby was born. Over these years we have seen tremendous advances in fertility treatments and lab techniques. We started with purified gonadotropin preparations, basic IVF and manual monitoring in labs. We upgraded ourselves to recombinant drugs, ICSI and automated systems, hence achieving excellent quality control in labs and reasonably good pregnancy and live birth rates. Newer protocols targeting personalized controlled ovarian hyperstimulation, more physiological and patient friendly medications targeting different patient groups, improving sperm selection by using magnification, magnetic field or physiology, putting the quality monitoring on a cloud, using artificial intelligence, genetic testing of embryos for aneuploidies or known genetic disorders, personalizing embryo transfers using the power of gene expression testing and doing the most atraumatic embryo transfers using ultrasound guidance have been some of the advances that we accustomed ourselves to in our urge to strive toward excellence. Even in this 21st century implantation is something which still keeps us baffled. We still droop our heads when it comes to dropping oocyte numbers and quality. We are at a stage where we are still trying to battle it out with the new weapons in our armory—endometrial and ovarian rejuvenation. Stem cell therapy is the new kid in the block whom we all look upon with hopes. This book is coming out at a time when 3rd party reproduction is coming under unreasonable scrutiny in the light of new laws.

Assisted reproduction has evolved significantly since the last edition of this textbook came out. Old information had to go away paving the way for newer advances. We saw the need for bringing out a new edition of this book where we had to not only update existing chapters with all the recent advances, but also remove old and outdated parts of the same. We had to keep up with the astonishing pace at which science is growing. So, we had to add a whole lot of new chapters. New chapters on endometrial and ovarian rejuvenation are examples. Medicolegal aspects of fertility and the new ART laws had to be addressed through new chapters. Nowadays we see many women coming to us at an advanced age attempting a pregnancy. Addressing ART in women with chronic medical disorders was the need of the hour. Similarly an honest attempt was made to discuss male infertility also in detail. The new chapters on varicocele and fertility issues in males with spinal cord injuries were refreshing additions in this regard. No book will be complete in this century if we did not discuss COVID and its effects on fertility. Last but not the least we understood the welcoming changes in the society towards sexuality, thus including new chapters on gender transformations and fertility options in the LGBTQ community.

This book is meant to be a companion for all professionals involved in ART: Clinicians, aspiring students, Embryologists and paramedical personnel working in an Infertility unit. It will serve as a ready reckoner covering all the important topics in reproductive medicine. It allows the readers a deep dive into the subject with an opportunity to go down many rabbit holes as well if they choose to do so.

I am grateful that students and clinicians have nurtured the previous 2 editions of this book. Participating with colleagues to collate this 3rd Edition of the Principles & Practice of ART has been a thoroughly enjoyable experience, but could not have been completed to a high standard without the dedication and precious time and skills of my coeditors. I am deeply honored to be their colleague and thankful for all the efforts they have put in.

Kamini A Rao

Preface to the First Edition

Infertility is a fast-emerging global disease. The speed, at which the incidence of infertility is rising, has been matched equally by the growth of our understanding of the disease and the pace of emerging new technologies. Thirty-five years after the birth of Louise Brown, the first child to be conceived by assisted reproductive technology (ART), the treatment options are mind-boggling. The use of medical interventions for fertility preservation has reached new heights. We are now able to cryopreserve embryos, spermatozoa and oocytes as well as ovarian tissue. The breakthrough technology of vitrification has ensured that egg banking is appropriate for women who wish to defer family building into later years when ovarian function may decline, or for women facing treatment such as cancer therapy that may diminish ovarian function or lead to menopause. With increasingly complex modalities, available for treatment, come the need for a clear, concise and practical textbook, which can serve as a ready-reckoner for healthcare providers.

The book has been divided into three volumes to adequately cover the enormity of the diverse field of reproductive medicine. The objective of the book is to present important and cutting-edge topics relevant to fertility and make it accessible to all ART specialists and gynecologists involved in treating infertile couples. All the chapters have been written by acknowledged pioneers and experts in their own respective areas with special emphasis on evidence-based medicine. Notwithstanding the limitations of our published literature, we have endeavored to provide a balanced view of existing information that is clinically relevant for the evolving areas of our specialty. The text is directed at a broad reader base and will be of immense value to clinicians, embryologists, andrologists, and ultrasonographers from all spheres, be they laboratory technicians, postgraduates, postdoctoral fellow students, private practitioners or researchers.

Volume 1: Infertility

This well-illustrated volume provides concise yet comprehensive practical information on the modern-day approach to the diagnosis and treatment of infertility. It starts from basic principles of reproductive physiology, before moving on to the evaluation and management of the infertile couple and then describes and explains the full armory of ART from ovulation induction and its complications to the outcome following ART. We have also introduced a section highlighting the dilemmas frequently encountered in the field of reproductive medicine in which contrasting points of view are presented. Some recent advances, such as cryopreservation of ovarian tissue and oocytes, have generated great excitement, because of the prospect of fertility preservation prior to cancer therapy which has been covered in-depth. Future clinical applications, such as endometrial stem cells and reproduction, are also dealt with in a separate section.

Volume 2: IVF and Laboratory Aspects of Andrology

The set-up of an in vitro fertilization (IVF) laboratory and the equipment that is used during the IVF process must provide an optimum environment for embryos while they are growing in the laboratory. The personnel should be adequately trained in reproductive research techniques as well as have the necessary technical and administrative skills to manage these laboratories. The text of this volume deals with the laboratory aspects of ART with an emphasis on practical information through which one can readily translate theory into clinical practice. It covers the whole of andrology and embryology dealing with it in four separate sections. The section on andrology deals with all aspects starting from semen examination and interpretation of reports to its cryopreservation. The techniques of intracytoplasmic sperm injection (ICSI), assisted hatching and polar body biopsy have been dealt with a special focus on practicalities. Recent newer techniques, such as intracytoplasmic morphologically selected sperm injection (IMSI), polarization microscopy and omics, have also been well covered. Laboratory management deserves utmost importance with all aspects of quality control and quality management playing a vital role in the success rates of an ART clinic. Practitioners wishing for a greater understanding of the intricacies of how a sperm meets an egg will find this volume especially useful in their clinical practice.

Volume 3: Atlas of Human Embryology

To complement the two volumes, we have designed a high-quality comprehensive Atlas of Human Embryology which offers an exciting, pictorial glimpse into oocytes and embryos at various stages of development. The text here is limited to a brief description of the images. Owing to sophisticated computer technology that is currently on hand, we have made great efforts to capture all the photographs on digital films and digital videotapes. This volume serves as a handbook and ready-reckoner for all embryologists who, when in doubt, can get a sneak peek of the images when working in the laboratory.

Throughout the book, the aim has been to explain issues clearly, simply and directly in such a way that it will be understood by gynecologists, infertility specialists as well as scientists and laboratory personnel. The end aim of the book is to help in optimizing results and generate ART treatment of high quality and we are confident that it works towards this end and that all our readers will appreciate the book's distinctiveness and merit.

Kamini A Rao
Howard Carp
Robert Fischer

Acknowledgments

We would like to express our gratitude to all the expert contributors, for their valuable time, humongous efforts and dedication to passing on the light to the seekers of knowledge.

A book of this magnitude and quality could never have been achieved without the singular efforts of the entire Milann team and the publication team of Shri Jitendar P Vij (Group Chairman) and Mr Ankit Vij (Managing Director) of M/s Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India, whose untiring work ensured that the book was released on time. A special mention of gratitude to Kritika Dua (Senior Development Editor) at Jaypee brothers for working with us tirelessly.

We will always remain indebted to Dr Shantala Kumari R for being there with us day and night through the mayhem of our final proof readings. Without your support, it would not have been possible to release this book on time.

We are deeply indebted to Kala Diwakar for the extra time and effort that she put into coordinating and corresponding with authors, constantly following up with them and the publishers was a mammoth of a task which she has gracefully managed to complete on time.

We are grateful to our families for being supportive through this tough journey. This success is fueled by your love and faith in us.

CHAPTER 1

Anatomy of the Reproductive System

Sonal Agarwal, Mir Jaffar

INTRODUCTION

The reproductive system or genital system is a system of organs working together for the purpose of reproduction. The two important functions of the female reproductive system are to produce female gamete and to nourish the developing offspring until birth. The male reproductive system has the primary function of generation of male gamete (sperm) and deposition of the same inside the female reproductive tract for the fertilization of female gamete (ovum).

FEMALE REPRODUCTIVE SYSTEM

The female internal genital organs include:

- Ovaries
- Uterine tubes
- Uterus
- Vagina.

Embryology

Origin

From the outer part of the intermediate mesoderm **(Fig. 1)**.

Development of Internal Reproductive Organs in Females

Paramesonephric ducts persist in females.[1] The internal portion of the genital cord undergoes fusion and forms uterus and vagina. This begins early in the third month of fetal life.

Medial walls fuse forming septum, which undergoes resorption from below upward. Fallopian tubes are formed from parts outside the cord. At about the fifth month, the uterocervical junction is marked by a ring-like constriction and at the sixth month, thickening of uterine walls begins. Future vaginal fornix is formed from ring-like outgrowth at

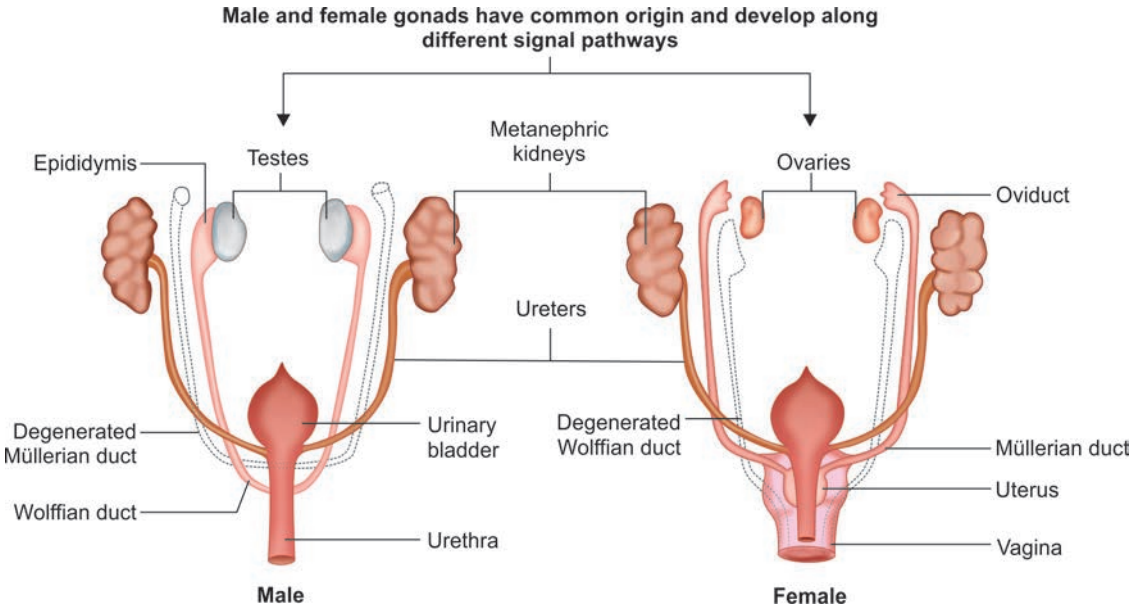

Fig. 1: Embryological development of gonads.

the lower end of the uterus. Simultaneously, the lumen of the vagina is formed by the breakage of central epithelial cells. The hymen is formed from the remnant of sinus tubercle.

Atrophy in Female

In the female, atrophy of paramesonephric bodies and ducts occurs. Epoophoron and paroophoron represent nonfunctional remains of the mesonephric ducts along with rudimentary blind tubules, situated in the mesosalpinx.

Remnants

The lower part of the mesonephric duct disappears, while the upper part persists as epoophoron, also called Gartner's duct. Suspensory ligaments of the ovary are remnants of the mesonephric duct too.

Gonads

Gonads start development initially from the mesothelial layer of peritoneum.

The ovary is covered by the surface layer named germinal epithelium. Immature ova originate from the cells of the dorsal endoderm of yolk sac. In ridge, they are called oogonia. A layer of connective tissue cells, called pregranulosa cells, surround oogonia. The embryological origin of granulosa cells is controversial. As in males, females also have gubernaculum, which pulls the ovary downward but is not as developed as in males. Later, this divides into ovarian and round ligament of uterus **(Fig. 2)**.

Skene's glands in female urethra are homologous to prostatic glands in males. Epithelial lining of the urogenital sinus has diverticula, which correspond to Bartholin's glands.

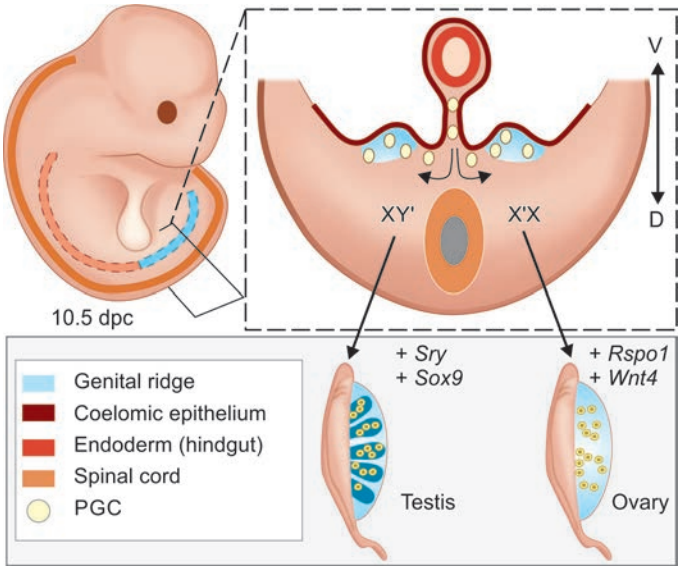

Fig. 2: Development of gonads through gonadal ridge. (PGC: primordial germ cells)

Development of External Genitalia

Until about the ninth week of gestation, the external genitalia of both sexes look the same because they follow a common path of development. The genital tubercle develops with a dorsal membrane, which covers urogenital opening. There is a development of labioscrotal fold, which forms the labioscrotal swelling. The urogenital fold evolves into labia minora and the labioscrotal swelling forms the labia majora.

Initially, the cloacal membrane comprises endoderm and ectoderm, which separates cloaca from the exterior. The separation of the rectum from the dorsal part of the cloaca occurs and the ventral part of the cloacal membrane contributes to the urogenital membrane. The primordial phallus is formed from the tubercle, which is the first rudiment of clitoris.

The corpus cavernosum of clitoris arises from the mesodermal tissue in phallus with cavernous vascular tissue in it. The prepuce is formed as ectodermal growth into the superficial part of the phallus; a horseshoe shape is seen on the coronal section. The ectodermal plate is divided centrally into two lamellae. This results in a cutaneous folding named as prepuce. It forms a hood over the glans. The sides of it grow dorsal and forward as the labioscrotal folds form labia majora. Labia minora arise from the lips of groove on the undersurface of phallus and the remaining part of the phallus forms clitoral glans.

Anatomy

Ovaries

The almond-shaped ovaries are the female gonads in which the germ cells develop. Endocrine function is also carried by female gonads. The support of the ovary is mesovarium, which is a short peritoneal fold. In prepubertal females, the ovary has a capsule called tunica albuginea and the surface is covered with a single cuboidal layer of germinal epithelium. The surface of the ovary is dull, has a grayish appearance, and is continuous with shiny peritoneal mesovarium. At puberty, repeated follicle rupture and ovulation start, which lead to distortion and scarring of the ovarian surface. Scarring is less in women on oral contraceptive pills. Lymphatics, vascular branches, and nerves pass through the suspensory ligament and cross pelvic brim and continue into mesovarium of the broad ligament. Due to lack of peritoneum, the oocyte is expelled into the peritoneal cavity at ovulation. Fimbriae of the infundibulum part of the fallopian tube trap the oocyte and peristaltic movement of the tube carries it to ampulla for fertilization.

During embryonic development, the germ cells are differentiated into oogonia, which divide mitotically and enter the first phase of meiotic division and get arrested at the diplotene stage of prophase-one stage without completing it. During fetal life, the primary oocytes are surrounded by a

spindle-shaped single layer of squamous cells—primordial follicle. Before puberty, the cortex contains only primordial follicle. Beginning at puberty under the influence of pituitary hormones [follicle-stimulating hormone (FSH)], the primordial follicles grow and enlarge to become primary, secondary, and the large mature follicles which can occupy the part of medulla also. Postpubertal ovary has follicles in different stages of development. In addition to the follicles, the ovary may contain a large corpus luteum of an ovulated follicle or corpus albicans of a degenerated corpus luteum. At birth, the cortex contains about 1–2 million primordial follicles. Most of the follicles degenerate before puberty by the process of apoptosis (programmed cell death). About 40,000 follicles persist at puberty and exhibit periodic changes during the rest of the reproductive life. Out of these, about 5–10 follicles undergo a process of maturation in each menstrual cycle. Mostly one follicle from any one of the two ovaries fully matures, ruptures, and discharges a secondary oocyte in the peritoneal cavity and is subsequently picked up by the respective fimbriae. Thus on an average, about 400 follicles attain such maturity during the reproductive life of a woman.

Ovary is mainly supplied by the ovarian artery branch of abdominal aorta and partly by uterine artery branches. Veins from the pampiniform plexus join to form one vein in the suspensory ligament of the ovary. The right ovarian vein ascends at an acute angle to drain into inferior vena cava and the left ovarian vein drains almost at the right angle into the left renal vein.[2]

Uterine Tubes

The uterine tubes (formerly called oviducts or fallopian tubes) are the channel through which the oocyte is carried from the periovarian peritoneal cavity to the uterine cavity. The uterine tubes lie in the mesosalpinx, forming the free anterosuperior edges of the broad ligaments. Tubes are in posterolateral location of lateral pelvic walls and arch anterosuperiorly to ovaries. In "immotile cilia syndrome", the transport of ova takes place only by peristalsis if at all carried by the tube to the uterine cavity. When an ovary does ovulate and release the oocyte, it is swept into the lumen of the uterine tube by the fimbriae which is further facilitated by the longitudinal grooves on the inner aspect of these fimbria, suction created by the ciliary beats of the tube and also by the peristalsis of the tubal musculature. During ovulation, the uterine tubes literally come close to the ovary to pick up the oocyte which may be hormoneregulated. Each tube presents two openings: (1) Uterine ostium which is 1 mm in diameter and opens into the superolateral angle of the uterus and (2) the other, pelvic (abdominal) ostium which is 3 mm in diameter and opens at the bottom of infundibulum near the corresponding ovary. The uterine tubes have four parts from lateral to medial end:

1. *Infundibulum:* The funnel-shaped distal end of the tube, closest to the ovary and about 1 cm long, opens into the peritoneal cavity through the abdominal ostium, the circumference of which is provided with the fimbria. One of the fimbriae is longer (ovarian fimbria) than the rest.
2. *Ampulla:* The widest and longest part (5 cm) is thin-walled, dilated, and tortuous. Fertilization of the ova usually takes place in the ampulla.
3. *Isthmus:* It is rounded and cord like because the walls are thicker than the lumen and resembles the spermatic cord in men. It joins the uterine tube to the uterus. The length of the isthmus measures about 3 cm. The exceedingly narrow lumen suggests the existence of an anatomical sphincter, which prevents the entrance of exogenous microorganisms from vagina to the peritoneal cavity.
4. *Uterine (interstitial/intramural/parts of uterine tube):* It is about 1 cm long, and traverses the thick musculature of the uterus at the junction of the fundus and the uterus to open into the uterine cavity via the uterine ostium **(Fig. 3)**.

Innervation of ovaries and uterine Tubes: Innervation is via both ovarian and uterine plexus. Afferent pain fibers along with descending sympathetic fibers of lumbar splanchnic nerves and ovarian plexus merge into cell bodies in T11–L1 sensory spinal ganglia. Inferior hypogastric plexuses and pelvic splanchnic nerves merge into cell bodies in the S2–S4 sensory ganglia.

Uterus

The uterus (womb) is pear shaped, has thick walls, and is a hollow muscular organ. The nongravid uterus is located in the lesser pelvis with cervix between the urinary bladder and the rectum. The normal position of the uterus is that of anteversion and anteflexion. The average size of a nongravid uterus is 7.5 × 5 × 2 cm and weight is about 90 g. Its dimensions change rapidly dramatically during pregnancy. At birth, the uterus is relatively large and has a body:cervix ratio of 2:1 because of maternal hormone influence in intrauterine life. Several weeks after birth, childhood dimensions and proportions are obtained. The body:cervix ratio becomes 1:1.

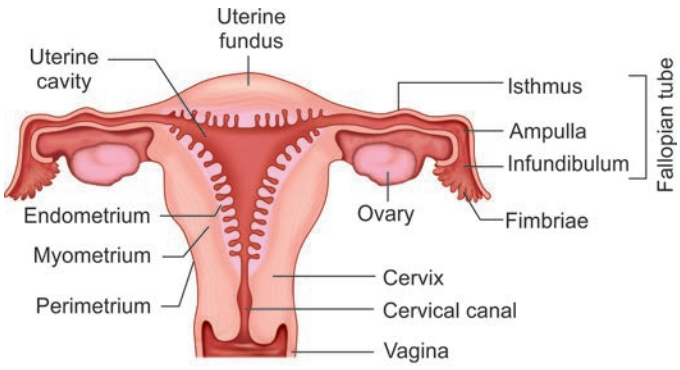

Fig. 3: Female reproductive system.

Because of the small size of the pelvic cavity, it remains in the abdomen and descends down afterward and becomes pelvic organ. Typical angulation between the uterus and vagina is not established. During puberty, the uterus (especially the body) grows rapidly in size thereby again assuming adult proportions because of hormonal exposure.

Axes of Uterus

Normally, the adult uterus is anteverted and anteflexed.

Anteversion: The angle between the cervices relative to the axis of the vagina measures about 90°, provided that the bladder and the rectum are empty. The anteversion is maintained by the forward pull on the uterine fundus by the traction of the round ligaments of the uterus, backward pull on the cervix by the traction of the uterosacral ligaments, and the intrinsic growth of the uterine musculature. Maintenance of the anteversion angle is an important prerequisite to prevent the prolapse of the uterus **(Figs. 4A and B)**.

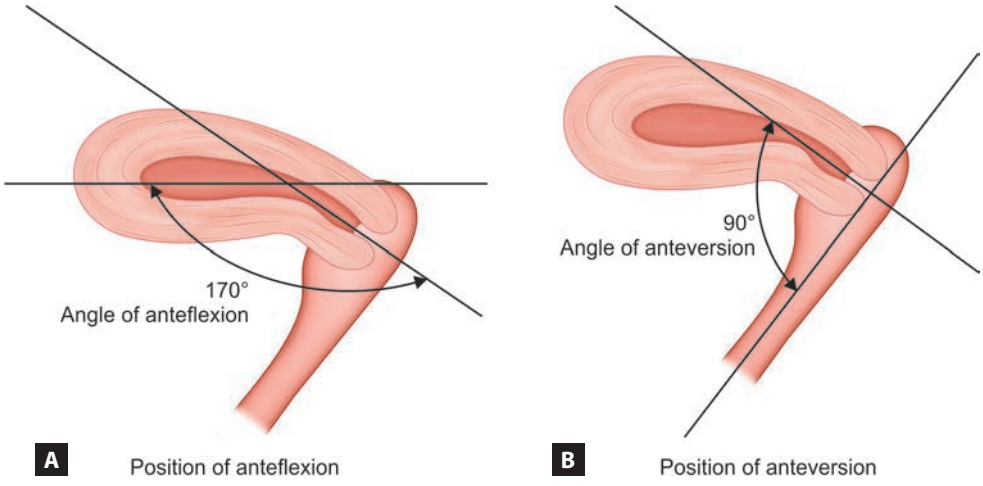
Anteflexion: It is the forward angle between the body and cervix at the isthmus, creating the angle of flexion measuring about 125° so that the main bulk of the uterus rests on the bladder for better support. On an empty bladder, the uterus is in transverse plane.

Flexion of the uterus takes place at the transverse plane of the internal orifice (os). Normally, the uterus rotates forward around this axis known as anteflexion. When it rotates backward (reverse direction), it is referred to as retroflexion. It is usually found in the cases of disrupted perineal body or weak pelvic floor muscles and ligaments.

Usually, the uterus lies in the median plane and is twisted to the right or left side. Sometimes, the fundus is tilted more to the right pelvic wall known as dextrorotation of the fundus. In such situations, the right uterine tube comes in more close contact with the lateral pelvic wall and may be related to the pelvic type of the vermiform appendix.

Consequently, the cervix is tilted more to the left side known as levorotation of the cervix.

The uterus is divided into body and cervix. The body lies between the layers of the broad ligament and is freely movable. It has two vesical and intestinal surfaces. The body is demarcated from the cervix by the isthmus of the uterus, a constricted segment, 1 cm long. The cervix of the uterus is 2.5 cm in length and cylindrical in the adult nonpregnant woman. The part between the isthmus and the vagina is called supravaginal part and the vaginal part protrudes in the superior most part of the anterior vaginal wall. The rounded vaginal part surrounds the external os of the uterus and is surrounded in turn by a narrow recess, the vaginal fornix. The supravaginal part is separated from the bladder anteriorly by loose connective tissue and from the rectum posteriorly by the rectouterine pouch. The slit-like uterine cavity is 6 cm in length from the external os to the wall of fundus. The uterine cavity continues inferiorly as the cervical canal. The uterine body has three coats: (1) Perimetrium which is the outer serous coat of the peritoneum with a thin layer of connective tissue; (2) myometrium which is the middle coat of smooth muscle with the main branches of vascular and nerve supply traversing through it; and (3) endometrium, which is the innermost coat with firm adherence to myometrium. Endometrium attains different histopathology during all the phases of the menstrual cycle. The endometrium or mucous membrane of the body of the uterus consists of surface epithelium and lamina propria of variable thickness depending on the stage of menstrual cycle. Before puberty, the surface is lined by the ciliated columnar cells; during the reproductive period, it is lined by the simple columnar epithelium because cilia cannot grow due to repeated destruction of the superficial part of the endometrium. Functionally, the endometrium consists of an outer basal layer and an inner functional layer. In a nonpregnant female, the inner functional layer with the uterine glands and blood vessels is sloughed off or shed during menstruation, leaving



Figs. 4A and B: Uterine axis.

intact the deeper basalis layer with the basal remnants of the uterine glands—the source of cells for regeneration of new functional layer. The basal layer is supplied by the straight basal arteries, whereas the functional layer is supplied by the spiral arteries which are highly sensitive to the hormonal changes in the blood and undergo vasoconstriction before menstruation with eventual casting of the endometrium due to ischemic necrosis followed by the hemorrhage.

Menstruation occurs only in primates and in mankind who possess the spiral arteries of the endometrium. Fundus and body are developed by the fusion of the intermediate parts of the two paramesonephric (Müllerian) ducts. While the cervix is developed from the upper part of the uterovaginal canal, which in turn is formed by the fusion of the lower vertical parts of the two paramesonephric ducts, the lower part of the uterovaginal canal forms the major portion of the vagina.

The principal supports of the uterus are both passive and active. Pelvic diaphragm acts as an active support. Change in tone is due to changes in intra-abdominal pressure conditions transmitted through the surrounding pelvic organs and the endopelvic fascia in which they are embedded. Passive support of the uterus is provided by its position. When intra-abdominal pressure is increased, the uterus is pressed against the bladder. The cervix has the least mobility due to condensed endopelvic fascia attached to it.

Arterial and Venous Supply of Uterus

The uterus is supplied by the uterine arteries mainly and collateral supply is through the ovarian arteries. Uterine plexus veins drain in internal iliac veins. Lymphatics from the fundus drain along the ovarian vessels to lumbar (caval/aortic) lymph nodes. The isthmic part of tubes and round ligament attachments drain into superficial inguinal lymph nodes.

Vagina

The vagina is a musculomembranous tube (7–9 cm long), extending from the cervix to the vaginal orifice. All vestibular glands have their opening in the vaginal vestibule. The vagina plays the role of a canal for menstrual bleeding, receives the penis and ejaculate during sexual intercourse, and communicates superiorly with cervix and inferiorly with vestibule of the vagina. The vagina does not have any glands in its wall. Mucous produced by cells in the cervical glands lubricate the vaginal lumen. In a nulliparous adult, the vagina is H-shaped in section with transverse folds called vaginal rugae which render the vagina highly distensible. Before puberty, rugae are absent. In the elderly, the vagina becomes less elastic and appears pale and smooth due to loss of rugae. Vagina is closely related to many pelvic floor muscles which provide support and act as potential sphincters for the vagina. All these muscles rhythmically contract during the orgasm.[3]

The vaginal epithelium exhibits minimal changes during the menstrual cycle. During the proliferative (follicular) phase of the menstrual cycle, under the influence of high estrogen secretion, the vaginal epithelium increases in thickness and stimulates the vaginal cells to synthesize and accumulate an increased amount of glycogen as these cells migrate toward the vaginal lumen into which they are shed off. The fermentative action of Doderlein's bacillus on glycogen-rich desquamated cellular debris (glycogen is converted to lactic acid) renders the vaginal fluid acidic which inhibits the growth of microorganisms or pathogenic invasion. Hence, the vaginal infections are more common after menopause as the glycogen content becomes lesser. Arterial supply is from tributaries of uterine artery and internal pudendal artery. The uterovaginal venous plexus drains into the internal iliac veins through the uterine vein. Lymphatic vessels from the superior part of the vagina drain to internal and external iliac lymph nodes, middle part to internal iliac nodes, and inferior part to sacral and common iliac nodes. External os drains into the superficial lymph nodes.

Innervation of the Uterus and the Vagina

Somatic supply is present in the inferior, one fifth to a quarter of the vagina in the form of deep perineal nerve. Sensations of touch and temperature are present. The upper portion of the vagina and uterus has visceral innervation by hypogastric and thoracolumbar spinal ganglia.

Applied Anatomy

- During childbirth, myometrial contractions are mediated hormonally at decreasing length intervals so as to dilate the lower segment of the uterus. During menses, myometrial contractions are responsible for cramping pain.
- Infections of the female genital tract can lead to peritoneal infections due to direct communication and vice versa. A major cause of tubal factor infertility is salpingitis.
- Patency of tubes can be checked by hysterocontrast salpingography (HyCoSy), ultrasound, and endoscopy.
- Ligation of uterine tubes is a surgical method of birth control. It can be done by either abdominal or laparoscopic route.
- Ectopic tubal pregnancy is the most common ectopic gestation occurring in approximately 1 in every 250 pregnancies. Late diagnosis can result in rupture of ectopic gestation which can lead to severe hemorrhage into the abdominopelvic cavity. It should be differentially diagnosed from appendix pathology and acute abdomen.
- Congenital anomalies such as unicornuate uterus, bicornuate uterus, doubled uterine cavities, and uterus didelphys are seen.
- Persistence of remnants of mesonephric ducts in the form of epoophoron can enlarge and result in cyst formation and torsion.

- Female brain has hermunculus in the clitoral cortex which on stimulation is associated with intercourse frequency. Research is being focused on this region in women with vaginismus and decreased libido.
- Increased intra-abdominal pressure can result in increased flexion and version. Damaged ligaments and weak supports of the uterus can cause uterovaginal prolapse and retroversion.
- *Infection of greater vestibular glands:* Palpable when infected. Occlusion can predispose to bartholinitis and cyst formation. It can lead to vulvar adenocarcinomas.
- Emphasis on prepartum classes (Kegel exercises) should be present to reduce the muscular obstruction to passage for fetus and decrease the chances of perineal muscle damage.
- Levator ani muscles are closely related to the vagina on its lateral side, and any pathology to these muscles is significantly responsible for either the painful intercourse or orgasm. From our clinical experience, we have noticed many patients, especially those suffering from coccydynia (tailbone pain) in which the levator ani muscle is mostly tender on rectal examination and surprisingly the same mechanism is seen in the males as well.
- Recent 3D organoid technology is developed for the study of female reproductive tract that mimics ovaries, fallopian tubes, endometrium, and cervix, as well as placental trophoblast. These 3D models help in further studies about the biology and physiology of the female genital system.[4]

Histology

The ovary has cuboidal germinal epithelium continuous with peritoneal mesothelium. Beneath it is a fibrous tunica albuginea capsule. Oviduct has mucosa, muscularis layer, and serosa with connective tissue.[5]

The uterus has mucosa, endometrium, myometrium, and peritoneal layer serosa. Endometrium consists of simple columnar epithelium (ciliated cells and secretory cells) and an underlying thick connective tissue stroma. Vagina has mucosa, muscularis, and adventitia.

MALE REPRODUCTIVE SYSTEM

Introduction

The male reproductive axis of hormones and organs is a well-efficient biological system. It is responsible for reproductive tract formation and development, pubertal maturation, and maintenance of fertility. Understanding the basis of male infertility is becoming a growing trend among infertility specialists because of the progressive decrease in semen parameters over recent years. To understand the basic pathophysiology and the cause of male infertility, it is imperative to have knowledge about the anatomy, physiology, development, and hormonal control of the male genital and duct system for the effective evaluation and treatment of male infertility.

Embryology

As urinary and genital systems are located closely and overlap each other, development of them is described as the development of urinary and reproductive systems together. Intermediate mesoderm forms the reproductive organs embryonically. These embryonic structures are the mesonephric ducts (Wolffian ducts) in males and the paramesonephric ducts (Müllerian ducts) in females.

Origin

Under the ectoderm in the outer intermediate mesoderm, there is C5–T3 vertebral segment, which is a series of short evaginations extending caudally from dorsal growth and fuses successively from before backward to form pronephric duct. It grows caudally to open into the ventral part of cloaca to form a mesonephric duct, which remains after the atrophy of pronephros duct.

Development of Internal Reproductive Organs in Male

In males, duct persists to form tube of epididymis, vas deferens, and ejaculatory duct. Seminal vesicles arise during the third month of fetal life from hinder part. A large part of the head of mesonephros atrophies leaving anterior efferent ducts of testicle and posterior ductuli aberrantes and paradidymis.

Paramesonephric Ducts

After the formation of mesonephric ducts, paramesonephric ducts develop. Each arises on the lateral aspect of the corresponding mesonephric duct as tubular invagination of cells lining the abdominal cavity. Ducts pass backward lateral to the mesonephric ducts, but toward the posterior end of the embryo they cross medially and lie side to side leading to the formation of the common genital cord. The mesonephric ducts end in an epithelial elevation and the sinus tubercle on the ventral part of the cloaca between the orifices of the mesonephric ducts. Sinus tubercle connects paramesonephric ducts with cloaca.

Atrophy in Males

Paramesonephric ducts atrophy and only traces of anterior ends form the appendix of testis of male, while terminal fused portions form the prostatic utricle in the floor of the prostatic urethra. This is due to production of anti-Müllerian hormone (AMH) by Sertoli cells of testes.

Gonads

Gonads initially develop from the mesothelial layer of peritoneum. Testis periphery is converted into tunica albuginea. The cords of the central mass form a network to become rete testis and seminiferous tubules. Via the rete testis, the seminiferous tubules become connected with efferent ducts of the testis. Descent of testes occurs followed by the development of gubernaculum.[6] Failure in this process leads to indirect hernia or infantile hydrocele.

The rectum gets separated from the dorsal part of cloaca and the ventral part becomes primary urogenital sinus. Sinus divides into superficial definitive urogenital sinus and deeper anterior vesicourethral portion. Vesicourethral portion is the deepest portion continuous with allantois. It absorbs ends of mesonephric ducts and associated ends of renal diverticula and gives rise to trigone of urinary bladder and prostatic urethra part. Remainder forms the body of the bladder and part of the prostatic urethra; its apex is prolonged to umbilicus as a narrow canal called urachus, which is obliterated in later life to form the median umbilical ligament in adults.

Prostate

A series of diverticular buds arise from the epithelial lining of the urogenital sinus and vesicourethral part of the cloaca, between the third and fourth months. These buds become tubular and form glandular substance of two lobes which fuse behind urethra and extend onto ventral aspect. The median lobe of prostate is formed as an extension of the lateral lobes between the common ejaculatory ducts and bladder.

Bulbourethral glands also arise as diverticula from the epithelial lining of urogenital sinus.

Development of External Genitalia

The urogenital fold evolves into shaft of the penis and labioscrotal swelling evolves into the scrotum. Genital tubercle develops into primordial phallus, the first rudiment of penis. Corpus cavernosum penis and corpus spongiosum penis arise from phallus with the development of cavernous spaces in it later on. The prepuce is formed by the growth of a solid plate of ectoderm, which is horseshoe shaped on the coronal section. A cutaneous fold of prepuce forms a hood over the glans. The pelvic portion of the cloaca undergoes more development, pushing phallic portion. The labioscrotal folds extend around to form scrotal area. During descent, along with testis, the scrotal area is drawn out to form scrotal sacs. The penis is developed from the phallus. The urogenital membrane undergoes absorption, forming a channel on the undersurface of the phallus; this channel extends only as far forward as the corona glandis. The longer urethra is formed by the greater growth of the pelvic portion of cloaca. Later, this opening, which is located on the dorsal side of the penis closes from behind forward. The urethral plate of the glans breaks and forms a median groove continuous with the primitive ostium. Groove closes leaving a small pipelike opening in between. Thus, the urogenital opening is shifted forward to the end of glans.[7]

Anatomy

During embryonic development, the male genital tract is a straight duct system with the developing testes high up inside the abdomen and the ejaculatory organ (penis) outside the body. Since testes need 1–2°C temperature lower than the normal body temperature to function normally, they descend down in the scrotum normally during birth outside the body forming a loop of duct system. Vasa deferentia run parallel to the urethra but in the opposite direction. The initial secretory part of the duct begins outside the body (scrotum), the middle part intra-abdominal, and the terminal ejaculatory part ends outside. The male internal genital organs include the testes, epididymides, ductus deferens, seminal glands, ejaculatory ducts, prostate, and bulbourethral glands.[8]

Testis is suspended in the scrotum by the spermatic cord which starts at deep inguinal ring lateral to inferior epigastric vessels, passes in inguinal canal, and comes out of superficial inguinal ring, ending at scrotum. The coverings of the spermatic cord include the following: Internal spermatic fascia, cremasteric fascia and muscle, and external spermatic fascia. It contains vas deferens, testicular artery, cremasteric artery, artery of ductus deferens, pampiniform venous and lymphatic plexus, sympathetic nerve fibers, and processus vaginalis. The cremaster muscle is responsible for the cold reflex which draws testis superiorly. Warm reflex is opposite to it. These occur to regulate temperature of testis for regulating spermatogenesis (1°C below core temperature).

The genital branch of the genitofemoral nerve (L1 and L2) innervates the cremaster striated muscle, while dartos is a smooth muscle innervated by the autonomic nerves **(Fig. 5)**.

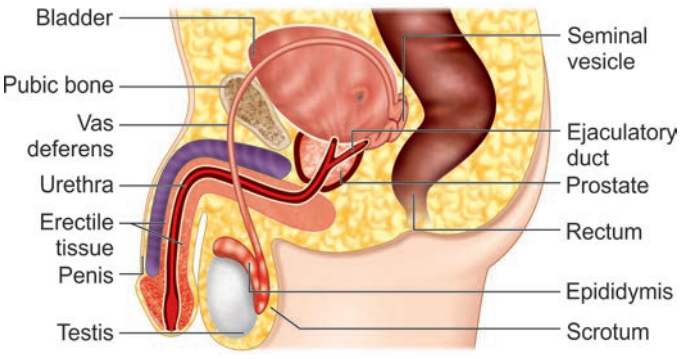


Fig. 5: Male reproductive tract.

Scrotum

The scrotum is the saccular part consisting of two layers—(1) heavily pigmented skin and (2) a fat-free dartos fascial layer along with smooth muscle fibers giving rugose appearance to scrotum. In cold conditions, contraction of the dartos muscle causes thickening of the integumentary layer as it is attached to the skin, and reduces scrotal surface area overall, thus reducing heat loss.

The scrotum is divided by scrotal raphe. It marks the line of fusion for embryonic labioscrotal swellings. Fascia does not contain fat. The arterial supply of scrotum is from the perineal artery (branch of the internal pudendal artery), deep external pudendal artery, and cremasteric artery. Scrotal veins accompany arteries. Superficial inguinal lymph nodes drain it. Innervation is by the genital branch of the genitofemoral nerve (L1, L2), ilioinguinal nerve (L1), posterior scrotal branches of the pudendal nerve (S2–S4), and perineal branches of the posterior cutaneous nerve of the thigh (S2, S3).

Testes

Testes are the male gonads suspended in the scrotum by the spermatic cords, with the left testis inferior to the right testis. Each has a volume of 15 mL or more and measures around 5 cm in length. The surface is covered by the visceral layer of the tunica vaginalis, except at attachment to epididymis and spermatic cord. Fluid separates visceral and parietal layers for free movement in scrotum. The testes have a tough fibrous outer surface, the tunica albuginea that thickens into a ridge on its internal and posterior aspects as the mediastinum of the testis. It has little distensibility; thus, any condition leading to edema can cause ischemic damage to the testis. Beneath tunica albuginea is a vascular layer called tunica vasculosa, which contains blood vessels with numerous mast cells.[9] A thin connective tissue septum extends from the mediastinum testis anteriorly and subdivides each testis into about 250 incomplete compartments or testicular lobules, each containing one to four coiled seminiferous tubules. The mediastinum contains a network of channels known as the rete testis, which receives the terminal segments of the seminiferous tubules (straight tubules) in which the sperms are produced.

Each testicular lobule contains tightly packed seminiferous tubules and sparse interstitial connective tissue. Each seminiferous tubule is lined by stratified germinal epithelium, containing proliferative spermatogenic (germ) cells and nonproliferating supporting (sustentacular) or Sertoli cells.[10] It is in these seminiferous tubules where spermatogenic cells divide, mature, and are transformed into sperms **(Fig. 6)**.

Surrounding each seminiferous tubule are connective tissue cells, blood vessels, nerves and lymphatic vessels, steroid-secreting cells, and the interstitial cells of Leydig-producing testosterone. Seminiferous tubules comprise 95%

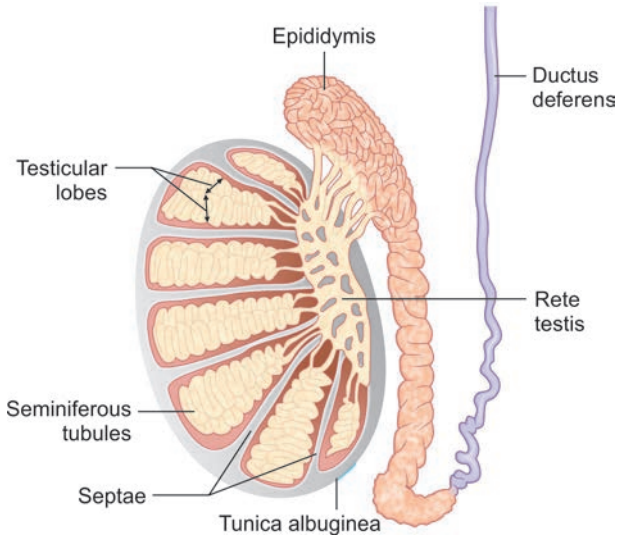

Fig. 6: Macroscopic structure of testes.

of testicular volume and are devoted to the production of spermatozoa. There are approximately 500 tubules per testis. The tubules are divided by fibrous septae and surrounded by the tough tunica albuginea.

Each tubule is 30–70 cm long and 200–300 μm in diameter. Tight convolutions can result in incomplete obstruction. As the tubule reaches the mediastinum, convolutions decrease and ultimately straighten out to form tubuli recti (straight ducts), which connect to the developmentally different set of network of tubules called rete testes. Sperm produced by the seminiferous tubules passes out of the testis into the ductal system, beginning with the rete testis to the epididymis and then to the vas deferens. Sperm in the vas deferens is joined by the seminal vesicle secretions as they pass through the prostate via the ejaculatory ducts into the urethra.

The long testicular arteries arise from the abdominal aorta just inferior to the renal arteries. Pampiniform plexus converge, forming the right testicular vein, which enters inferior vena cava, and the left testicular vein, which enters left renal vein and surrounds the testicular artery in the spermatic cord. It provides thermoregulation. The lymphatics drain into bilateral lumbar and preaortic lymph nodes. The autonomic nerves contain vagal parasympathetic and visceral afferent fibers and sympathetic fibers from T10 to T11 segment.

Epididymis

The epididymis is an elongated structure on the posterior surface of the testis, which receives sperms from efferent ductules through rete testis. It has convolutions and appears solid. The epididymis has three parts: (1) head, which is the superior extended part composed of lobules of coiled ends of 12–14 efferent ductules; (2) body, which is major part consisting of the tightly convoluted duct of the epididymis; and (3) tail, which is tapering continuation with the ductus deferens.[11] It is made up of tightly packed convoluted tubules

with little supporting loose connective tissue. These efferent ductuli are very fine and lined by highly ciliated columnar epithelium for maximum absorption of water, both to increase the concentration of sperms as well as to transport the sperms from testes to epididymis by creating the suction effect. The walls have myoid cells, which undergo frequent contractions to enhance the absorption of fluid as well as the mobilization of sperms.

All these minute ductules of the head of the epididymis join together and form one single duct, which coils on itself called the canal of epididymis or epididymal duct. It forms most of the body and tail of the epididymis and lies alongside the posterolateral border of the testis. The epididymal duct is approximately 6 m in length. The duct is lined by pseudostratified columnar epithelium with nonmotile stereocilia due to the absence of axoneme. The passage of sperms across the epididymis takes 7–10 days. However, the transit time is dependent on the amount of sperms produced; the higher the sperm production, the lesser the transit time it takes. From head to tail, it moves by spontaneous peristaltic movements during which sperms attain their maturity, motility, and fertilization capacity. The tail of the epididymis is evolved as the sperm storage organ only in animals forced to wait for female ovulation. Maturation of sperms is dependent on the luminal flow of testosterone. Prominent dilatation of the epididymal head is known as "Bayle's sign", which is palpable in case of epididymal obstruction or absent vas deferens in men.

Ductus Deferens

The ductus deferens, a primary component of the spermatic cord, has thick muscular walls and a minute lumen, giving it a cord-like firmness. It begins in the tail of the epididymis, runs via the inguinal canal, and ends by joining the duct of seminal gland to form ejaculatory duct. The relationship of ductus deferens to ureter is similar to that of uterine artery to ureter in the female but is of lesser significance.

In adults, vas measures about 25 cm in length and can be palpated as a 3–5 mm thick string on both sides of the scrotum. The ductus deferens enlarges and forms ampulla of ductus deferens (2 cm in length) before its termination. Ampulla also serves as the storage for the sperms prior to the ejaculation but is controversial because of the temperature issues. Because of the long and complicated course of the duct, absence of the duct, or multiple blocks in the duct, surgical retrieval followed by the assisted reproductive technology (ART) is preferred over corrective surgeries.

The vas has three robust layers of smooth muscles: Outer and inner longitudinal and middle circular layers. These muscles are under the sympathetic stimulation and show mass contraction when stimulated which transport spermatozoa from the epididymis tail to the prostatic urethra within a second.

Artery to ductus deferens supplies ductus deferens. Veins drain into testicular vein including distal pampiniform plexus.

Seminal Glands

Each seminal gland (vesicle) is an elongated structure lying between the fundus of the bladder and rectum, 5 cm long approximately. Seminal glands do not store sperms as believed earlier. They secrete a thick alkaline fluid mixed with fructose and coagulating agent that mixes with sperms as they pass into ejaculatory ducts and urethra.

Inferior vesical and middle rectal arteries supply it. Veins accompany it. The secretion of the gland is viscid, yellowish-white alkaline fluid and forms the bulk of the semen which is rich in fructose, prostaglandin, and a coagulating enzyme—vesiculase. The activity of the mucous membrane is regulated by the secretion of the androgen (testosterone). Fructose is believed to serve as an energy source of sperms. The seminal glands contain 40 million times higher concentrations of prostaglandins than the blood. In cases of absent vas deferens, the seminal glands are also absent in most of such cases as they have the same developmental origin (Wolffian duct system) **(Fig. 7)**.

Ejaculatory Ducts

The ejaculatory ducts arise by the union of the ducts of the seminal glands with the ductus deferentes approximately 2.5 cm long. The ejaculatory ducts converge to open on seminal colliculus by tiny, slit-like apertures on, or just within the opening of the prostatic utricle. Ducts traverse the glandular prostate but secretions from prostate gland do not join seminal fluid till ejaculatory ducts terminate in the prostatic urethra. Ejaculatory ducts have the same blood supply as ductus deferens. The veins join the prostatic and vesical venous plexuses.

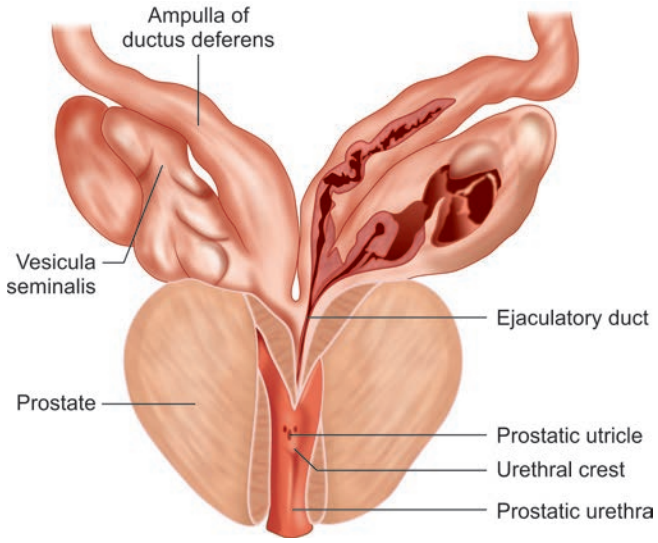

Fig. 7: Seminal glands.

Prostate

Prostate is a firm and walnut-shaped gland with a size of approximately 4 × 3 × 2 cm and is the largest accessory gland of the male reproductive system surrounding the prostatic urethra. Two-third part is glandular and one-third is fibromuscular. Capsule is fibrous and neurovascular, incorporating the prostatic plexuses of veins and nerves.[12]

The prostatic ducts are 20–30 in number opening chiefly on the posterior wall of the urethra through sinuses. Prostatic fluid is acidic and milky fluid forming 20% of the semen volume and is biochemically very active. Prostatic secretions contain a large amount of enzymes that play a role in both semen clotting and liquefaction. The enzyme vesiculase induces clotting and a number of proteases, peptidases, and hyaluronidase, which cause the breakdown of the clot.

Inorganic elements such as zinc, magnesium, and calcium are also present. Zinc is known to provide protection of spermatozoa against spermiophagic cells in the female genital tract and acts as a chelating agent by protecting free sulfhydryl groups present on protamines so as to prevent "superstabilization" of the condensed chromatin of sperm.

The prostatic arteries are mainly branches of inferior vesical, internal pudendal, and middle rectal arteries. The prostatic venous plexus drains into internal iliac veins. It is continuous with the vesical venous plexus and the internal vertebral venous plexus.

Bulbourethral Glands

Bulbourethral glands are also known as Cowper's glands. They are pea sized. Ducts open in spongy urethra in bulb of penis. Their mucus-like secretion enters the urethra during sexual arousal.

Innervation of Male Pelvis

The ductus deferens, seminal glands, ejaculatory ducts, and prostate are richly innervated by sympathetic nerve fibers with presynaptic cell bodies in the intermediolateral cell column of T12–L2 (or L3) spinal cord segments.

Presynaptic parasympathetic fibers from S2 to S3 spinal cord segments traverse pelvic splanchnic nerves and join the inferior hypogastric or pelvic plexuses. During orgasm, the sympathetic system stimulates contraction of the internal urethral sphincter to prevent retrograde ejaculation. Simultaneous stimulation causes rapid peristaltic contractions of ductus and secretion from seminal and prostate glands results in expulsion of semen during ejaculation. Parasympathetic fibers traverse the prostatic nerve plexus to form the cavernous nerves that pass to the erectile bodies of the penis, which are responsible for producing penile erection.

Vascular Supply and Lymphatic Drainage

The arterial supply of the scrotum is from the perineal artery (branch of the internal pudendal artery), deep external pudendal artery, and cremasteric artery. Scrotal veins accompany the arteries. Lymphatic drainage is by superficial inguinal lymph nodes. The long testicular arteries arise from the abdominal aorta just inferior to the renal arteries. Pampiniform plexus converges into right and left testicular veins. The lymphatics of testis drain into preaortic and lumbar lymph nodes. The artery to ductus deferens is the arterial supply of ductus deferens. Veins drain into the testicular vein, including the distal pampiniform plexus. Inferior vesical and middle rectal arteries supply seminal vesicles. Veins accompany it. The arteries to ductus deferens supply the ejaculatory ducts. The veins follow prostatic and vesical venous plexuses. Prostatic arteries are mainly the branches of inferior vesical arteries, internal pudendal, and middle rectal arteries. Prostatic venous plexus drains into internal iliac veins. It is continuous with the vesical venous plexus and the internal vertebral venous plexus.

Applied Anatomy

- The common method of sterilizing males is vasectomy. Ductus deferens is ligated through an incision in the superior scrotum. No scalpel vasectomy is done these days. Reversal of vasectomy is successful in young patients of less than 30 years of age and having <7 years of postoperative time. An operating microscope-aided reattachment of ends of sectioned ductus is done.
- Seminal gland enlargement and abscesses can be palpated during a rectal examination. For microscopic examination, seminal glands are massaged to release secretions to detect the organism for gonococci infection.
- Prostate hypertrophy is common after middle age affecting urination by distorting the prostatic urethra and causing dysuria, urgency, nocturia, cystitis, and kidney damage. Examination can be done by digital rectal examination.[13]
- Prostate-specific antigen (PSA) is secreted by prostate, clinically used as a clinical marker in suspected cases of carcinomas.
- Ejaculatory duct obstruction can be suspected in fructose-negative cases which can be resected through transurethral resection of duct (TURD).
- Men with premature ejaculation are advised to practice training voluntary muscles.
- Horizontal testes are more prone to torsion injuries.
- Small size testis is indicative of damage to the seminiferous epithelium which forms the major portion of the testicular volume. It can be measured by an orchidometer.
- Small and firm testes, usually <3 mL in volume, are found in men with Klinefelter syndrome.
- Patients with hypogonadotropic hypogonadism have small testes, but size usually measures between 5 and 12 mL.

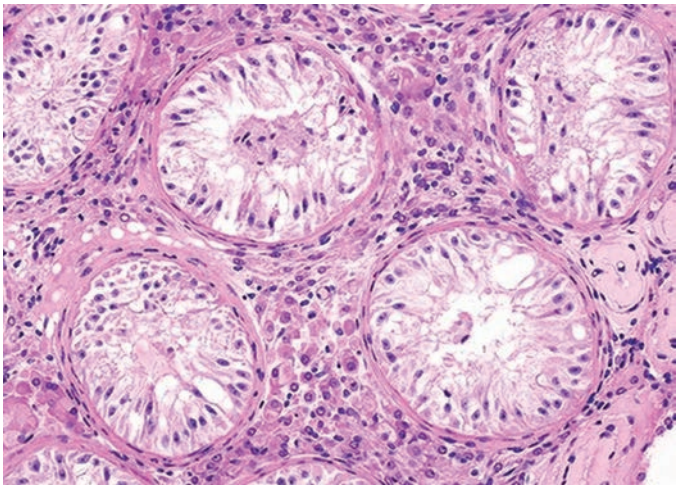

Fig. 8: Sertoli cell-only syndrome—histological section.

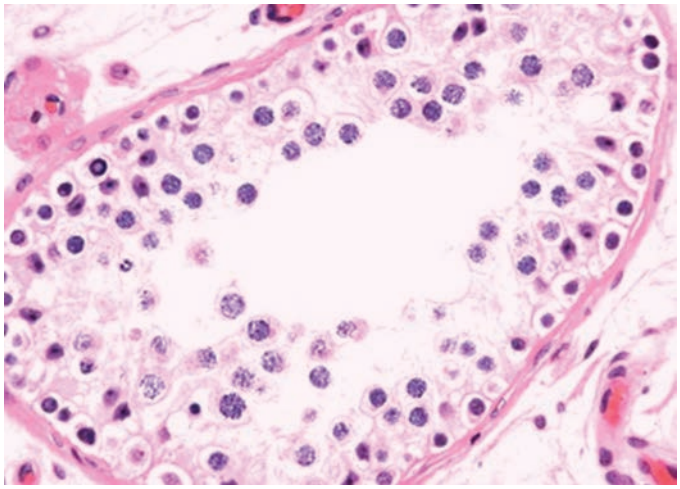

Fig. 9: Histological section of maturation arrest syndrome.

- Microdeletions in Y chromosome are found in higher rates in infertile men than in fertile controls. Azoospermia factor (AZF) focus at Yq11 has partial deletion of AZFa, AZFb, and AZFc with Sertoli cell-only syndrome **(Fig. 8)**, maturation arrest **(Fig. 9)**, and occasional spermatogenesis, respectively.
- *Anesthesia for sperm retrieval techniques*: Local anesthesia in percutaneous epididymal sperm aspiration (PESA) or testicular or epididymal sperm aspiration (TESA) can be achieved by injecting 10 mL of 1% lignocaine solution along sides of vas deferens near external inguinal ring. This is called spermatic cord block. Only in apprehensive patients, intravenous sedation can be given as backup. For microsurgical procedures, general anesthesia is preferred.

Penis

The penis is the male copulatory organ and provides a common outlet for urine and semen. It consists of glans, body, and root. It is composed of three cylindrical cavernous bodies of erectile tissue: the paired corpora cavernosa and single corpus spongiosum. Penis is in anatomical position when erect and its dorsum is anterior in flaccid condition. The skin of the penis is thin, darkly pigmented relative to adjacent skin, and connected to the tunica albuginea by loose connective tissue. At the neck of the glans, the skin and fascia of the penis are prolonged as a double layer of skin, the prepuce (foreskin) which in uncircumcised males covers the glans penis mostly.

Penis is supplied by the dorsal artery of penis, deep artery, and artery of bulb of penis. Cavernous space blood is drained through prostatic venous plexus.

Innervation of penis: The nerves derive from the S2–S4 spinal cord segments and spinal ganglia, passing through the pelvic splanchnic and pudendal nerves, respectively. Sensory and sympathetic innervation is provided primarily by the dorsal nerve of the penis.

Erection, emission, ejaculation, and remission: When a male is stimulated erotically, arteriovenous anastomoses are closed and smooth muscles relax due to parasympathetic stimulation. This results in increased blood flow to cavernous spaces in corpora of penis. The bulbospongiosus and ischiocavernosus muscles compress veins impeding venous flow return. As a result, engorgement of erectile bodies occurs resulting in erection.

Emission (expression of secretions into the urethra) is a sympathetic response (L1–L2 nerves). During ejaculation, expulsion of semen occurs through the external urethral orifice due to closure of internal urethral sphincter (sympathetic) and contraction of urethral and bulbospongiosus muscle (parasympathetic). After ejaculation, the penis becomes flaccid due to relaxation of muscles allowing blood to drain from cavernosa to deep dorsal vein.

The first part of the semen comes from the cauda of the epididymis suspended in prostatic fluid. Spermatozoa in zinc-rich prostate fluid preserve motility, vitality, and the stability of their nuclear chromatin. The second part is mainly composed of a fluid from the seminal glands, which is rich in fructose and prostaglandin. The first part of the ejaculate is deposited on to the cervical mucus comprising spermatozoa in prostatic fluid and the second part of the semen mainly from seminal glands forms the plug to prevent backflow of the first part of the ejaculate. Semen collected in a predetermined sequence is known as a "split ejaculate".

Semen

Semen is a grey opalescent fluid. Testes have 5% contribution to ejaculate and seminal vesicles and prostate make up to 90%. The remaining 5% of the ejaculatory volume is formed by the bulbourethral and urethral glands. These volumes are outlined in **Table 1**.[12] Secretions have an important role. Minor changes also in consistency of fluid have a profound effect. Reproductive failure can be the result of pathology in one of the accessory glands rather than the result of any abnormality of sperm production.

TABLE 1: Contribution of secretions of each gland to make up seminal fluid.[12]

Source of secretion	*Ejaculate (%)*
Testes and efferent ducts	5
Prostate	13–33
Seminal gland	46–80
Bulbourethral glands	2–5

After ejaculation, mixing of components takes place and thus loss of any part of the semen sample during ejaculation can result in a false-positive abnormality in semen analysis.

Testicular Contribution

No major contribution is there toward volume so after vasectomy, semen volume does not change. The fluid from testis enters efferent ductules and is known as rete testis fluid. This fluid is rich in testosterone which is bound to androgen-binding protein (ABP) secreted by the Sertoli cells. Rete testis fluid also contains inhibin, ceruloplasmin, and transferrin.

Reduction in their concentration is seen in men with epididymal obstruction and Sertoli cell dysfunction.

Lactate dehydrogenase C4 is an enzyme released when sperms die or break up. Its presence may indicate damage of sperm during passage through the epididymal duct. L-carnitine and glycerophosphorylcholine are added through the passage in the epididymal duct.

Seminal Vesicles and their Secretions

Seminal vesicle secretions make 40–60% of the total ejaculatory volume. They have a major effect on the functions of sperm and physical properties of seminal plasma. The secretion is alkaline and contains fructose, prostaglandins, and fibrinogen-like substrate on which the enzyme vesiculase acts to induce clotting. The fructose component is absent in some mammals such as dogs and horses. Prostaglandins may act as calcium ionophores.

Prostatic fluid is biologically active and contains enzymes involved in semen clotting and liquefaction. It also contains protease, peptidase, and hyaluronidase. The prostatic secretions also contain the bacteriostatic amine called spermine, acid phosphatase, citrate, calcium, zinc, and magnesium. Crystallization may be seen when a semen sample is left for some time and pH of the seminal plasma is allowed to fall.

Secretions of the bulbourethral and urethral glands have little significance. Immunoglobulin G present in it is responsible for antisperm antibodies.

Endocrinology of the Testis

Leydig cells secrete testosterone and Sertoli cells secrete inhibin and ABP and follistatin in the testis. This is controlled by pituitary gonadotropins—luteinizing hormone (LH) and FSH which in turn are under control of the hypothalamic hormone, gonadotropin-releasing hormone (GnRH). LH acts on Leydig cells and FSH acts on Sertoli cells. A concentration gradient for testosterone thus exists between the interstitial tissue and the interior of the Sertoli cell. ABP testosterone complex is formed within the Sertoli cell and provides androgen for spermatogenesis. This ABP testosterone complex enters the lumen of the seminiferous tubules by exocytosis. Testosterone has a negative paracrine feedback action for LH on the pituitary–hypothalamic axis. Inhibin acts as negative feedback for FSH secretion. It is produced in two forms known as b-A and b-B. The subunit b-B is present only in male serum.

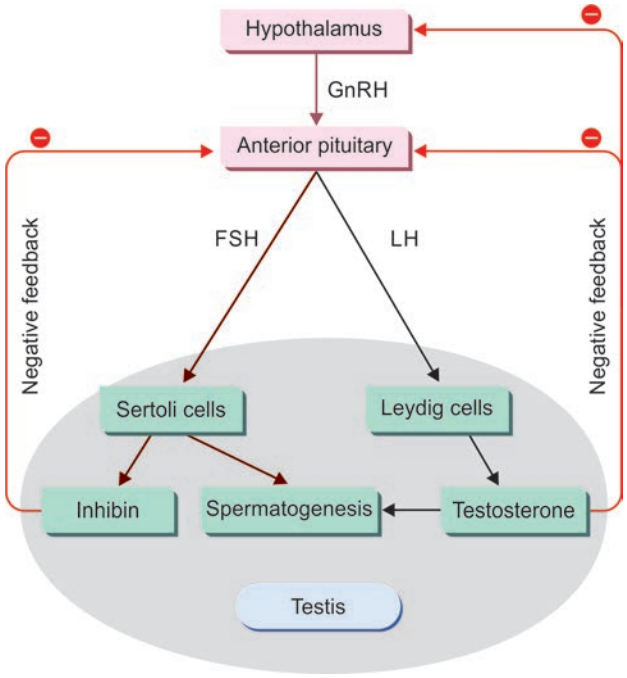

Fig. 10: Hormonal circuit for male reproduction.
(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)

There is an inverse relationship between inhibin B and FSH in male sera, but no such relationship exists between inhibin A and FSH levels in the serum of male patients. Damage to the Sertoli cell reduces inhibin B production and therefore will cause an increase in FSH secretion. Activin stimulates FSH production.[14]

Follistatin also suppresses FSH secretion, but it is much less potent than inhibin. Sertoli cells also produce modulating substance to act on Leydig cells. Thus, it is a complex interrelationship between cells and axis **(Fig. 10)**.

Histology

Interstitial tissue is interspersed with convoluted tubules and has tunica vasculosa testis tissue beneath tunica albuginea.

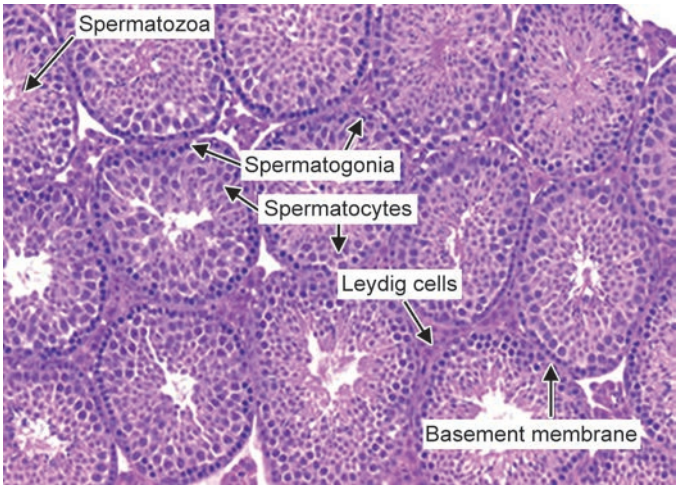

Fig. 11: Normal histology of testes.

Tubules are surrounded by three to four layers of smooth muscle cells or myoid cells **(Fig. 11)**.

Primary spermatocytes are visible in cross sections of seminiferous tubules. Incomplete cell divisions result in syncytium of cells with bridges of cytoplasm in between. Spermatids lie in the lumina of seminiferous epithelium. They are small with nucleus in eccentric position. During condensation, the nucleus becomes smaller and stains darker.

The nucleus of Sertoli cells is ovoid or angular and contains a large nucleolus. The nuclear membrane fold is characteristic of Sertoli cells, but not always visible in a light microscope. Tight junctions form a blood–testis barrier.

Spermatozoa pass through tubuli recti having low columnar epithelium and rete testis having flattened or cuboidal epithelium into a number of ductuli efferentes, containing both absorptive and ciliated cells.

The ductuli efferentes are lined by tall pseudostratified columnar epithelium. Toward the basal lamina are present a number of small nuclei, belonging to basal cells of the ductus epididymidis. These cells regenerate the epithelium.

The vas deferens is lined by pseudostratified columnar epithelium with long stereocilia.

Simple columnar epithelium of prostatic secretory ducts changes into transitional type near openings of ducts. Corpora amylacea in secretory alveoli are the characteristic features of prostate with round eosinophilic bodies.

Seminal vesicles mucosa is branched into anastomosing folds of honeycomb-like structure with columnar or pseudostratified lining. Lumen is filled with acidophilic secretion.

CONCLUSION

Within the milieu of producing progeny, female reproductive system has four major functions i.e. to produce egg, transport and sustain cells, to produce hormones and nurture developing embryo. These functions are carried through ovaries, fallopian tubes, uterus and accessory organs. Like that of female, male reproductive system also has a role in formation of a new individual i.e. to fulfil reproduction. Male reproductive system has one pair testes, excretory ducts network, glands like prostate, seminal vesicles, bulbourethral glands and penis.

KEY POINTS

- The human reproductive system is a complex arrangement of specialized organs.
- These organs function efficiently under the influence of neural and hormonal signals together with each other to produce a new life.

CHAPTER 2

Regulation and Physiology of Menstrual Cycle

Arveen Vohra

INTRODUCTION

The normal menstrual cycle is one of the most complex, elegant, and yet one of the simplest physiologic processes. It is mandatory for a clinician and infertility consultant to completely understand the menstrual cycle. The menstrual cycle, under the control of the endocrine system, is necessary for reproduction. It is the cycle of changes that occurs in the ovary and uterus for the purpose of sexual reproduction, being essential for the production of eggs and for the preparation of the uterus for pregnancy. The normal menstrual cycle is the orderly cyclic hormone production and parallel proliferation of the uterine lining in preparation for implantation of the embryo failing, which it prepares for the next cycle.

Menstruation is defined as the cyclic, orderly sloughing of the uterine lining in response to the interactions of hormones produced by the hypothalamus, pituitary, and ovaries. Menarche is typically followed by 5–7 years of relatively long cycles that gradually decrease in length and become regular. Variations in cycle length reflect differences in the length of the follicular phase, as the luteal phase is fairly consistent.

In humans, the menstrual cycle is a monthly cycle that averages 28 days per cycle. It varies in different women and even in the same woman during various cycles. Menstrual cycle is counted from the first day of menstrual bleeding. Each menstrual cycle can be divided into three phases based on the following ovarian and endometrial events:

1. *Ovarian cycle (events in the ovary):* It consists of the follicular phase, ovulation, and luteal phase along with the luteal–follicular transition phase.
2. *Uterine cycle (events in the uterus):* It consists of menstruation, proliferative phase, and secretory phase.

This chapter encompasses in detail the neuroendocrinology and physiology of menstrual cycle, which in synchrony are responsible for the regulation of the menstrual cycle in women. The genomic profiling, which has now highlighted the various hormonal and the hormone receptor polymorphisms, is also discussed along with newer concepts in primordial follicle activation.

REPRODUCTIVE NEUROENDOCRINOLOGY

Introduction

The female and male reproductive systems function as an orchestra in harmony with a set of reproductive hormones under the influence of regulatory hormones secreted by the hypothalamus and pituitary gland. Initially, the pituitary gland was considered as the master of the endocrine orchestra, but recently, the hypothalamus has equitably replaced this status. The hypothalamus exerts its influence via neurotransmitters transported to the pituitary gland by means of a portal vessel network in response to both peripheral and central nervous system signals.

The hypothalamus and the pituitary are essential for the operation of the menstrual cycle, in synchrony with the endocrine feedback by the ovary on the anterior pituitary that leads to ovulation. The physiology of the menstrual cycle is dependent on signaling whereby the "ovarian clock" modulates hypothalamic–pituitary function as well as endometrial proliferation and secretion.

The predominant hormones involved in the menstrual cycle are gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), estrogen, and progesterone. GnRH is secreted by the hypothalamus, the gonadotropins FSH and LH are secreted by the anterior pituitary gland, and estrogen and progestins are secreted at the level of the ovary. GnRH stimulates the release of FSH and LH from the anterior pituitary, which in turn stimulate the release of estrogen and progestin at the level of the ovary.

Hypothalamo-hypophyseal Portal Circulation

Hypothalamus

The hypothalamus is a small, cone-shaped neural structure situated at the base of the brain above the optic chiasma

TABLE 1: Pituitary releasing factors from the hypothalamus.	
Hypothalamic hormone	***Action***
Gonadotropin-releasing hormone (GnRH)	Controls the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)
Corticotropin-releasing hormone (CRH)	Controls the release of adrenocorticotropic hormone (ACTH)
Growth hormone-releasing hormone (GHRH)	Regulates the release of growth hormone (GH)
Thyrotropin-releasing hormone (TRH)	Regulates the secretion of thyroid-stimulating hormone (TSH)

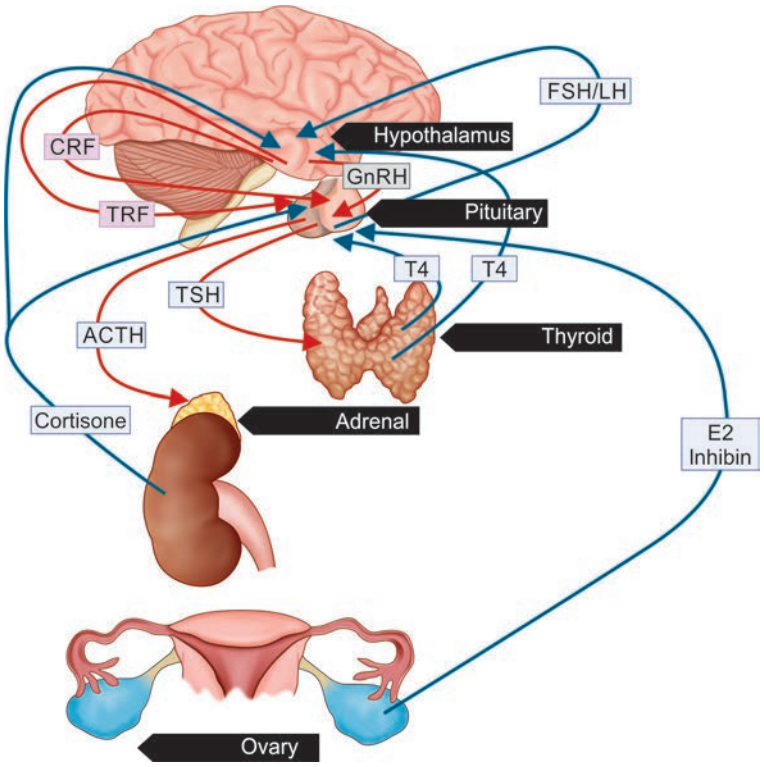

Fig. 1: Pituitary-releasing factors that control the endocrine function of the ovaries, thyroid, and adrenal glands. Note the feedback from the target hormones (marked in blue lines).
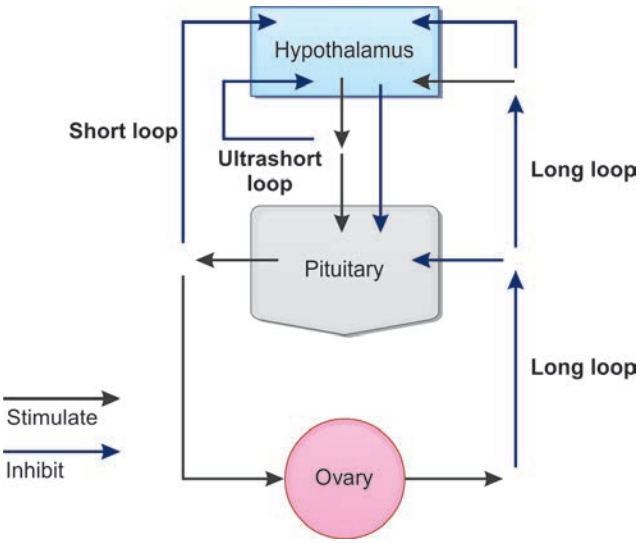
(ACTH: adrenocorticotropic hormone; CRF: corticotropin-releasing factor; E2: estradiol; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing factor; LH: luteinizing hormone; TRF: thyrotropin-releasing factor; TSH: thyroid-stimulating hormone; T4: thyroxine)

and below the third ventricle forming the lower part of diencephalon. It is connected directly to the pituitary gland and is the source of many pituitary secretions.

The hypothalamus has peptidergic neural cells that secrete releasing and inhibiting hormones. These cells resemble both neurons and endocrine gland cells and respond to signals in the bloodstream as well as to neurotransmitters within the brain in a process known as *neurosecretion*. These neurotransmitters are secreted at the nerve terminal. Neuroendocrine agents originating in the hypothalamus have positive stimulatory effects on growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), and the gonadotropins **(Table 1 and Fig. 1)**.

Several levels of feedback to the hypothalamus exist and are known as the long, short, and ultrashort feedback loops **(Flowchart 1)**. The long feedback loop is composed of endocrine input from circulating hormones, just as feedback

Flowchart 1: Hypothalamic–pituitary–ovary feedback loop mechanisms.



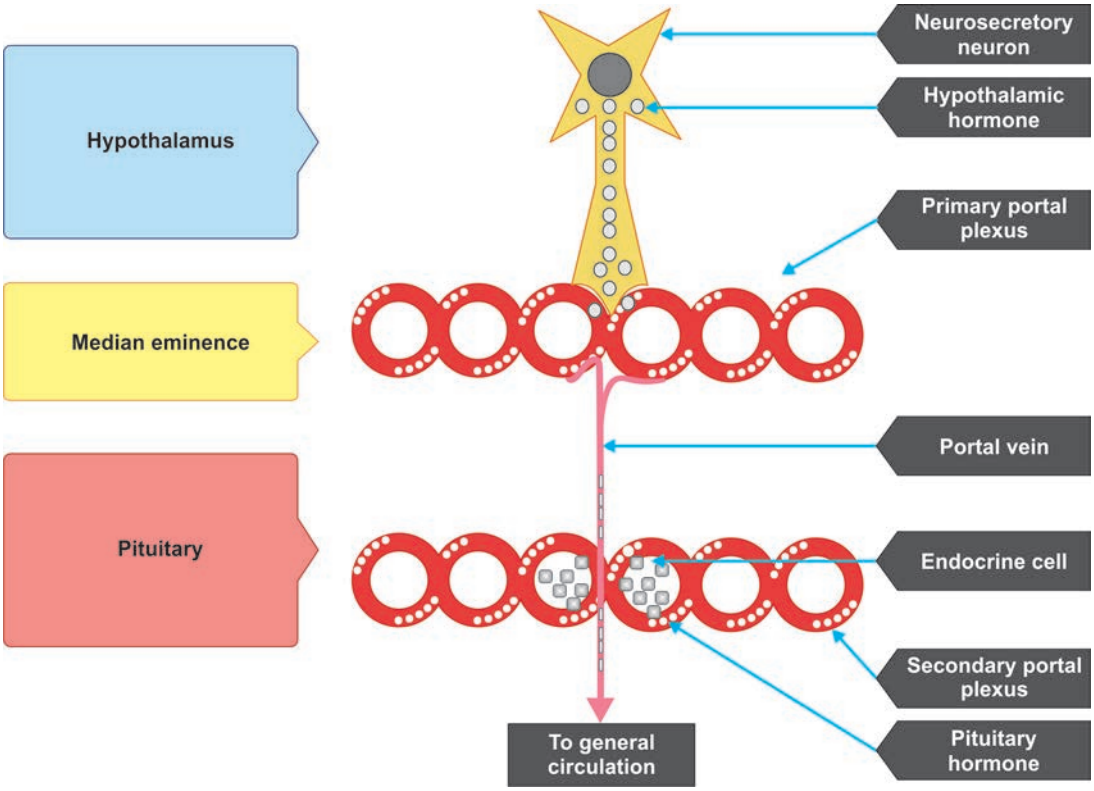


Fig. 2: Hypothalamic–pituitary axis with the portal system.

of androgens and estrogens on to steroid receptors is present in the hypothalamus. In short-loop feedback, pituitary hormones send feedback to the hypothalamus and serve important regulatory functions. Hypothalamic secretions may directly feedback to the hypothalamus itself in an ultrashort feedback loop.[1,2]

Pituitary

The pituitary consists of two lobes—anterior (adenohypophysis) and posterior (neurohypophysis), which are structurally different. The unique fenestrated capillaries in this region eliminate the blood–brain barrier in the median eminence and permit bidirectional feedback control. The anterior pituitary is under the influence of the hypothalamus by means of neurohormones released into this portal circulation. There also exists retrograde flow so that pituitary hormones can be delivered directly to the hypothalamus, creating the opportunity for pituitary feedback on the hypothalamus. Short vessels that originate in the posterior pituitary that in turn receive their arterial supply from the inferior hypophyseal arteries provide an additional blood supply **(Fig. 2)**.

HORMONES IN FEMALE REPRODUCTION

Gonadotropin-releasing Hormone

Gonadotropin-releasing hormone (also called luteinizing hormone-releasing hormone or LHRH) is the controlling factor for gonadotropin secretion. There is a single neurohormone (GnRH) for both FSH and LH. It is a decapeptide with the gene located on chromosome 8p and works through its own receptor, encoded on chromosome 4q. It is produced by neurons with cell bodies primarily in the arcuate nucleus of the hypothalamus and in many extrapituitary tissues, such as the ovarian follicle and the placenta. GnRH has autocrine–paracrine functions throughout the body **(Fig. 3)**.

Pulsatile secretion of GnRH: The half-life of GnRH is only 2–4 minutes. A prominent feature of the reproductive system is the absolute requirement for pulsatile secretion of GnRH from the arcuate nucleus of the hypothalamus into the pituitary portal system for normal gonadotropin secretion. The increase in the GnRH pulses marks the onset of puberty. GnRH is unique as it regulates the secretion of two hormones—FSH and LH—and must be secreted in a pulsatile fashion within a critical range in frequency and amplitude. Knobil et al. showed that in hypothalamic-lesioned monkeys receiving GnRH, intermittent stimulation of the pituitary results in secretion of LH and FSH, whereas constant GnRH stimulation leads to suppression of gonadotropin levels.[3]

The frequency of GnRH secretion is once per 90 minutes in the early follicular phase, which increases to once per 60–70 minutes in the late-follicular phase. Lower GnRH pulse frequencies favor FSH secretion and higher frequencies favor LH secretion. Pulsatile GnRH secretion is more frequent but lower in amplitude during the follicular phase.

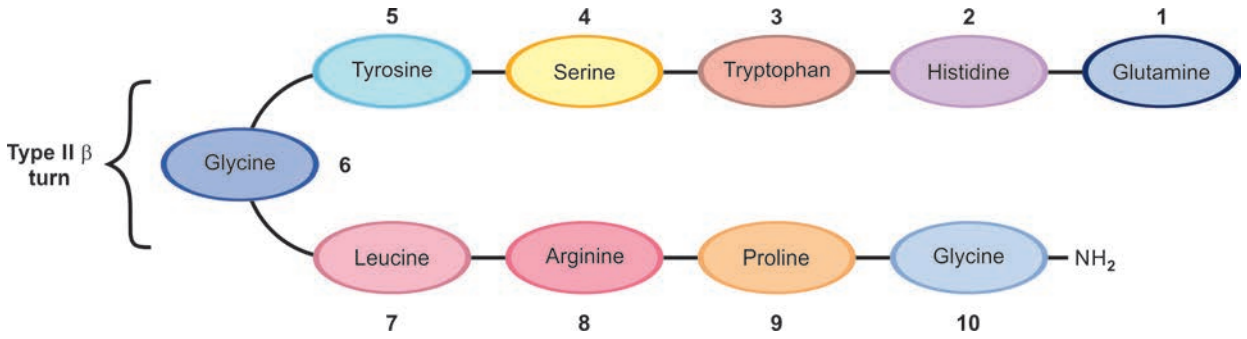

Fig. 3: Structure of gonadotropin-releasing hormone molecule.

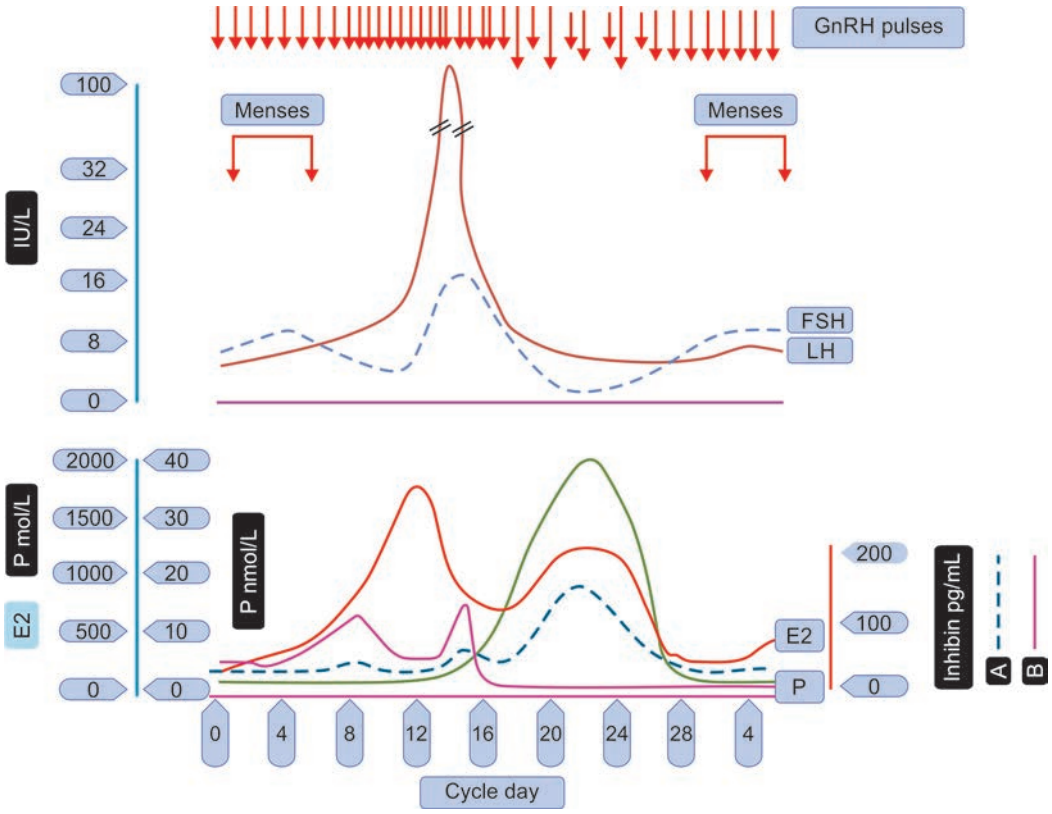

Fig. 4: Gonadotropin-releasing hormone (GnRH) pulsatility affecting gonadotropin and steroid release during menstrual cycle. (E2: estradiol; FSH: follicle-stimulating hormone; LH: luteinizing hormone; P: progesterone)

An increase in frequency and amplitude during mid-cycle favors LH surge necessary for ovulation. Slowing of pulse frequency in the late-luteal phase favors FSH synthesis and allows the rise in FSH essential for the next cycle **(Fig. 4)**.

Control of GnRH pulses: Catecholamines such as norepinephrine, dopamine, and serotonin, and transmitters, such as opiates and prostaglandins, also appear to influence the secretion of GnRH from the hypothalamus. Norepinephrine seems to stimulate GnRH release, whereas dopamine, serotonin, endogenous opioids, and corticotropin-releasing hormone (CRH) appear capable of inhibiting or suppressing GnRH, as witnessed by the association of stress with hypothalamic amenorrhea in some women. Biogenic catecholamines modulate GnRH pulsatile release by influencing the frequency (and perhaps the amplitude) of GnRH discharge **(Flowchart 2)**.

The *dopamine* tuberoinfundibular tract arising within the medial basal hypothalamus and terminating in the median eminence provides the dopaminergic effect on the pituitary. Dopamine is directly secreted into the portal blood, thus behaving like a neurohormone. It directly suppresses GnRH activity and is transported via the portal system to directly and specifically suppress pituitary prolactin secretion.

Neuropeptide Y (NPY), a polypeptide, stimulates appetite, decreases heat production, and increases insulin and cortisol secretion. The secretion and gene expression of NPY in hypothalamus are regulated by gonadal steroids.

It stimulates pulsatile release of GnRH and potentiates gonadotropin response to GnRH.[4]

Kisspeptin is a hypothalamic neuropeptide encoded by the gene *Kiss1*, which has recently emerged as a key central regulator of gonadotropin secretion. The kisspeptin neurons have estrogen and progesterone receptors and are essential for the normal development of puberty.[5]

Kisspeptins and their receptors are expressed by neurons in the arcuate and anteroventral periventricular nuclei of the hypothalamus. **Figure 5** shows structure of kisspeptin.

Puberty is regulated by the maturation of kisspeptin neurons as well as by interactions between kisspeptins and leptin.[6]

The obligatory kisspeptin signaling for normal puberty is evidenced by a failure to progress through puberty in individuals with mutations in genes encoding kisspeptin and its receptor, G-protein coupled receptor 54 (GPR54).[7]

Neurokinin B (NKB) and dynorphin (Dyn) are cotransmitters of kisspeptin signaling **(Figs. 6A to D)**.[6]

Sex steroids can regulate *Kiss1* gene expression both positively and negatively, depending on the physiological environment. Some studies have demonstrated that administration of kisspeptin, as the longer kisspeptin fragment kisspeptin-54 (Kp54), stimulates gonadotropin secretion in healthy women and in women with hypothalamic amenorrhea. However, another study suggested that kisspeptin-10 does not stimulate gonadotropin secretion in women.[8]

Various studies have shown that intravenous infusion of kisspeptin-10 can stimulate LH pulse frequency in men. This is, however, still a controversial area where more research is needed.[9] Assessment of gonadotropin response to the administration of exogenous kisspeptin provides a novel investigative tool to assess GnRH neuronal function in vivo in reproductive health medicine **(Figs. 7A to C)**.

Kisspeptin agonists may be used to localize lesions causing hypothalamic–pituitary–gonadal axis dysfunction and evaluate the gonadotrophic potential of subfertile individuals. Kisspeptin antagonists may be used as contraceptives in women through the prevention of premature luteinization during in vitro fertilization and also in the treatment of sex steroid-dependent diseases and metastatic cancers.

The role of kisspeptins as ovulation triggers is also being studied extensively.

KISS1R/Kiss1r is desensitized with continuous kisspeptin exposure. In animals, intermittent kisspeptin administration can raise LH levels. However, LH gets suppressed after continuous administration of kisspeptin, as it induced long-lasting depolarization in GnRH neurons, followed by

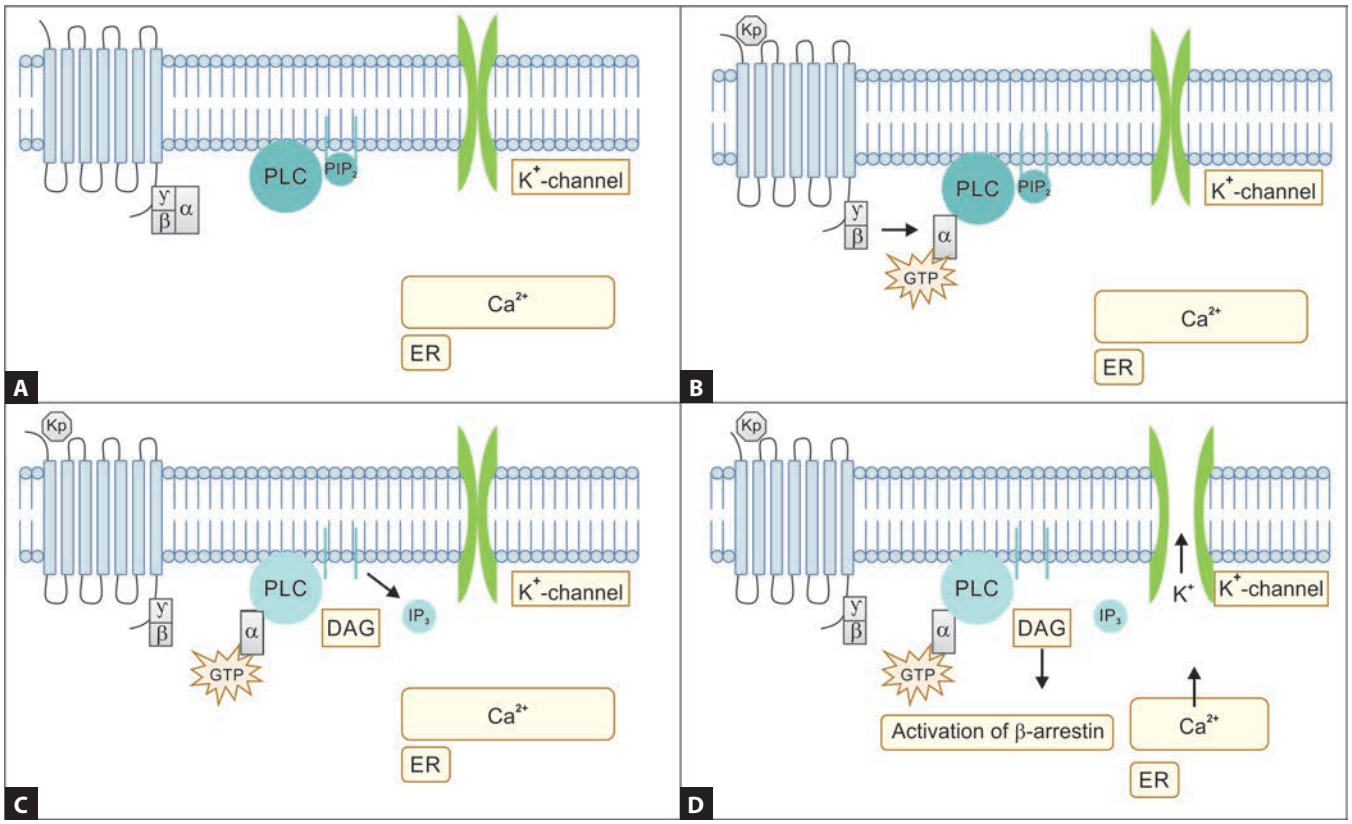


Figs. 6A to D: (A) KISS1R in the dormant state; (B) kisspeptin ligand (Kp) binding activating the G protein subunit, Gq/11α, and subsequently phospholipase C (PLC); (C) PLC activation leading to the formation of inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG); (D) IP_3 causing the release of intracellular calcium (Ca^{2+}) from the endoplasmic reticulum (ER). PLC-independent mechanisms open the potassium (K^+) channels. These events depolarize the kisspeptin neuron. (GTP: guanosine triphosphate; PIP_2: phosphatidyl inositol bisphosphate)[6]

desensitization. This desensitization is not due to GnRH depletion but due to clathrin-mediated internalization of arrestin and KISS1R in internalized vesicles after kisspeptin activation.[6]

Activins, Inhibins, and Follistatins

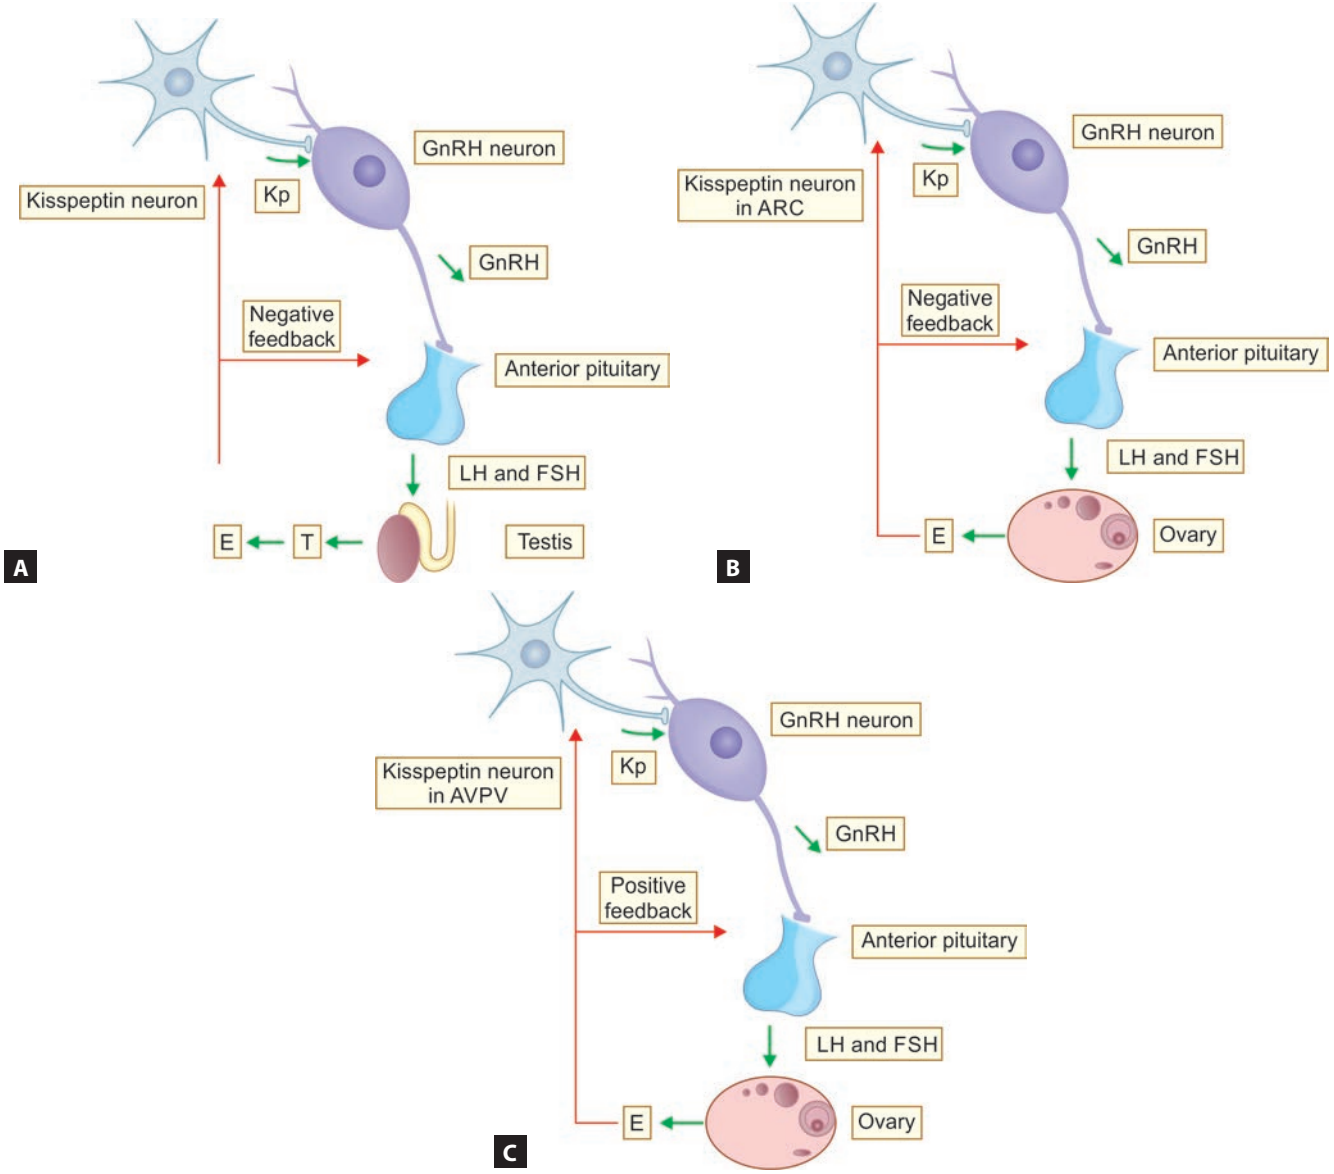
Intrapituitary cytokines and growth factors provide an autocrine–paracrine system for regulating pituitary cell development and replication as well as pituitary hormone synthesis and secretion. Activins and inhibins are peptide members of the transforming growth factor-beta (TGF-β) superfamily.

Inhibins are secreted by granulosa cells. FSH stimulates secretion of inhibin, and inhibin suppresses FSH secretion. Inhibin blocks synthesis and secretion of FSH, prevents upregulation of GnRH receptors, and at high levels, may also promote degradation of gonadotropins.

The inhibins, named for their inhibitory control of FSH, are composed of two dissimilar peptides linked by disulfide bonds. There are two forms of inhibin that are composed of one of the two inhibin β subunits and a closely related α subunit to form inhibin A or inhibin B. Inhibin B, peaking in mid-follicular phase, amplifies the withdrawal of FSH from other follicles allowing emergence of the dominant follicle. After appearance of LH receptors and formation of corpus luteum (CL), it comes under control of LH and inhibin A dominates. Inhibin has little or no effect on GH, ACTH, and prolactin production.[10,11] Inhibin blocks the synthesis and secretion of FSH, prevents the upregulation of GnRH receptors, and at high levels, may also promote degradation of gonadotropins.

Activins are derived from granulosa cells and pituitary gonadotrophs. They are composed of two subunits identical to the β subunits of inhibin A and B. They augment FSH secretion but inhibit prolactin, ACTH, and GH responses.[11-13] Marked increase in activin tone helps in FSH-dependent follicle selection. Activin increases pituitary response to GnRH by enhancing GnRH receptor formation. The effects of activin are blocked by inhibin and follistatin.[14,15]

Follistatin, also called the FSH-suppressing protein, is a glycopeptide secreted by a variety of pituitary cells, including the gonadotrophs. Its main action is inhibiting FSH synthesis, secretion, and the FSH response to GnRH, probably by binding to and decreasing activity of activin.[16,17] Activin stimulates follistatin production and inhibin prevents this response.



Figs. 7A to C: The diagram shows that (A) kisspeptin (Kp) stimulates gonadotropin-releasing hormone (GnRH) secretion and subsequent gonadotropin release. Testosterone (T) is aromatized to estrogen (E), which exerts negative feedback on the anterior pituitary gland and hypothalamus. (B) E exerts negative feedback on GnRH via Kp neurons in the arcuate nucleus (ARC). (C) E exerts positive feedback on GnRH via Kp neurons in the anteroventral periventricular nucleus (AVPV).
(FSH: follicle-stimulating hormone; LH: luteinizing hormone)

Endogenous Opioids and Effects on Gonadotropin-releasing Hormone

The endogenous opioids are three related families of naturally occurring substances produced in the CNS that represent the natural ligands for the opioid receptors.[18-20] They exert their effects by binding to the G protein-coupled receptors, delta opioid receptor (DOR), kappa opioid receptor (KOR), and mu opioid receptor (MOR). These include:

- *Endorphins* (α, β, γ) are produced in the hypothalamus from the precursor proopiomelanocortin (POMC) with morphine-like activity and help in regulation of temperature, appetite, mood, and behavior.
- *Enkephalins* are most widely distributed opioid peptides in the brain and function primarily in regulation of the autonomic nervous system. Proenkephalin A is the precursor for the two enkephalins of primary importance: Methionine–enkephalin and leucine–enkephalin.
- *Dynorphins* are produced from the precursor prodynorphin that serves a function similar to that of the endorphins, producing behavioral effects and exhibiting high analgesic potency.

Endorphins appear to inhibit GnRH release within the hypothalamus, resulting in inhibition of gonadotropin secretion but have no effect on the pituitary response to GnRH.[21] The principal endogenous opiates affecting GnRH

release are β-endorphin and Dyn, probably by modulation of the catecholamine pathway, principally norepinephrine. β-endorphins are 5–10 times more potent than morphine. Ovarian sex steroids can increase the secretion of central endorphins, further depressing gonadotropin levels.[22] Endorphin levels vary significantly throughout the menstrual cycle, with peak levels in the luteal phase and a nadir during menses.[23] The dysphoria experienced by some women in the premenstrual phase of the cycle may be related to a withdrawal of endogenous opiates.

The emerging evidence indicates the participation of opioid peptides in the regulation of reproductive function through a direct local action within reproductive tissues, mainly the endometrium. Various studies have reported the role of these peptides in different phases of endometrial development and implantation; however, more research is needed.[24]

Prolactin

Prolactin is a 198 amino acid polypeptide, with the gene expression occurring in the lactotrophs of the anterior pituitary gland, decidualized endometrium, and the myometrium. The prolactin secreted in these various sites is identical, but differences in messenger ribonucleic acid (mRNA) indicate differences in gene regulation. Three types of prolactin have been identified based on size and structural modifications that are the result of glycosylation, phosphorylation, additions and deletions—little, big, and big–big prolactin.

Prolactin secretion is under tonic inhibitory control by the hypothalamic secretion of dopamine. The dopamine action in the pituitary is mediated by receptors coupled to inhibition of adenylate cyclase. Among the five forms of the dopamine receptor divided into two functional groups, D1 and D2, the D2 type is the predominant receptor in the anterior pituitary gland. Prolactin secretion follows a circadian rhythm, with the maximum secretion 5–8 hours after the onset of sleep. The release is pulsatile with the frequency of pulses reaching maximum in the mid-cycle and then declining in the luteal phase.

Prolactin homeostasis is regulated mainly by prolactin itself, feeding back on the dopamine-releasing neurons. Prolactin gene transcription is principally stimulated by estrogen, thyroid-releasing hormone (TRH), breast manipulation, drugs, stress, exercise, hormones including TRH (explaining the hyperprolactinemia seen with TRH elevation in hypothyroidism), vasopressin, γ-aminobutyric acid (GABA), β-endorphin, vasoactive intestinal peptide, epidermal growth factor (EGF), angiotensin II, and possibly GnRH.[25,26]

It has a direct action on the ovaries, which is responsible for the menstrual irregularities associated with hyperprolactinemia **(Box 1)**.

BOX 1: Effects of hyperprolactinemia on female reproductive function.

- Disrupts normal follicular development
- Inhibits aromatase enzyme
- Premature destruction of the corpus luteum
- Atresia of the dominant follicle
- Inhibits progesterone synthesis by the corpus luteum
- Induces uterine adenomyosis

Other Factors

Prostaglandins and catechol estrogens possibly act as neuromodulators by altering the function of catecholamines through inhibition of tyrosine hydroxylase and competing for the enzyme catechol-O-methyltransferase.

Leptin induces weight loss due to decreased appetite and food consumption and an increase in heat production and activity, associated with a decrease in the NPY expression. The *Lep* gene in humans is located on chromosome 7q31 and leptin receptor gene is located on chromosome 1. Fasting and exercise decrease leptin secretion and increase NPY in the arcuate nucleus. The NPY neurons stimulate feeding and inhibit heat production by inhibiting sympathetic nervous activity.[27]

Ghrelin is a complex hormone that stimulates the release of GH and is secreted mainly in the stomach, intestine, pituitary, hypothalamus, kidney, ovary, testes, and placenta. It is the only hormone known that stimulates food intake. The regulation of food intake occurs via the NPY pathway, with ghrelin and leptin having opposing actions. It is reduced with food intake and increased with fasting.

Differential Control of Follicle-stimulating Hormone and Luteinizing Hormone Secretion

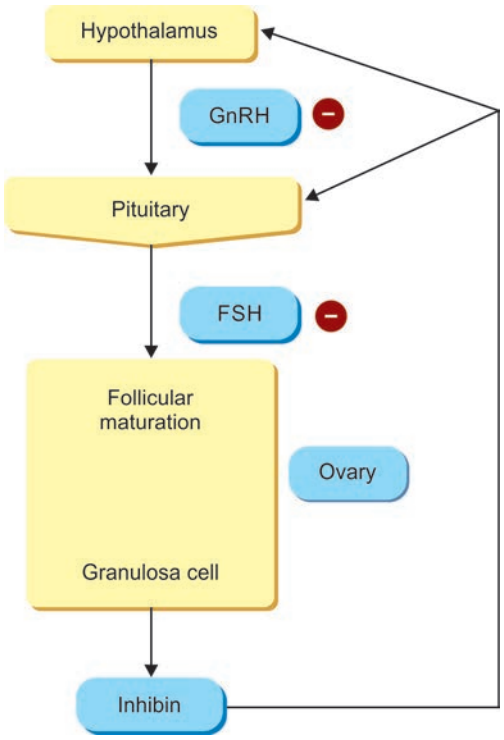
The anterior pituitary secretes the major hormone releasing factors—FSH, LH, TSH, and ACTH along with GH and prolactin. FSH and LH are both glycoproteins that share identical α subunits along with TSH and placental human chorionic gonadotropin (hCG) and differ only in the structure of their β subunits, which confers receptor specificity.

Although secreted from common gonadotrophs, FSH and LH have markedly different functions in the control of ovarian physiology. The divergent control of FSH and LH is achieved through a combination of differential control of their synthesis and secretion by GnRH. The preferential control of FSH synthesis is by the activin/follistatin system, and differential feedback by ovarian steroids and inhibins **(Flowchart 3)**.

Follicle-stimulating Hormone

Follicle-stimulating hormone is essential for follicular growth. It induces estrogen and progesterone secretion at the level of the ovary by activating aromatase and p450 enzymes and exerts negative feedback on GnRH secretion.

Flowchart 3: Role of follicle-stimulating hormone (FSH) and inhibin in controlling ovarian function.



(GnRH: gonadotropin-releasing hormone)

BOX 2: Functions of follicle-stimulating hormone (FSH) in menstrual cycle.

- Selection and maturation of dominant follicle
- Proliferation of granulosa cells
- Aromatization within granulosa cells
- Induction of FSH and LH receptors on granulosa cells
- Production of autocrine–paracrine factors—activin and inhibin
- FSH surge helps in ovulation
- Prevents germ cells from atresia in luteal–follicular transition

(LH: luteinizing hormone)

FSH further induces the proliferation of granulosa cells and expression of FSH and LH receptors on granulosa cells. The rise in FSH during the LH surge helps in ovulation by stimulating plasminogen activator activity **(Box 2)**.

Luteinizing Hormone

Luteinizing hormone is secreted by the anterior pituitary gland and is required for both growth of preovulatory follicles, and ovulation and luteinization of the dominant follicle. During the follicular phase of the menstrual cycle, LH induces androgen synthesis by theca cells that is essential for robust steroidogenesis; stimulates proliferation, differentiation, and secretion of follicular thecal cells; and increases LH receptors on granulosa cells. The preovulatory LH surge drives the oocyte into the first meiotic division and initiates luteinization of thecal and granulosa cells. The resulting CL produces high levels of progesterone and some estrogen.

TABLE 2: Impact of different concentrations of luteinizing hormone (LH) on the menstrual cycle.

Effects below LH threshold	*Effects within LH window*	*Effects above LH ceiling*
Absent paracrine signaling between granulosa and theca	Normal follicular growth and development	Suppression of granulosa proliferation
Inadequate androgen and estrogen synthesis	Adequate granulosa proliferation and functional maturation	Follicular premature luteinization
Compromised oocyte maturation	Normal estrogen and androgen biosynthesis	Compromised oocyte development
	Optimum oocyte maturation	

The LH-dependent phase of preovulatory follicular development proceeds normally only if LH is present at concentrations within the *LH window*, which is over the threshold level and beneath the ceiling value **(Table 2)**.

Pharmacogenomics—Follicle-stimulating Hormone and Luteinizing Hormone Polymorphisms

Response to hormones depends on variations in the gene sequence of the receptor or the ligand. Association studies assess whether a gene variant is present more often than expected in a population and evaluate whether a medical condition or a phenotype is associated with a gene variant. Gene variants may consist of insertions or deletions of one or more bases, or may be single-base changes, known as single-nucleotide polymorphisms (SNPs). A genetic variant is considered a polymorphism when it reaches a frequency higher than 1% in a sample population; otherwise, it is considered a gene mutation.

With the advent of pharmacogenomics, various polymorphisms have been identified that may lead to impaired responses to various hormones (FSH and LH) and steroids (estrogen and progesterone). The effects of variations in different biochemical pathways involved in estrogen production and action (aromatase and estrogen receptor genes), folliculogenesis [bone morphogenetic protein 15 (BMP15), growth differentiation factor-9 (GDF-9), and anti-Müllerian hormone (AMH)], and other areas have been observed. These variations may alter the response to controlled ovarian stimulation (COS). In this chapter, we will discuss about the common variations in FSH and LH hormones and their receptors.

Follicle-stimulating Hormone Polymorphism

With advancements in the pharmacogenomics, various polymorphisms have been identified that attribute to altered function and efficacy of FSH.

Follicle-stimulating hormone works by binding to its specific receptor, the follicle-stimulating hormone receptor (*FSHR*, gene ID: 2492, location: 2p21–p16, OMIM: 136435). Research now highlights the role of common genetic variants of *FSHR* and FSH beta subunit (*FSHB*, gene ID: 14308, location: 11p13, OMIM: 136530) in the determination of individual serum hormone levels and target organ response. However, controversies exist concerning the impact of genetic polymorphisms of these genes on gonadotropin treatment and some contradictory findings have been published, necessitating further research.[28]

The current evidence suggests that the combination of *FSHR* and *FSHB* genotypes is predicted to have a much stronger impact than either one alone, on both male and female gonadal function. This is because about 20% of people are carriers of the allele combinations associated with lower serum FSH levels and lower *FSHR* expression or activity. The advent of powerful, sensitive, and inexpensive techniques assessing several SNPs simultaneously will be very helpful in the identification of the patients at infertility risk.[29]

The *FSHR* gene is located at chromosome region 2p21 and consists of 10 exons. A large number of SNPs in the gene have been identified (1,488 SNPs). The most common and well-studied SNPs in *FSHR* are Thr307Ala (rs6165) and Asn680Ser (rs6166). Both polymorphisms are located within exon 10, where Thr307Ala is located in the extracellular domain of the protein (the hormone-binding area) and Asn680Ser is located in the intracellular domain. These two polymorphisms are in near complete linkage disequilibrium.

The *FSHR* 680Ser variant is usually associated with elevated basal levels of FSH and elevated gonadotropin requirements during COS. A29 polymorphism reduces expression of *FSHR*. S680 is a "resistance factor" to FSH stimulation determining a higher ovarian threshold of the gonadotropin and reflecting a different pattern of ovarian secretion during the cycle transition phase. Another *FSHR* polymorphism, G/A, located in the promoter region at position 29, could modulate ovarian response to FSH and may require higher gonadotropin doses for COS.

The Asn680 allele has been found to be a risk factor and predictor of severity of symptoms for ovarian hyperstimulation syndrome (OHSS).[29]

Luteinizing Hormone Polymorphism

Luteinizing hormone beta (LHB) polypeptide encodes the beta subunit of the hormone and determines the specificity of binding to luteinizing hormone/choriogonadotropin receptor (LHCGR). LH has a key role in steroidogenesis and folliculogenesis (with FSH), ovulation, and luteinization.

The *LHB* gene is located at chromosome region 11p13 and has three exons. A number of polymorphisms in the gene have been identified (179 SNPs). Three polymorphisms in the coding area have been found to lead to decreased LH activity: Polymorphisms Trp8Arg and Ile15Thr have been associated with slightly suppressed fertility, menstrual irregularities causing infertility and recurrent pregnancy loss, and the Gly102Ser SNP has been associated with infertility and menstrual disorders.[29]

Luteinizing hormone receptor: LH exerts its actions by binding to its cell surface receptor, *LHR* (also known as LHCGR, as LH and hCG bind to the same receptor). The *LHR* gene is located at chromosome region 2p21, consisting of 11 exons, and several common polymorphisms have been identified (over 520 SNPs). Polymorphisms 18insLeuGln, Asn291Ser, and Ser312Asn in the *LHR* gene are associated with increased receptor activity, and their possible effects in steroid hormone-related diseases have been suggested, though still not established.[29]

Hypothalamic–Pituitary–Ovarian Axis

In the presence of a GnRH pulse, the pituitary and ovarian hormones exert mutual control over the circulating levels of one another. The complex interactions between pituitary and ovarian hormones involve forward control, positive feedback, and negative feedback mechanisms and serve to sustain a self-perpetuating monthly endocrine cycle **(Fig. 8)**.

Ovarian Feedback on the Hypothalamus and Pituitary

Estrogen

Estrogen produced at the level of the ovary is crucial for the development of the antrum and maturation of the

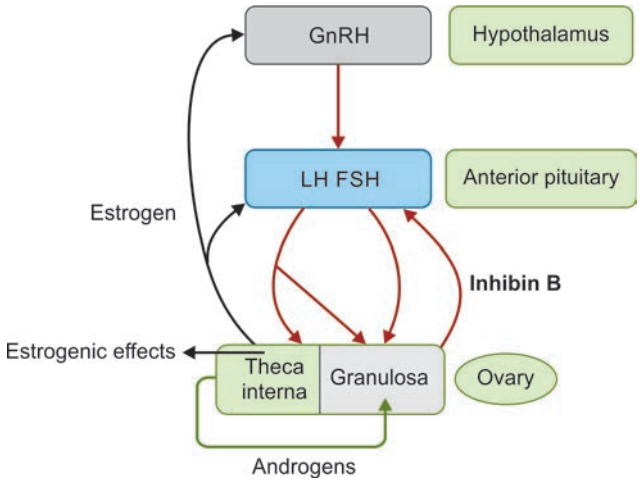


Fig. 8: Hypothalamic–pituitary–ovarian axis.
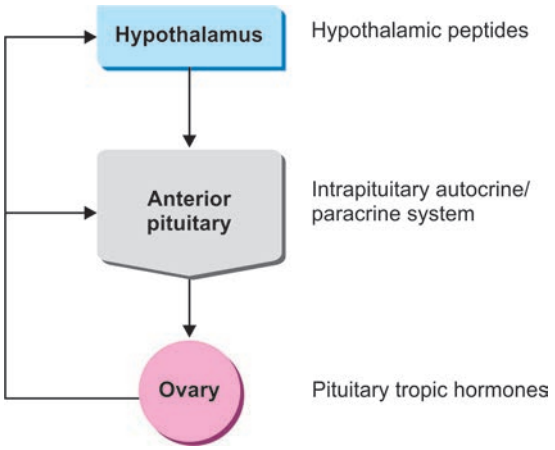
(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)

Flowchart 4: Hypothalamic and ovarian control of pituitary secretions.



Graafian follicle. Estrogen is predominant at the end of the follicular phase, directly preceding ovulation. Estradiol, the most potent and abundant estrogen, is primarily derived from androgens produced by thecal cells. The androgens migrate from the theca cells to the granulosa cells, where they are converted into estradiol by aromatase enzyme. The actions of estradiol include induction of FSH receptors on granulosa cells, proliferation and secretion of follicular and thecal cells, induction of LH receptors on granulosa cells, and proliferation of endometrial stromal and epithelial cells. At low circulating levels, estrogens exert negative feedback on FSH and LH secretion, and at very high levels, estrogens exert positive feedback on LH secretion.[30] Estrogen further induces proliferation of estrogen-converting granulosa cells and synthesis of estrogen receptors, establishing a positive feedback loop on itself. In the endometrial cycle, estrogen induces proliferation of the endometrial glands **(Flowchart 4)**.

Progesterone

Progesterone is secreted at the level of the ovary, primarily by luteinized follicles. The levels increase just prior to ovulation and peak 5–7 days postovulation. It stimulates the release of proteolytic enzymes from thecal cells that ultimately prepare for ovulation. Progesterone further induces migration of blood vessels into the follicle wall and stimulates prostaglandin secretion in follicular tissues. During the luteal phase, progesterone induces swelling and increased secretion of the endometrium **(Flowchart 4)**.

Gonadotropin-releasing Hormone Dynamics and Pituitary Responsiveness

The interplay between pituitary and ovarian hormones gives rise to a stereotyped pattern of hormone levels during the menstrual cycle. The graph shows relative hormone trends in an average 28-day cycle **(Fig. 9)**.

Physiology of Menstrual Cycle

Following the exhaustive discussion about the neuro-endocrinological control and the hypothalamic–pituitary–ovarian (HPO) axis, the understanding of the physiology of menstrual cycle becomes comprehensive. The menstrual cycle is divided into four phases based on the ovarian cycle as described below **(Fig. 10)**.

1. Follicular phase (further classified into early- and late-follicular phases)
2. Ovulatory phase
3. Luteal phase
4. Luteal–follicular transition phase.

Based on the uterine cycle, it may be divided into:

- Proliferative phase
- Secretory phase
- Menstruation

Ovarian Cycle

The menstrual cycle is divided into four phases based on the ovarian cycle.

Follicular Phase

The follicular phase of the menstrual cycle spans from the first day of menstruation until ovulation. The primary goal is to develop a viable follicle capable of undergoing ovulation. The early events of the follicular phase are initiated by a rise in FSH levels at the luteal–follicular transition attributed to a decrease in progesterone, estrogen, and inhibin levels at the end of the previous cycle and the subsequent removal of inhibition of FSH. Rise of FSH rescues a cohort of preantral follicles from apoptosis—a phenomenon called recruitment, which requires a certain minimum concentration of FSH called *FSH threshold*. The time frame for which this threshold surpasses the level of FSH needs to be maintained for follicular recruitment and growth. This is called *FSH window* **(Fig. 11)**.

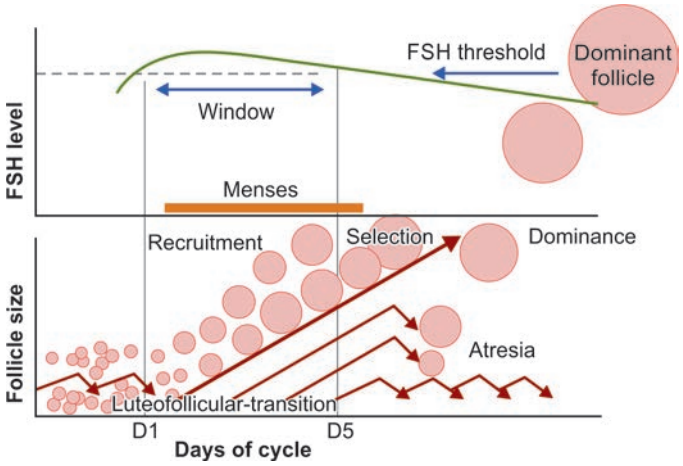

Fig. 11: Concept of follicle-stimulating hormone (FSH) window and threshold.

This requires an orderly sequence of events and a series of sequential actions of hormones and autocrine-paracrine peptides on the follicle, through a period of initial growth from a primordial follicle through the stages of the preantral, antral, and preovulatory follicle.[31,32] As folliculogenesis has already been described in another chapter, this chapter only discusses the physiological attributes of the ovarian events **(Fig. 12)**.

Primordial Follicle

The primordial germ cells originate in the endoderm of the yolk sac, allantois, and hindgut of the embryo and by 5–6 weeks of gestation, they have migrated to the genital ridge. A rapid mitotic multiplication of germ cells begins at 6–8 weeks of pregnancy, and by 16–20 weeks, the maximum number of oocytes reaches to a total of 6–7 millions in both ovaries.[33] The primordial follicle is nongrowing and consists of an oocyte, arrested in the diplotene stage of meiotic prophase, surrounded by a single layer of spindle- shaped granulosa cells.

Until the follicle numbers are exhausted, some grow while some undergo atresia, uninterrupted by even pregnancy, ovulation, or periods of anovulation, continuing through infancy and up to menopause. The rate of decrease in follicle number is proportional to the total number present, implying that the most rapid decrease occurs before birth resulting in 2 million oocytes at birth and 300,000 at puberty. Out of these, about 400 follicles will ovulate during a woman's reproductive years[33] **(Fig. 13)**.

Intrafollicle signaling regulating primordial follicle activation: The phosphatidylinositol 3-kinase (PI3K) pathway, the mechanistic target of rapamycin complex 1 (mTORC1) pathway, the p27Kip1 (p27) cyclin-dependent kinase (CDK) system, and several oocyte-specific transcription factors have been shown to play roles in regulating the activation of dormant oocytes in the mammalian ovary.

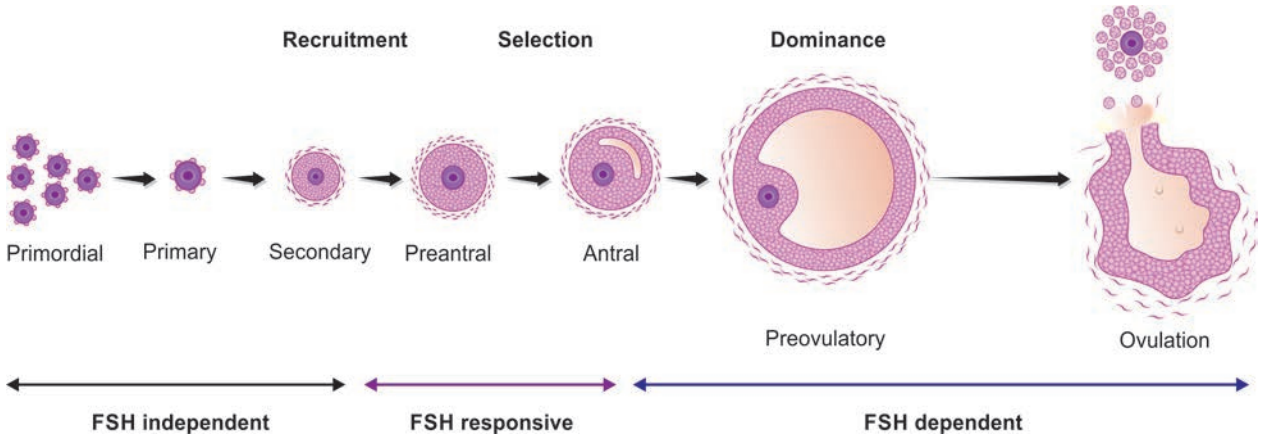

Fig. 12: Stages of follicular growth. (FSH: follicle-stimulation hormone)

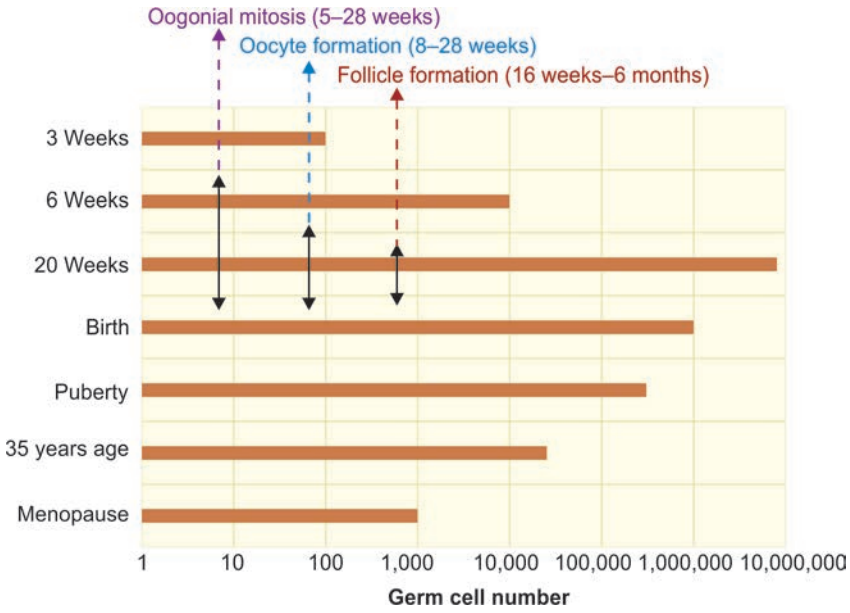

Fig. 13: Changes in germ cell numbers in relation to age.

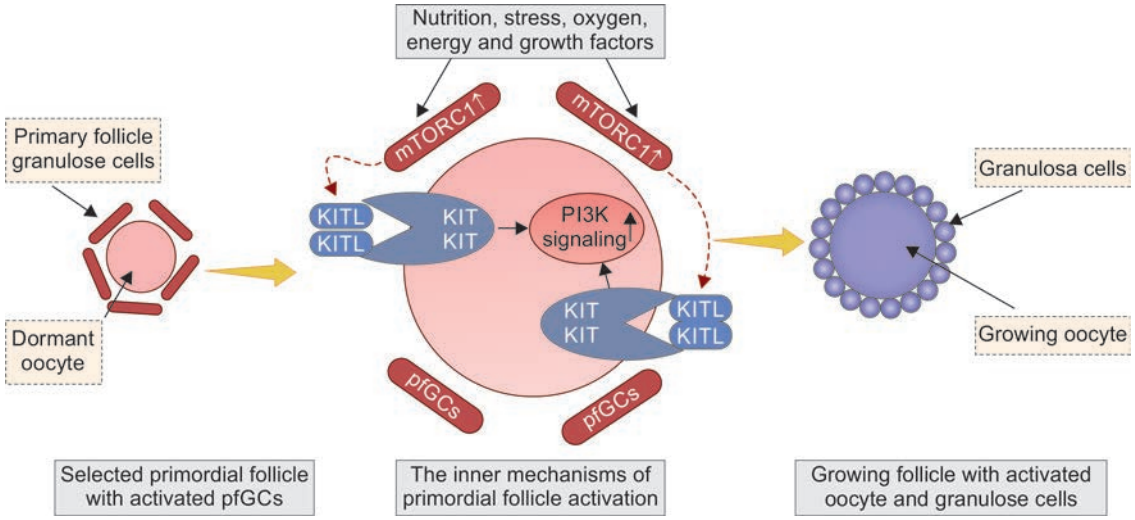

Fig. 14: Primordial follicle activation model for the mammalian ovary.
(KITL: KIT ligand; mTORC1: mechanistic target of rapamycin complex 1; pfGCs: primordial follicle granulosa cells; PI3K: phosphatidylinositol 3-kinase)

Recent evidence suggests that the somatic primordial follicle granulosa cells (pfGCs) play an important role in initiating the activation of primordial follicles in the adult ovary. It is primarily achieved through mTORC1 activation in pfGCs, which mediates the differentiation and proliferation of the flattened pfGCs into cuboidal granulosa cells and simultaneously promotes KIT ligand (KITL) expression. KITL secreted from the pfGCs subsequently binds to the KIT receptor on the oocyte surface, resulting in the phosphorylation of KIT Y719, which then activates intraoocyte PI3K signaling. The PI3K signaling in the dormant oocytes is then responsible for triggering the events that awaken the oocyte from its quiescence into a robust developmental state.[34]

In the adult mammalian ovary, only a small proportion of dormant primordial follicles are awakened to move on to further developmental stages. In response to stimulation by nutrition and other factors, the mTORC1 signaling is activated in the pfGCs of selected primordial follicles, leading to their differentiation and proliferation. The activated mTORC1 signaling in pfGCs also stimulates an upregulation of KITL secretion. KITL binds to KIT on the surface of the dormant oocyte, which leads to activation of PI3K signaling. Activated PI3K signaling in oocytes awakens the dormant oocytes and stimulates their growth **(Fig. 14)**.

The application of this understanding of primordial follicle activation could be beneficial for women with low ovarian reserve and for cancer survivors.

Primary Follicle

With multiplication of the cuboidal granulosa cells, the primordial follicle becomes a primary follicle. The granulosa cell layer gets separated from the stromal cells by a basement membrane called the basal lamina. The stromal cells are further subdivided into theca interna and theca externa.

Rescue from atresia: The early growth of follicles occurs over the time span of several menstrual cycles, approximately 85 days. The follicle destined to ovulate is one of a cohort that is recruited at the luteal–follicular transition.[35] Until a late stage, the growth is independent of hormonal regulation.[36] Eventually, this cohort of follicles reaches a stage where unless recruited or rescued by FSH, it is doomed toward apoptosis, a programmed physiologic cell death.[37]

Recruitment is the process by which the cohort of follicles responding to FSH at the beginning of the cycle gets rescued from apoptosis and competes for the selection of the dominant follicle.

Early signs of follicular development are an increase in the size of the oocyte, cuboidal pattern of granulosa cells—a change from their original squamous shape and the appearance of gap junctions between the granulosa cells and the oocyte, essential for nutritional, metabolite, and signal interchange **(Fig. 15)**.

Follicular atresia is regulated by endocrine factors, such as FSH and LH, and by paracrine factors, including insulin-like growth factor 1 (IGF-1), EGF, basic fibroblast growth factor (bFGF), tumor necrosis factor-alpha (TNF-α), interleukin 6 (IL-6), and others.

Preantral Follicle

With accelerated growth promoted by the gonadotropins, the granulosa cells undergo a multicellular proliferation leading to an increased production of not only estrogen but also other steroids, such as androgens and progestins. The oocyte also enlarges and is surrounded by zona pellucida, an acellular glycoprotein membrane. FSH receptors are acquired through which FSH aromatizes androgens to estrogens, generating an *estrogenic microenvironment*.[38] Together, FSH and estrogen synergistically promote a rapid accumulation of FSH receptors, allowing the follicle to respond to relatively low concentrations of FSH **(Fig. 15)**.

Androgens have a complex role in early follicular development. At low concentrations, androgens serve as a substrate for FSH-induced aromatization to the extent of even enhancing the enzyme. But, in androgen-rich environment, the limited capacity of aromatization is overwhelmed and the preantral granulosa cells instead favor the conversion of androgens to more potent 5α-reduced androgens.[39] These androgens inhibit aromatase activity and FSH-induced LH receptor formation as they cannot convert to estrogen leading the follicle toward atresia.[40,41] Hence, the fate of the preantral follicle is in delicate balance depending on the ability to convert an androgen-dominant microenvironment to an estrogen-dominated microenvironment for survival **(Box 3)**.

Formation of gap junctions: Oocytes are unable to use glucose, as an energy source to support meiotic maturation, cannot transport certain amino acids, and lack both the enzymes

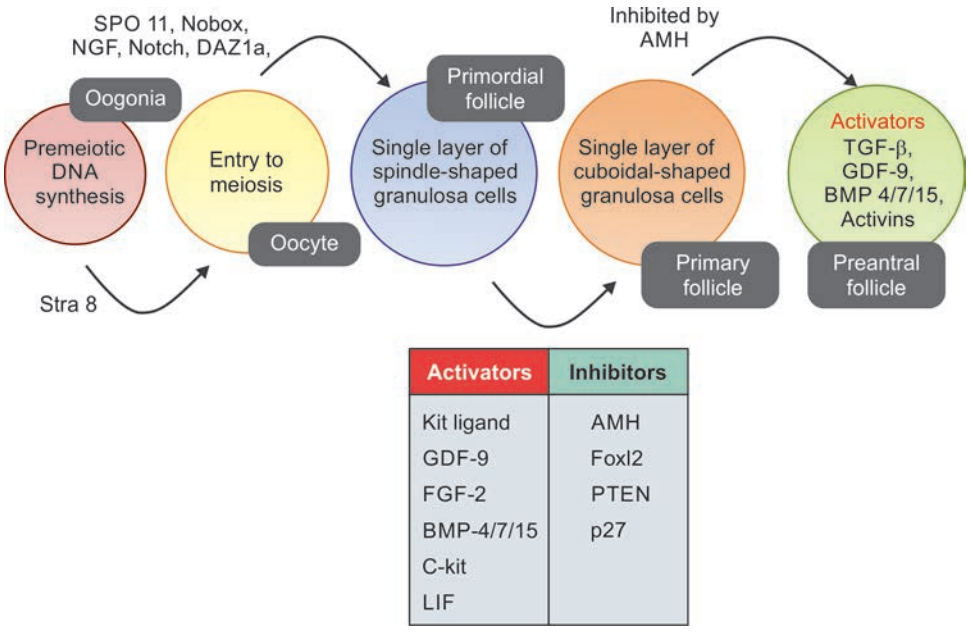

Fig. 15: Series of events in follicular development. Note the genes involved in early stages of folliculogenesis.

necessary for cholesterol synthesis and the receptors for its uptake. This is overcome by the presence of gap junctions that link the oocytes to the granulosa cells. Their role is to allow passage of small molecules such as ions (e.g., calcium), metabolites (e.g., pyruvate, nucleic acids, and inositol), amino acids (e.g., L-alanine), cholesterol, and intracellular signaling molecules [e.g., cyclic adenosine monophosphate (cAMP)] between granulosa cells and oocytes. In mice, targeted deletions of gap junction proteins (known as connexins) disrupt follicular and oocyte development.

Consequently, oocytes are dependent on adjacent granulosa cells for growth and multiplication of the granulosa cells and for nutrition, metabolism, transport, and regulation of oocyte development.[42,43] In turn, oocytes stimulate glycolysis, amino acid transport, and cholesterol synthesis in granulosa cells via paracrine and juxtacrine signals to meet their demands. Connexin expression in ovarian follicles is upregulated by FSH and downregulated by LH.[44] In addition, FSH maintains an open channel in the gap junctions, a pathway that is closed by LH.[45] After ovulation, the gap junctions are important in the CL, where their function is regulated by locally produced oxytocin.[46]

The bulk of oocyte growth occurs in preantral follicles, where the oocyte is closely associated with relatively undifferentiated granulosa cells. Upon follicular antrum formation, which approximately corresponds to the end of the oocyte growth phase, the granulosa cells differentiate into two anatomically and functionally distinct lineages: The mural granulosa cells that line the wall of the follicle and that have principally a steroidogenic role and the cumulus cells (CCs) form an intimate association with the oocyte. CCs possess highly specialized transzonal cytoplasmic projections that penetrate through the zona pellucida and form gap junctions at their tips with the oocyte, forming an elaborate structure called the cumulus–oocyte complex (COC).

Antral Follicle

Follicular fluid accumulated in the intercellular spaces of the granulosa eventually coalesces into a cavity—the antrum. This fluid being rich in hormones, growth factors, and cytokines, nurtures the oocyte. The granulosa cells surrounding the oocyte form the cumulus oophorus. LH is normally not present in the fluid until the mid-cycle. Antral follicles with the lowest androgen/estrogen ratios are most likely to house a healthy oocyte.[47] The synthesis of steroids

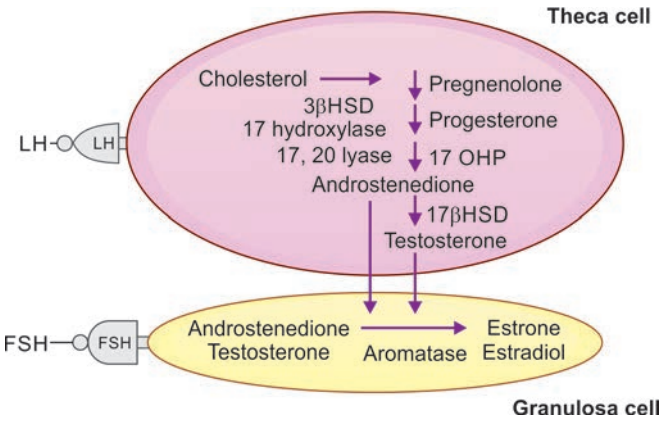

Fig. 16: Two-cell, two-gonadotropin concept.
(FSH: follicle-stimulating hormone; HSD: hydroxysteroid dehydrogenase; LH: luteinizing hormone; OHP: hydroxyprogesterone)

is functionally compartmentalized within the follicle as the two-cell system.

Two-cell, two-gonadotropin concept in follicle selection: FSH receptors are present only on the granulosa cells. LH receptors are present only on theca cells.[48] LH optimizes final stages of maturation. FSH-stimulated estrogen production from the granulosa cells is dependent on LH-stimulated androgen production by the theca cells. This is not fully functional until the later part of antral development. Theca cells are characterized by expression of LH receptors, 3β-hydroxysteroid dehydrogenase, and cyp-P450c 17, which are essential for internalizing low-density lipoprotein (LDL) cholesterol into mitochondria and thereby converting 21 carbons to androgens.[49] Granulosa cells lack these receptors and in fact express FSH receptors and cyp-450 aromatase to convert androgen substrate from theca into estrogens. Increased expression of aromatase indicates increased follicular maturity. Exclusive function of P450c 17 in theca cells and aromatase in granulosa cells is the basic principle of the two-cell, two-gonadotropin theory.[50]

Pure FSH treatment causes early development of follicles, but estradiol production is limited.[51,52] Some aromatization occurs from the androgens of adrenal glands, but robust steroidogenesis is not possible. Only a follicle with more number of FSH receptors, higher aromatase activity, and robust steroidogenesis is selected as dominant follicle **(Fig. 16)**.

Selection of the dominant follicle: The successful conversion to an estrogen-dominant follicle marks the selection of a follicle destined to ovulate. This process is attributed to a few of the estrogen actions, namely positive influence of estrogen on FSH within the maturing follicle and a negative feedback relationship with FSH at the hypothalamic–pituitary level serving to withdraw gonadotropin support. The dominant follicle, with its high concentration of FSH receptors, continues to acquire more FSH even as FSH levels

decrease. The remaining, poorly FSH receptor-endowed follicles ultimately show reduced aromatase activity, granulosa proliferation, and function and hence undergo an irreversible atretic change.

The dominant follicle matures and secretes increasing amounts of estradiol, which is essential for its complete maturation. At this critical moment, estrogen exerts positive feedback on LH, generating a dramatic preovulatory LH surge.

Tumor necrosis factor-α, which is produced in the granulosa cells, inhibits FSH stimulation of estradiol secretion, except in the dominant follicle.[53]

Selection of the dominant follicle is established during days 5–7, and consequently, peripheral levels of estradiol begin to rise significantly by day 7 of the cycle.[54] The dominant follicle has two significant advantages, mainly its acquisition of a greater content of FSH receptors due to a rate of granulosa proliferation that surpasses the proliferation of its cohorts and the enhancement of FSH action because of its high intrafollicular estrogen concentration, a consequence of local autocrine–paracrine molecules. Thus, the dominant follicle is more sensitive to FSH, and as long as a critical duration of FSH exposure is initially present, the dominant follicle continues to develop.[55] Improved theca vascularity allowing a preferential delivery of gonadotropins to the dominant follicle also contributes.[54]

In order to respond to LH surge and become a CL, granulosa cells must acquire LH receptors. With increasing concentrations of estrogen, FSH changes its focus of action from upregulation of FSH receptors to upregulation of LH receptors.[56] Moreover, LH can induce development of its own receptors in FSH-primed granulosa cells. LH plays a critical role in the final stages of follicular development, providing support for final follicular maturation.[57,58]

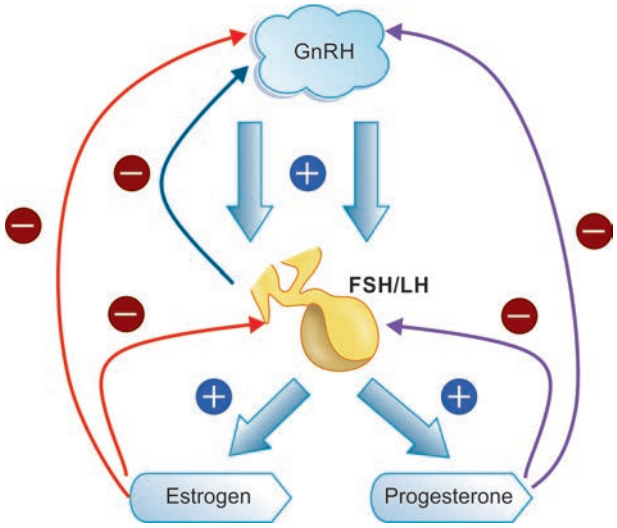

Fig. 17: Feedback mechanism.

TABLE 3: Role of mid-cycle surge of gonadotropins.

LH surge	*FSH surge*
Resumption of meiosis in the oocyte	Frees the oocyte from follicular attachments → free floating oocyte in the antral fluid
Luteinization of granulosa cells to secrete progesterone	LH receptors on granulosa cells → adequate luteal function
Cumulus expansion	Cumulus expansion
Prostaglandin and eicosanoid synthesis → follicular rupture	Plasminogen → plasmin: Follicular rupture
LDL cholesterol internalization → corpus luteum steroidogenesis	

(FSH: follicle-stimulating hormone; LDL: low-density lipoprotein; LH: luteinizing hormone)

Feedback System

The FSH secretion is very sensitive to the negative inhibitory effects of estrogen at low levels, and at higher levels, this effect of estrogen is supplemented by inhibin. In contrast, the transition from suppression to stimulation of LH release occurs as estradiol fulfills two critical events—estradiol concentration rising above 200 pg/mL and sustained for about 50 hours, usually occurring when the dominant follicle reaches 15 mm in diameter[59,60] **(Fig. 17)**.

Preovulatory Follicle

The preovulatory follicle gets a hyperemic appearance with the granulosa cells enlarging and acquiring lipid inclusions and the theca cells getting vacuolated and vascular. The oocyte also proceeds in meiosis, approaching completion of its reduction division. Approaching maturity, the preovulatory follicle, produces increasing amounts of estrogen, peaking at 24–36 hours prior to ovulation.[61] The onset of LH surge occurs when peak levels of estradiol are reached. In providing the ovulatory stimulus to the selected follicle, the LH surge seals the fate of the remaining follicles, with their lower estrogen and FSH content, by further increasing the androgen superiority.

Luteinizing hormone promotes luteinization of the granulosa in the dominant follicle producing progesterone, which via its own receptors and only after adequate estrogen priming facilitates the positive feedback of estrogen on LH. If administered before the estrogen stimulus or in doses high enough to achieve a blood level >2 ng/mL, progesterone blocks the mid-cycle LH surge. Hence, appropriate low levels of progesterone derived from the maturing follicle contribute to the precise synchronization of the mid-cycle LH and the FSH surge **(Table 3)**.

With the smaller follicles undergoing atresia, theca cells form the stromal tissue, enhancing androgen production to enhance libido and accelerate atresia.

Role of inhibin, activin, follistatin, and growth factors: The actions of these factors come together as described here.

Inhibin and activin regulate androgen synthesis in theca cells.[62] Inhibin enhances and activin suppresses the stimulatory action of LH and/or IGF-1 on thecal androgen synthesis, and inhibin can overcome the inhibitory action of activin. In the granulosa cells of immature follicles in the early follicular phase, activin enhances FSH activities, including FSH receptor expression, aromatization, and LH receptor expression, while simultaneously suppressing theca androgen synthesis to allow estrogen microenvironment.[63] Inhibin B reaching a peak in the mid-follicular phase amplifies the withdrawal of FSH from other follicles allowing the emergence of the dominant follicle. In the late-follicular phase, rise in levels of inhibin B and reduced activin promote androgen synthesis in the theca in response to LH and IGF-2 to provide substrate for even greater estrogen production in the granulosa, which will act to trigger LH surge.

In the mature granulosa of the dominant preovulatory follicle, activin serves to prevent premature luteinization and progesterone production. Activin further peaks at menses allowing FSH to rise appropriately at the time of luteal–follicular transition.

Insulin-like growth factors and binding proteins help in folliculogenesis. Binding proteins help in function of growth factors. Insulin-like growth factor-binding protein 4 (IGFBP-4) decreases the availability of IGF-1 and dominant follicles have IGFBP-4 protease and increased availability of growth factors. Role of IGF-2 is clearer in folliculogenesis, as in Laron-type dwarfism, there is a deficiency of IGF-1 but normal folliculogenesis.[64] IGF-2, being the most abundant IGF in human ovarian follicles, has a vital role in stimulating estrogen production and granulosa cell mitosis.[65] It facilitates the action of FSH on the granulosa cells and the action of LH on the theca cells.

Ovulation

Ovulation is the phase of menstrual cycle in which a mature egg is released from the ovarian follicle into the fallopian tube. In humans, ovulation occurs about midway through the menstrual cycle, after the follicular phase. The few days surrounding ovulation (from approximately days 10 to 18 of a 28-day cycle) constitute the most fertile phase.

Ovulation occurs in the morning in springs and in the evening in autumn and winter. It occurs 55% of the time from the right ovary. Oocytes from the right ovary are said to have a higher potential for pregnancy.[66] Contralateral ovulation favors pregnancy more than ipsilateral ovulation, while ipsilateral ovulation occurs more with advancing age.[67]

The underlying physiology of ovulation is complex. The pulsatile GnRH secretion forms an important prerequisite for normal pituitary secretion. However, the feedback responses regulating gonadotropin levels are controlled primarily by ovarian steroid feedback on the anterior pituitary cells.

The inhibiting tone of endogenous opiates is reduced at the time of the ovulatory surge, allowing a release from suppression. This is probably a response to estrogen-induced decrease in opioid receptor binding and subsequent opioid release.

The primary oocyte is in a state of arrest in the late prophase of meiosis I.[33] Until ovulation, high cAMP levels inhibit resumption of meiosis of the oocyte. During the surge, LH blocks cAMP transport into the oocyte, thus removing inhibition of meiosis and allowing meiosis to resume. Meiosis suppression by oocyte maturation inhibitor and luteinization inhibitor is also removed.[68] LH surge causes disruption of gap junctions, and the transport of cAMP from granulosa cells to oocytes is halted. Gap junction integrity in the oocyte is also contributed by nitric oxide (NO). NO resists resumption of meiosis and breakdown of gap junctions until a massive LH surge overcomes this resistance.

The LH surge also induces release of proteolytic enzymes in association with FSH rise, which degrade the cells at the surface of the follicle, and stimulates angiogenesis in the follicular wall and prostaglandin secretion. These effects of LH cause the follicle to swell and rupture. LH surge also causes luteinization of granulosa cells, progesterone production, expansion of cumulus, and production of prostaglandins.

At ovulation, the secondary oocyte (arrested until fertilization in the metaphase of meiosis II) and its surrounding corona radiata are expelled into the peritoneal cavity. The oocyte adheres to the ovary and the muscular contractions of the fallopian tube bring the oocyte into contact with the tubal epithelium to initiate migration through the oviduct.

The onset of the LH surge appears to be the most reliable indicator of impending ovulation, occurring 34–36 hours prior to follicle rupture.[69] The LH surge usually lasts for 48–50 hours.[69] Threshold concentration of LH must be maintained for 14–27 hours for full maturation of oocytes to occur.[70] Ovulation occurs 10–12 hours after LH peak and 24–36 hours after estradiol peak.[71,72]

The LH surge tends to occur at around 3:00 AM, beginning between midnight and 8:00 AM in over two-third of women.[60] LH may be detectable in the urine by evening.

Progesterone rise increases the distensibility of the follicular wall and promotes proteolytic activity to digest collagen in the follicular wall, making it thin and stretched out, facilitating rupture. It also acts to terminate the LH surge by exerting a negative feedback effect at higher concentrations.

Escape of ovum is associated with thinning and degeneration of collagen in the follicular wall. Plasminogen

activators release plasmin and generate collagenase to disrupt follicular wall.

Plasminogen inhibitory system active before and after ovulation prevents inappropriate disruption of follicular wall. Ovulation is the result of proteolytic digestion of follicular apex called stigma.

Prostaglandins, mainly prostaglandin E2 (PGE2) but also prostaglandin F2 alpha (PGF2α), and other eicosanoids, such as hydroxyeicosatetraenoic acid (HETE), are increased markedly in preovulatory follicular fluid in response to LH surge.[73-75] Cyclooxygenase-2 (COX- 2) inhibitors block follicular rupture without affecting luteinization and oocyte maturation.[76,77] Prostaglandins act to free proteolytic enzymes from the follicular wall and may promote angiogenesis and hyperemia. They also help to contract smooth muscle, aiding extrusion of oocyte cumulus mass.

The FSH surge, a result of preovulatory progesterone rise, expands and disperses the CCs allowing the oocyte–CC mass to become free-floating in the antral fluid just before follicular rupture. Also, FSH peak promotes plasminogen activator production and an adequate LH receptor concentration, ensuring adequate luteal phase functioning. This explains why GnRH agonist ovulation trigger is more physiological as it causes both LH and FSH surges **(Flowchart 5)**.

Decline of LH surge: Within hours after LH rise, there is a precipitous drop in plasma estrogens. This LH fall may be due to loss of the positive stimulating action of estradiol or to an increasing negative feedback of progesterone. High levels of progesterone inhibit pituitary secretion of gonadotropins by inhibiting GnRH pulses at the level of the hypothalamus. In addition, high levels of progesterone can antagonize pituitary response to GnRH by interfering with estrogen action.

The abrupt decline in LH may also reflect exhaustion of pituitary LH stores due to downregulation of GnRH receptors.[78,79]

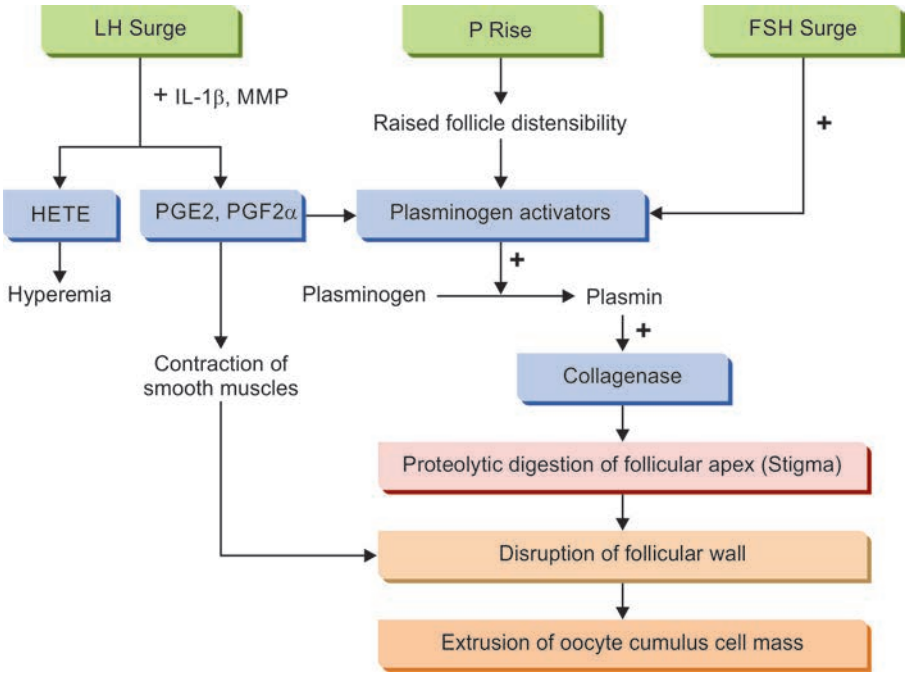
Activity of a nonsteroidal ovarian substance, named gonadotropin surge-attenuating factor (GnSAF), is hypothesized to regulate the amplitude of the endogenous LH surge at mid-cycle, by antagonizing the sensitizing effect of estradiol on the pituitary.[80] It is produced by the granulosa cells and has a role in prevention of premature luteinization. All these events lead to shutdown of LH surge.

Luteal Phase

Normal luteal function requires optimal preovulatory follicle development. Granulosa and theca lutein cells continue to enlarge and accumulate yellow pigment lutein. For successful steroidogenesis and supply of adequate LDL cholesterol substrate, good vascularization is required. Rapid vascularization is mediated by vascular endothelial growth factor (VEGF).[81] By day 8 or 9 after ovulation, a peak of vascularization is reached, associated with peak levels of progesterone and estradiol in the blood. CL has highest blood flow per unit mass of body and spontaneous bleeding can occur specially in anticoagulated patients.

The luteal phase is defined by the luteinization of the follicles forming CL initiated by the LH surge. The major

Flowchart 5: Key events leading to ovulation.



(FSH: follicle-stimulating hormone; HETE: hydroxyeicosatetraenoic acid; IL-1β: interleukin-1β; LH: luteinizing hormone; MMP: matrix metalloproteinase; P: progesterone; PGE2: prostaglandin E2; PGF2: prostaglandin F2)

effects of the LH surge are the conversion of granulosa cells from predominantly androgen-converting cells to predominantly progesterone-synthesizing cells and the expression of new LH receptors that foster increased progesterone synthesis with some estrogen secretion. LH regulates LDL receptor binding, internalization, and processing.[82] Induction of LDL receptors in granulosa cells occurs in response to LH surge. Progesterone secretion by the CL peaks between 5 and 7 days postovulation. High progesterone levels exert negative feedback on GnRH, and subsequently, GnRH pulse frequency decreases, leading to reduced FSH and LH secretion. The CL further loses its FSH and LH receptors. Lacking stimulation by FSH and LH, after 14 days CL undergoes atresia. With the decline in both estrogen and progesterone levels, an important negative feedback control on FSH is removed, and FSH levels rise once again to initiate the next menstrual cycle.

If fertilization and subsequent implantation of the blastocyst do not occur, the CL undergoes apoptosis and becomes the corpus albicans, a white scar. Luteal apoptosis involves a loss of LH-binding receptors and is mediated by prostaglandins.

The life span of CL depends on tonic LH secretion as evident by prompt luteolysis occurring when GnRH antagonist or agonist is continued in the cycles. Estrogen and progesterone production by CL is under control of LH. High levels of estrogen, progesterone, and inhibin A suppress new follicular growth.

The CL is not homogenous as it is composed of luteal cells, endothelial cells, leukocytes, and fibroblasts.[83] Nonsteroidogenic cells form 70% of the cells. Endothelial cells (35%) contribute to the vasoactive compounds.[84]

Luteal cells are of two types—large cells and small cells.[83] Large cells formed from granulosa cells are the sites of steroidogenesis, whereas small cells formed from theca cells contain receptors and provide a stimulus for large cells to function.[85]

The LH surge to menses is on an average about 14 days ranging from 11 to 17 days, with short luteal phase occurring in about 5–6% of women.[86]

Luteal phase cannot be extended for long despite continuous LH stimulation, suggesting an active luteolytic mechanism. CL rapidly declines 9–11 days after ovulation. NO, prostaglandin F2α, endothelin-1, TNF-α, and proteolytic enzymes such as matrix metalloproteinase (MMP) are involved in luteolysis.[87]

Emerging hCG from pregnancy rescues the CL. mRNA for hCG can be detected in the six- to eight-cell human embryo, i.e., even before implantation, and it can be detected in the mother about 6–7 days after ovulation.[88] Thus, the embryo is capable of preimplantation signaling and higher levels of estradiol and progesterone can be measured in the maternal circulation even before maternal hCG is detectable.

Luteal–Follicular Transition

The luteal–follicular transition is a period of selective increase in FSH beginning about 2 days before the onset of menses.[89]

It occurs due to:

- Demise of CL results in nadir in circulating levels of estradiol, progesterone, and inhibin.
- Decrease in negative feedback effect of luteal steroids and inhibin (particularly inhibin A).
- Change in pulsatile GnRH secretion toward an increasing pulse frequency which favors predominant FSH secretion.[90]

The increase in FSH is instrumental in rescuing approximately a 70-day cohort of follicles from atresia, allowing a dominant follicle to begin its emergence **(Fig. 18)**.

Uterine Endometrial Cycle

The uterus is a dynamic structure, responding in a sensitive fashion to classic hormonal signals (the endocrine events of the menstrual cycle) ***(see* Fig. 10)**. Cyclical changes in the endometrium prepare for implantation in the event of fertilization and necessitate menstruation in the absence of fertilization. The integrated evolutionary cycle of endometrial growth and regression is described in four phases:

1. Proliferative or follicular phase
2. Secretory or luteal phase
3. Preparatory phase for implantation
4. Menstrual phase or the phase of endometrial breakdown.

Morphologically, the endometrium consists of an upper two-third "functionalis/functionale" layer, which is the site of proliferation and secretion meant for blastocyst implantation, and a lower one-third "basalis" layer serving as the source of regenerative endometrium after menstrual breakdown.[91]

The functionalis layer is subdivided further into two parts:

1. *Stratum compactum:* A superficial layer closer to the lumen, composed of gland necks and dense stromal cells.
2. *Stratum spongiosum:* The deeper functionale layer adjacent to the underlying basale layer contains predominantly endometrial glands, increased interstitial tissue, and less dense stroma.

The functionalis undergoes changes throughout the menstrual cycle and is shed during menstruation, while the basalis remains constant during the menstrual cycle and regenerates the functionalis each month. Almost two-third of the functioning endometrium is shed out during menstruation. The residue is a stable, basalis component and a small, variable amount of residual stratum spongiosum **(Fig. 19)**.

Proliferative or Follicular Phase

The proliferative or follicular phase spans from the end of the menstruation until ovulation. As estrogen secretion

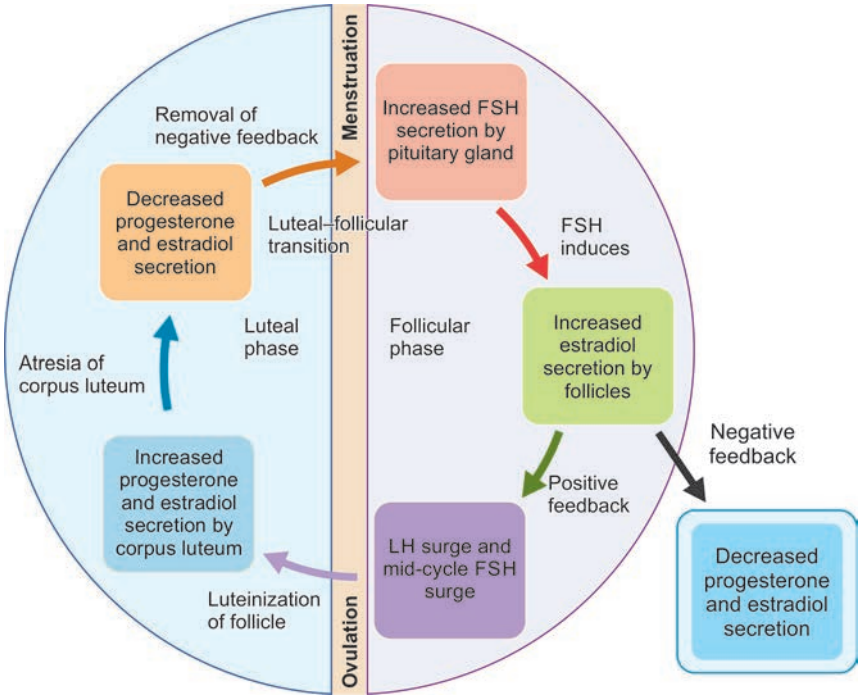


Fig. 18: Summary of ovarian events in menstrual cycle.

		Proteolysis regulation	

Fig. 19: Biological functions of endometrium in different stages of uterine cycle. (DNA: deoxyribonucleic acid)

occurs, mitosis and pseudostratification predominate. Rapid re-epithelialization and proliferation of cells from the stumps of glands in the basalis layer, especially in the isthmic and tubal ostial sites, is initiated within 24–48 hours. By days 5–6, there is onset of stromal growth. There is proliferation of all elements slowly at first but later at a rapid pace. Ovarian follicular phase corresponds to proliferative phase.

By the mid-follicular phase, increasing levels of estrogen from the growing follicle induce proliferation of the functionalis from stem cells of the basalis, proliferation of endometrial glands, and proliferation of stromal connective tissue. Endometrial glands are elongated with narrow lumens and their epithelial cells contain some glycogen. Glycogen, however, is not secreted during the follicular phase. As the

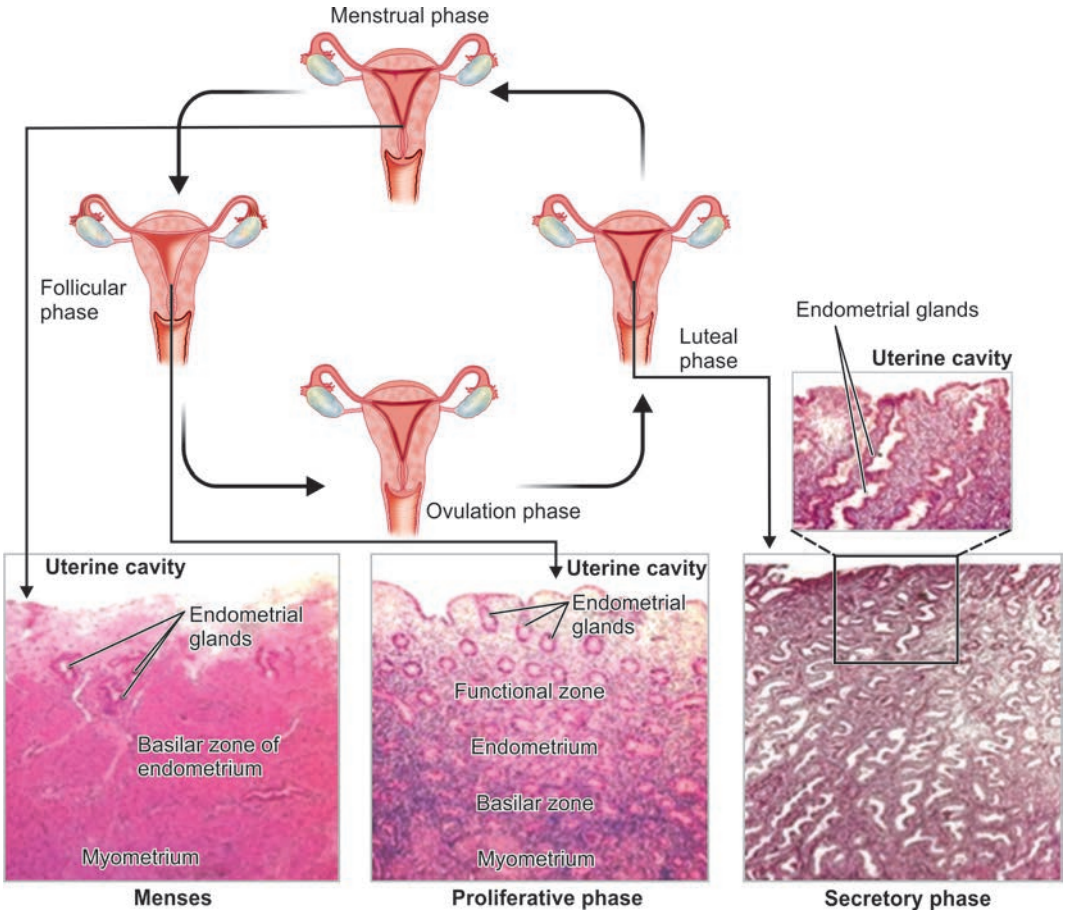

Fig. 20: Changes in endometrial histology in different stages of uterine cycle.

glands get tubular, epithelium becomes columnar with the nuclei placed at the base. Stromal cells, initially compact, evolve through subepithelial congestion. Spiral arteries elongate and span the length of the endometrium but remain unbranched **(Fig. 20)**.

Proliferation peaks on days 8–10 of the cycle reflecting peak estrogen receptors and concentration.[92] The thickness of the endometrium measures about 4–6 mm in the mid-follicular phase, and by the end of the proliferative phase, the mean endometrial thickness on ultrasound increases to "trilaminar pattern" of 12 mm. Pseudostratification of the cells lining the glandular epithelium also peaks immediately before ovulation.

Secretory or Luteal Phase

The secretory or luteal phase begins at ovulation and lasts until the menstrual phase of the next cycle. In the early luteal phase, progesterone induces the endometrial glands to secrete glycogen, mucus, and other substances. These glands become tortuous and have large lumens due to increased secretory activity. The spiral arteries extend into the superficial layer of the endometrium. Due to the effects of progesterone from the CL on an estrogen-primed endometrium, proliferation ceases, and there is a decline in mitosis. Surface epithelium becomes more columnar and ciliated at places. Glands enlarge to get a cork-screw shape. Subnuclear glycogen vacuolation is an evidence of progesterone effect but does not confirm ovulation. Blood vessels undergo marked spiraling. Endometrial trilaminar pattern is lost, and there is an increased and uniform echogenicity of the endometrium **(*see* Fig. 20)**.

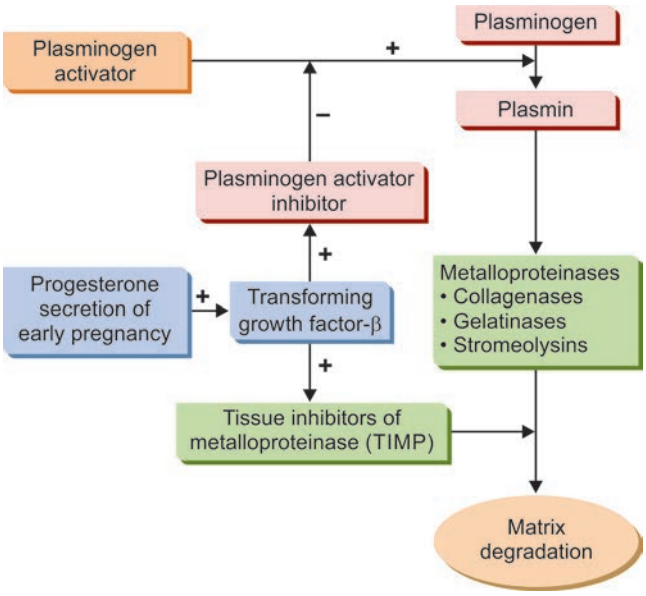
Implantation Phase

Around the 7th–13th postovulation day (days 21–22 of the cycle), the distended tortuous secretory glands are prominent with some intervening stroma. The endometrium has three distinct zones—basal, middle lace- like edematous stratum spongiosum, and superficial stratum compactum. Engorged vessels, intense infiltration of leukocytes, synthesis of prostaglandins and growth factors, decidualization of stromal cells, and a complex array of peptides and cytokines mark this phase meant to receive and nurture the blastocyst. It is discussed in detail in the chapter on implantation.

The mid- to late-secretory endometrial glands become increasingly tortuous, and the stroma becomes edematous and vascular. If implantation of the blastocyst into the

endometrium does not occur and hCG is not present, the glands begin to fragment and collapse in the late-luteal phase. In the absence of fertilization by day 23 of the menstrual cycle, the CL begins to degenerate and consequently ovarian hormone levels decrease. As estrogen and progesterone levels decrease, the endometrium undergoes involution. On days 25–26 of the menstrual cycle, endothelin and thromboxane begin to mediate vasoconstriction of the spiral arteries. The resulting ischemia may cause some early menstrual cramps. By day 28 of the menstrual cycle, intense vasoconstriction and subsequent ischemia cause mass apoptosis of the functionalis **(*see* Fig. 20)**.

Flowchart 6: Key events leading to endometrial breakdown.



Menstrual Phase or Phase of Endometrial Breakdown

In the event of nonestablishment of pregnancy, the fixed life span of the CL gets completed and the waning levels of estrogen and progesterone initiate important endometrial events. These events include blood stasis, arteriolar spasm, tissue necrosis, ischemia, and eventually enzymatic autodigestion caused by release of lysosomal proteolytic enzymes.[93]

The menstrual phase begins as the spiral arteries rupture secondary to ischemia, releasing blood into the uterus, and the apoptosed endometrium is sloughed off and usually lasts 4 days. Menstruation begins in different areas of the endometrium at different times. Sloughing of the endometrium occurs predominantly in the fundus and

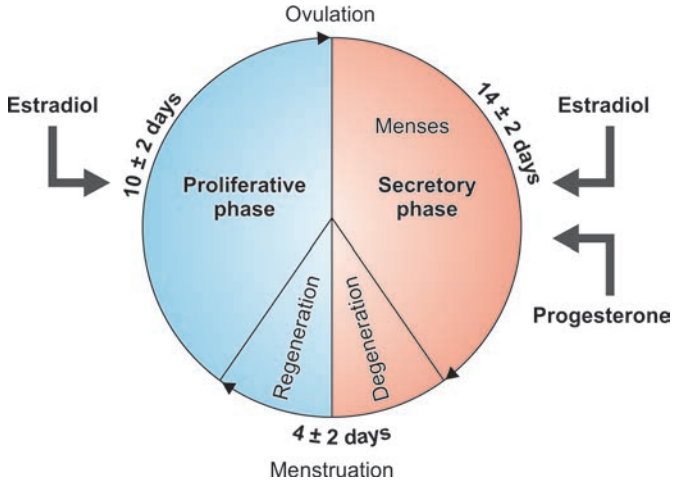


Fig. 21: Summary of endometrial events in menstrual cycle.

TABLE 4: Summary of ovarian and uterine events in a 28-day menstrual cycle with hormonal dynamics.

Days	*Ovarian events*	*Endometrial events*	*Hormonal dynamics*
1–4	*Recruitment:* Cohort of follicles start growing	Endometrial lining sloughs	• E2 and P4 are low • FSH and LH are released from inhibition
5–7	*Selection:* A single follicle is destined to ovulate. No surrogate follicle	Endometrium proliferates	Plasma E2 rises due to secretion from selected dominant follicle
8–12	*Dominance:* • Atresia of all other follicles except dominant follicle • Dominant follicle thrives uniquely, despite the suppressive milieu	Increased E2 stimulates the growth of glands and stroma	Increased E2 and inhibin will inhibit FSH
13–15	*Ovulation:* • Mediated by follicular enzymes and prostaglandins • Oocyte is induced to complete its first meiotic division	Transition from proliferative to secretory endometrium	LH surge induced by high plasma E2 (positive feedback)
15–25	Corpus luteum forms	Secretory endometrium develops	• P4 and E2 are secreted • FSH and LH secretion is inhibited, so no new follicle develops
25–28	*Luteolysis:* • Corpus luteum degenerates • Recruitment of new follicles for next cycle	Endometrium begins to slough due to withdrawal of progesterone support	• Plasma E2 and P4 decrease release of hypothalamus and pituitary from negative feedback • FSH begins to rise

(E2: estradiol; FSH: follicle-stimulating hormone; LH: luteinizing hormone; P4: progesterone)

minimally in the isthmus or cornual regions, and the natural cleavage point is between basalis and spongiosum. Autolysis with subsequent desquamation of the stratum functionale layer begins. The bleeding occurs from broken arteries, veins and capillaries, and stromal hematoma. Arterial and venous blood, remnants of endometrial stroma and glands, leukocytes, and red blood cells are all present in the menstrual flow. Blood along with the superficial functional layer is shed into the uterine cavity **(Flowchart 6)**.

Cessation of menstruation occurs due to a combined effect of prolonged vasoconstriction, myometrial contraction, and local aggregation of platelets with fibrin deposition. Resumption of estrogen secretion leads to repair of endometrium from the basalis layer. Regeneration of the endometrium begins 36 hours after menses onset at the isthmic recesses and the cornual region even as endometrial shedding continues in other areas of the uterus. Bleeding usually ceases by cycle day 5 after complete re-epithelialization of the endometrium is accomplished.

Endometrial regeneration occurs in response to injury and is not hormone mediated **(Fig. 21 and Table 4)**.

KEY POINTS

- The neuroendocrinological control of menstrual cycle is of prime importance for fertility in women. As clearly evident, it involves a complex interplay of hormones produced by the hypothalamus, pituitary, and ovaries during the monthly reproductive cycle.
- The hormonal regulation of the reproductive system is complex and imperative for the proper functioning of the gonads (oogenesis and spermatogenesis), thus maintaining the vital menstrual function in females along with fertility in both genders.
- The developments in the field of pharmacogenomics have improved the understanding of infertility and the variable patient response to COS. With the understanding of mechanism of primordial follicle activation, infertility treatment could be advanced especially in women with low ovarian reserve.
- Although more research should be performed, the use of existing primordial follicles as a source for obtaining fertilizable oocytes as a new treatment for female infertility is just around the corner.
- Hence, the clinicians and specifically the infertility specialists need to have an in-depth understanding of the underlying physiology and neuroendocrinology for better patient care in their day-to-day practice.

MULTIPLE CHOICE QUESTIONS WITH ANSWERS

1. Shortly before menstruation:
   a. Blood levels of estrogen and progesterone decrease
   b. Blood levels of estrogen and progesterone increase
   c. Blood levels of FSH stabilize
   d. The CL secretes progesterone
2. During the menstrual cycle:
   a. LH stimulates estrogen production by follicles
   b. FSH stimulates growth of the ovarian follicles
   c. LH stimulates the formation of a CL from the collapsed follicle
   d. All of the above
3. Which of the following is true?
   a. Endorphins stimulate GnRH release within the hypothalamus
   b. α-Endorphin is 10 times more potent than morphine
   c. β-Endorphin is 10 times more potent than morphine
   d. Endorphin levels are lowest in the luteal phase
4. Which of the following is associated with the CL of menstruation, not the CL of pregnancy?
   a. Ovarian luteotropins (estrogens, IGF-I, IGF-II)
   b. hCG produced by the trophoblast of the chorion
   c. LH and prolactin
   d. Corpus albicans
5. Which are the hormones NOT secreted by the anterior pituitary?
   a. FSH b. LH
   c. GnRH d. TSH
6. Which of the following specifically inhibits FSH, but not LH?
   a. Progesterone b. Estradiol
   c. Inhibin d. Androgen
7. Chronic high levels of which of the following lead to a positive feedback loop in the HPO axis?
   a. Dopamine b. Estrogen
   c. Inhibin d. Progesterone
8. Theca cells produce androgens (e.g., testosterone) that diffuse into granulosa cells under the influence of:
   a. Estradiol b. Testosterone
   c. LH d. FSH
9. Which of the following statements about prolactin is false?
   a. Prolactin secretion is under tonic inhibitory control of dopamine
   b. Prolactin secretion follows a circadian rhythm
   c. Prolactin has a direct action on the ovaries
   d. Prolactin secretion is under tonic inhibitory control of TSH
10. A 19-year-old woman presents with complaints of no periods for the past 7 months. During this time, she started college and felt that her stress level had increased. The patient also changed her eating habits, which led to a weight decrease from 66 to 45 kg. She

has noted no other changes in her health. Which of the following tests should be ordered initially?

a. TSH, prolactin
b. Testosterone, β-hCG
c. FSH, β-hCG
d. Prolactin, β-hCG, dehydroepiandrosterone sulfate (DHEAS)

ANSWERS

1. a	2. d	3. c	4. d	5. c
6. c	7. b	8. c	9. d	10. a

CHAPTER 3

Oogenesis and Folliculogenesis

Suvarna Rathor Zirpe

INTRODUCTION

The ovary plays a dual role, reproductive as well as endocrine, in the female body. It acts as a reproductive organ by production and periodical release of the female gamete—oocyte. Regnier de Graaf was one of the first to recognize ovary as a producer of egg.[1] Earlier scientists believed that follicle itself was egg. The discovery that oocyte was enclosed within the follicle was made by Karl Ernst von Baer in 1827.[2] The ovary acts as an endocrine organ by producing hormones such as estrogen, progesterone, and testosterone, which are responsible for pubertal growth and menstrual cycle.

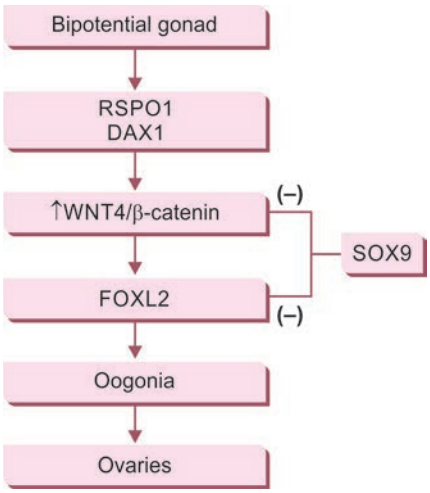
In this chapter, we review and understand the process of oogenesis and folliculogenesis, various stages of development, and the role of different factors involved in this process. This will help us to understand the clinical implications of the process.

FORMATION OF FEMALE GONADS

If the indifferent gonad is destined to become testis, differentiation will occur at 6–9 weeks. In the absence of SRY (sex-determining region on Y chromosome), ovary formation is initiated. Both ovary and testis formation require dominantly acting genes. SRY causes testis development via upregulation of *SOX9* (SRY-related HMG box gene). Overexpression in either *DAX1* (dosage-sensitive sex reversal, adrenal hypoplasia critical region, on chromosome X, gene 1) or *WNT4* (member of wingless family of genes)/*RSPO1* (R-spondin-1) antagonizes testis formation and promotes the development of ovary. Also *FOXL2* (forkhead box protein L2) inhibits the upregulation of *SOX9* and promotes the formation of ovary **(Flowchart 1)**.

Primordial germ cells (PGCs) appear first in the dorsal wall endoderm of yolk sac near the allantois as a cluster of 100 cells by 3–4 weeks of gestation.[3] PGCs migrate to the hindgut and dorsal mesentery by fourth and fifth weeks of gestation, respectively.[3] Gonadal tissue colonization by germ cells is completed by 7 weeks of gestation. Germ cells are

Flowchart 1: Formation of female gonads.



essential for the formation and maintenance of the ovary. In the absence of germ cells, the gonad degenerates into cord-like structures.[4] The migration of germ cells to the gonadal ridge happens as shown in **Figures 1A and B**.

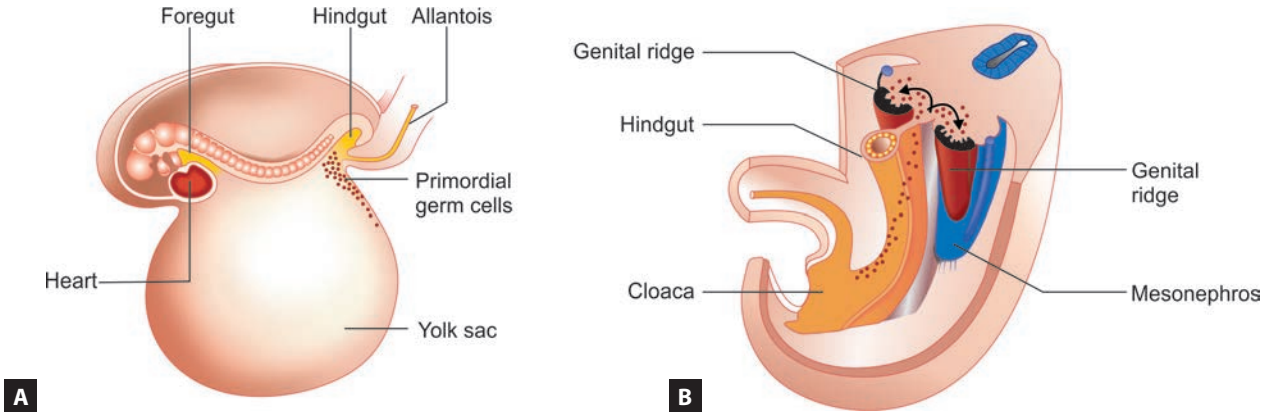
Oogenesis: It is a process of developing a mature oocyte from an oogonium.

Folliculogenesis: It is the maturation of the ovarian follicle (densely packed shell of somatic cells containing the oocyte) from primordial follicle into a large preovulatory follicle.

STAGES OF OOGENESIS

Oogenesis starts in *prenatal life* as early as 4 weeks of gestation. During the process of oogenesis, all primary oocytes get arrested at the diplotene stage of prophase I of the first meiotic division, until puberty. In *postnatal life* after puberty, there is reinitiation of further development of primary oocyte to form a mature oocyte. The different stages of development in oogenesis are as follows:

- Primordial germ cell
- Oogonia



Figs. 1A and B: Primordial germ cell migration.

- Primary oocyte
- Secondary oocyte
- Oocyte maturation
- Oocyte activation.

Primordial Germ Cells

Primordial germ cells reach gonads by 7 weeks of gestation. They undergo rapid proliferation and increase from merely 10,000 at 6 weeks of gestation to 6 lakhs at the 8th week, and to 6 million at the 20th week of gestation. Then the rate of oogonial mitosis slowly decreases and mitosis stops at 28 weeks of gestation. Simultaneously, there is onset of oogonial atresia at around 8 weeks which is maximum around 20 weeks of gestation. At birth, around 1 million germ cells exist in the ovary of which only 3–4 lakhs will remain till puberty due to atresia. Around 1% (300) manage to grow till the ovulatory state before menopause.[5]

Oogonia

Primordial germ cells on reaching gonads are called oogonia. They have high mitotic activity and undergo rapid mitosis and multiplication before the onset of meiosis. This mitotic activity ceases by 28 weeks of gestation. Formed oogonia are bound together in cellular bridges forming syncytium (clusters of cell). In these connected oogonia, there is synchronous onset of the subsequent meiosis. Mitosis and the simultaneously occurring oogonial atresia determine the final ovarian reserve.

Primary Oocyte

After the onset of meiosis, oogonia are called primary oocytes. Oogonia enter meiosis around 8–13 weeks of gestation. Gene *Stra8* is crucial for meiosis as DNA synthesis fails to occur in *Stra8* null mice.[6] Meiosis begins with a prophase stage, which is further divided into five stages: (1) Leptotene, (2) zygotene, (3) pachytene, (4) diplotene, and (5) diakinesis. On entering into the diplotene stage of prophase, oocytes go into a protracted resting phase called dictyate. The primary oocyte gets arrested at the first meiotic prophase stage, dictyate. Chromatin in the meiotically arrested oocytes is encapsulated by a nuclear structure and is called the *germinal vesicle (GV)*. GV oocytes are present in the primordial follicles. Recommencement of meiosis occurs in postnatal life just prior to ovulation.

It was believed that the number of primary oocytes is predetermined and cannot be increased beyond those indigenously laid down when the ovary was formed.[7,8] But few recent studies have shown oocyte regeneration from putative germ cells in bone marrow and peripheral blood.[9,10] In a recent study, oocytes and offspring were generated from female germ stem cells (FGSC) in mice.[11] These findings have significant implications for human reproduction, preservation of the fertility, and prevention of some health problems.

The remaining stages of development in oogenesis, i.e., secondary oocyte, oocyte maturation, and activation (all occurring in postnatal life after puberty), will be described after the stages of folliculogenesis.

STAGES OF FOLLICULOGENESIS

Oogonia are surrounded by somatic cells from the primitive gonads to form a follicle. The primary function of a follicle is to support the oocyte growth. Vascularization of ovarian cortex marks the beginning of folliculogenesis, which starts around the fourth month of gestation.

Different stages of development in folliculogenesis are shown in **Figure 2**.

- Primordial follicle
- Primary follicle
- Secondary/preantral follicle
- Antral follicle
- Selection and dominance of follicle
- Graafian/preovulatory/mature follicle.

Most of the growing follicles progress till antral stage and then undergo atresia. But after puberty, gonadotropins rescue few of the antral follicles and they continue to grow; out of these, one dominant follicle is formed every month,

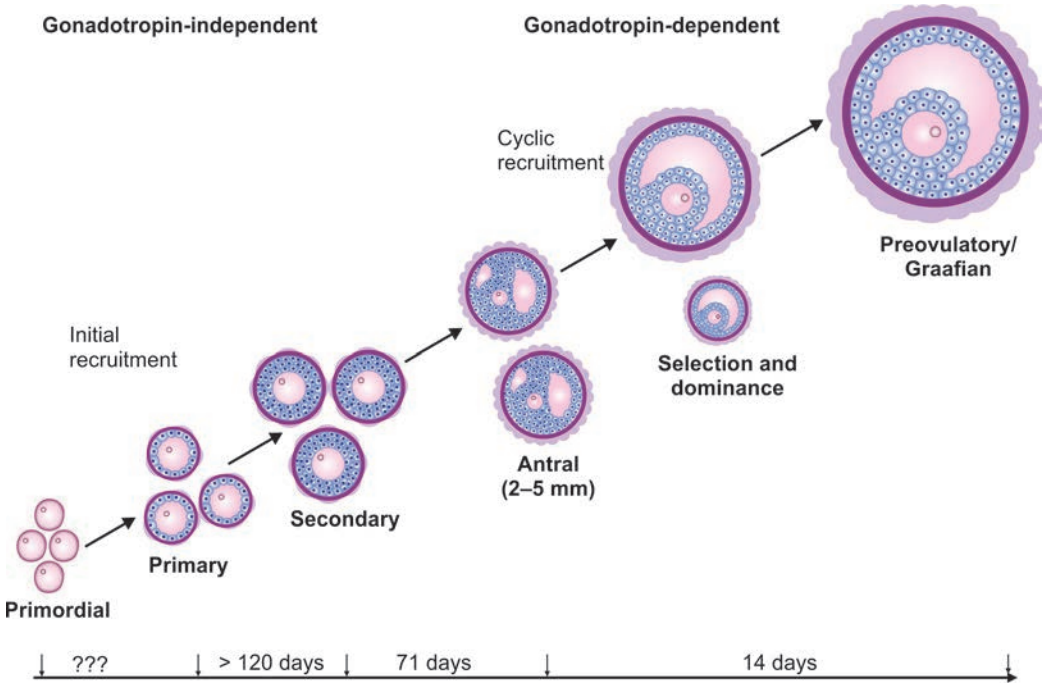


Fig. 2: Stages of folliculogenesis.

which ovulates. It takes 14 days to form a Graafian/dominant follicle from the antral follicle, but >85 days for a secondary follicle to grow into a Graafian follicle[12] **(Fig. 2)**. Moreover, it is estimated that >120 days might be required for the formation of secondary follicle from primary follicle and even longer for the formation of primary follicle from primordial follicle[12] **(Fig. 2)**. Thus, the whole growth phase of a follicle is greater than eight menstrual cycles or 220 days.

Primordial Follicle

Primordial follicle (30–60 μm) contains primary oocyte encircled by flattened pregranulosa cells. Its formation starts in the intrauterine life by the 15th week and is completed 6 months after birth. Various genes involved in its formation are transcription factors, meiosis-specific enzymes, zona proteins, and nerve growth factors. The total number of primordial follicles in the ovary ascertains the reproductive life span of a female. The process by which primordial follicles undergo further development is called "initial recruitment." Initial recruitment is moderated by various stimulatory and inhibitory hormones and locally produced growth factors.

Primary Follicle

Primary follicle (60 μm) has primary oocyte encircled by zona pellucida and granulosa cells which have become cuboidal from flattened state. Certain growth factors and extracellular matrix components having autocrine and paracrine effects act as stimulators and inhibitors **(Table 1)** in the transition of primordial to primary follicles.[13-15]

TABLE 1: Factors acting as stimulators and inhibitors in the formation of primary follicle from primordial follicle.

Stimulators	*Inhibitors*
• Kit ligand FGF-2 (basic fibroblast growth factor) – Keratinocyte growth factor – Leukemia inhibitory factor – BMP4/7/15 (bone morphogenetic protein) – Growth differentiation factor 9	• PTEN tumor suppressor gene (phosphatase and tensin homolog deleted on chromosome 10) – Tsc1/mTORC1 (tumor suppressor Tsc1) • Foxo3a (forkhead transcription factor) – P27 (cyclin-dependent kinase inhibitor 1B) – Foxl2 (winged-helix transcription factor) – Anti-Müllerian hormone

Inhibitory signals keep primordial follicles in the resting state (mice studies). Premature activation of the primordial follicle happens if there is loss of function of any of the inhibitory molecules.

FOXL2 has a crucial role in the transition of pregranulosa cells to granulosa cells. *FOXL2 mutation* has been associated with premature ovarian failure (POF) in humans[16] and also causes blepharophimosis, ptosis, and epicanthus inversus syndrome in humans.[17]

In polycystic ovaries, there is increased accumulation of primary follicles which is termed stockpiling. The explanation for stockpiling is either a slower rate of loss by atresia or higher initial population of primordial follicles in polycystic ovaries.[18]

Significance of anti-Müllerian hormone (AMH): It is a dimeric glycoprotein belonging to transforming growth factor beta (TGF-β) family. AMH is manufactured by the granulosa cells of primary, preantral, and small antral follicles from 36 weeks of intrauterine life. It is a detector of ovarian reserve having least inter- and intracycle variability. At puberty, AMH levels are at its peak and become obscure after menopause.[19] AMH inhibits the recruitment of primordial follicles. Thus in the absence of AMH, there is increased recruitment of primordial follicles leading to follicular depletion from the ovaries. Also AMH reduces follicle responsiveness to follicle-stimulating hormone (FSH) and acts as a negative regulator of follicle selection.[20] It is also a predictor of response to ovarian stimulation. The cutoff range for poor responders is 0.5–1.1 ng/mL (≤3.6–7.8 pmol/L) and for hyperresponders is >3.5 ng/mL (25 pmol/L).

Anti-Müllerian hormone is secreted from small- and medium-sized antral follicles, which are typically increased in polycystic ovaries; thus, significantly higher levels of AMH are seen in this population. Similarly, with the increasing age, there is a simultaneous decrease in small- and medium-sized follicles due to continuous atresia responsible for lower AMH levels in this population.

Recruitment of follicles: It includes initial and cyclic recruitment of follicles. As shown in **Figure 2**, in *initial recruitment*, the dormant primordial follicles are continuously recruited for further development. It starts immediately after the follicle formation and continues throughout life. After the initial recruitment, the follicle grows but the oocyte still remains arrested in the stage of prophase of meiosis I and the nonrecruited follicles remain dormant. As functional gonadotropin receptors are not developed in primordial follicles, FSH and luteinizing hormone (LH) are unlikely to have a role in the initial recruitment.[21] The above-mentioned stimulators and inhibitors may have a role in the initial recruitment. *Cyclic recruitment* occurs after puberty and is due to increase in FSH in the circulation that rescues a cohort of antral follicles (2–5 mm in diameter) from atresia in every cycle. Oocyte in these follicles is competent of resuming meiosis. Out of this cohort, one becomes the dominant follicle and the rest undergo apoptosis.

Atresia of oocytes: It is a continuous and ongoing process. It starts as early as 8 weeks of gestation. Oocytes which are not encircled by the granulosa cells for the formation of primordial follicle are lost by apoptosis. On entering the initial recruitment, the follicle progresses till the antral stage; after that, it automatically undergoes atresia. It is only after puberty that few antral follicles are conserved from atresia by cyclic recruitment, developing into mature Graafian follicle and ovulation. It is still not well understood why millions of germ cells are wastefully lost while only few [300–400 (1%)] reach the ovulatory stage. It has been proposed that factors such as age, pregnancy, lactation, hypophysectomy, unilateral ovariectomy, hormones, nutrition, ischemia, grafting, and X irradiations may influence follicular atresia.

Secondary/Preantral Follicle

Secondary follicle (120–150 μm) contains primary oocyte, zona pellucida, multiple layers of granulosa cells, and basal lamina surrounded by theca cells. An intricate network of capillary vessels is formed between the layers of theca cells. Although FSH receptors may be expressed on preantral follicles, the role of FSH in its development is debated. Members of TGF superfamily produced from granulosa and theca cells, activins from granulosa cells, GDF-9, oocyte-derived bone morphogenetic protein 15 (BMP15), and thecal cell-derived BMP-4/7 play a significant role in the growth of secondary follicle.

Granulosa cells do not have their own blood supply. Blood–follicle barrier is formed by the basal lamina. Between the granulosa cells, there exists an extensive network of gap junctions formed by connexin proteins. These gap junctions are extremely important in follicle development. They form an effective conveyance among the granulosa cells and also with the oocyte. In mice deficient for connexin 43 and 37, follicles do not grow beyond primary and preantral stages, respectively.[22,23]

Antral Follicle

There is further multiplication of granulosa and theca cells, increased vascularization, growth of oocyte, and formation of fluid-filled spaces which merge and form a cavity called antrum. These antral follicles are around 2–5 mm in diameter and can be seen on ultrasonography. Day 2 antral follicle count (AFC) is a crucial indicator of ovarian reserve. On the antral follicles, FSH and LH receptors are present on granulosa cells and theca cells, respectively. At this stage, follicles are dependent on FSH and LH for further development and are rescued from atresia by *cyclic recruitment* **(Fig. 2)**. The selective rise in serum FSH beyond a critical "threshold" level during the luteal follicular transition is a potent stimulus for the recruitment and growth of follicle. Rise in FSH also leads to maturation of granulosa cells, induction of LH receptors on it, stimulation of aromatase activity, and inhibin biosynthesis by granulosa cells. All these together lead to selection and dominance of only one follicle in natural cycle.

Following are the important concepts to be understood in folliculogenesis:

- *Follicle-stimulating hormone threshold:* According to this concept, FSH concentrations need to transcend a distinct level to stimulate ovarian follicle growth.
- *Follicle-stimulating hormone window/gate:* It is the period for which the elevated level of FSH above the threshold

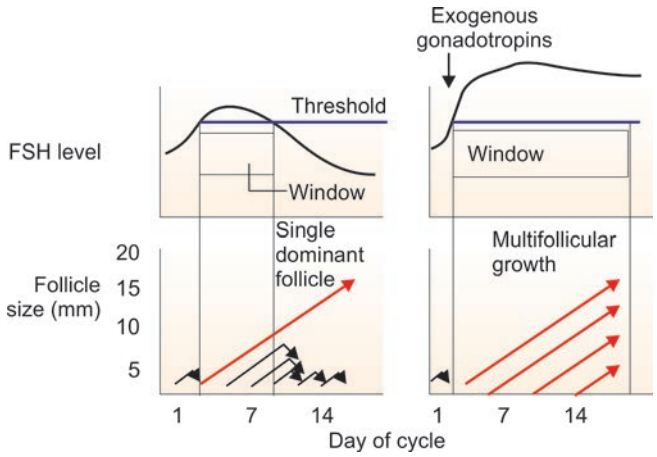

Fig. 3: Concept of FSH threshold and FSH window. (FSH: follicle-stimulating hormone)

needs to be maintained for follicular recruitment and growth.

- *Luteinizing hormone window:* This indicates the concentration of LH essential for follicular growth and selection of dominant follicle. A *threshold* and *ceiling* level for LH (therapeutic window) is proposed, below the threshold estrogen production is inadequate, and beyond the ceiling level LH may be deleterious to follicular growth.
- *Luteinizing hormone surge:* It is the rise in LH that stimulates the series of events leading to ovulation.

Follicle-stimulating hormone threshold and window concept **(Fig. 3)** help us to understand the monofollicular growth in a natural cycle. FSH on rising beyond the threshold stimulates recruitment and growth of follicles. FSH falls below the threshold due to the rising estrogen level which maintains the FSH window in natural cycle leading to monofollicular development.

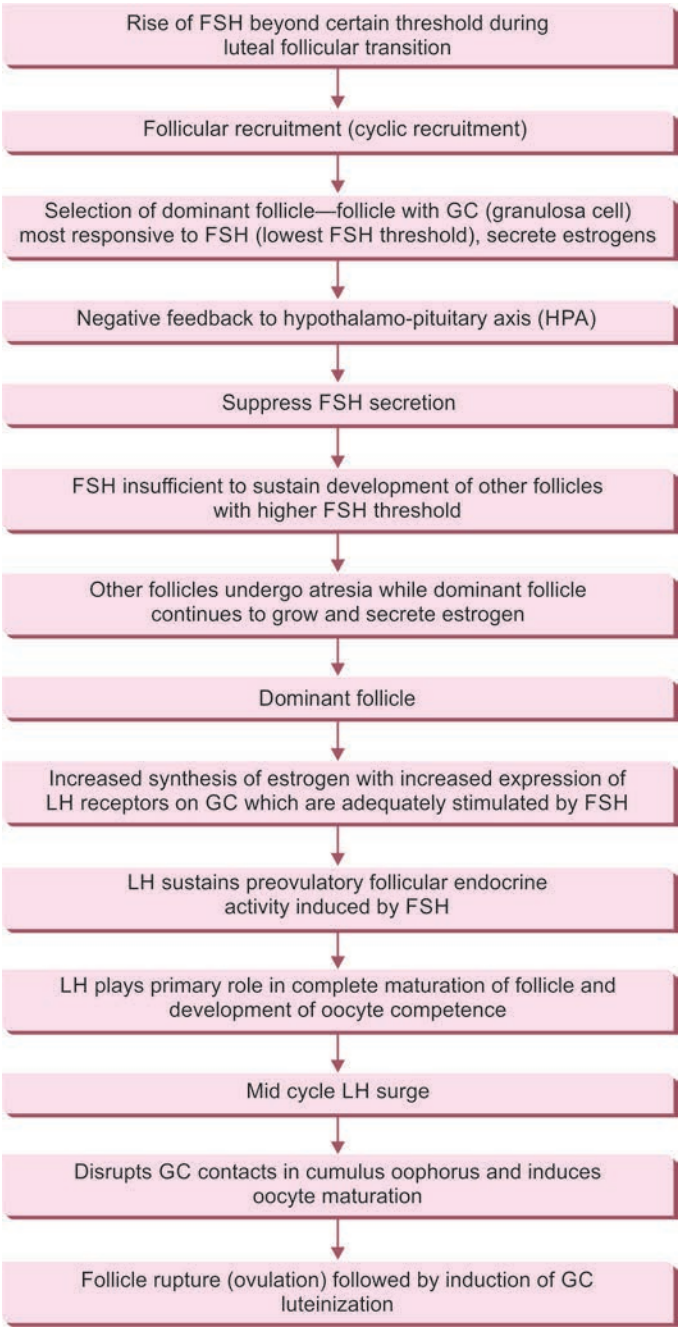
It also forms the basis for multifollicular growth in stimulated cycles. The FSH window is extended by giving FSH externally above the threshold which leads to recruitment and continuous growth of many follicles leading to multifollicular development.

Selection and Dominance of Single Follicle

Changes occurring in the granulosa and theca cells in response to FSH and LH explain the selection and dominance process. The follicle whose granulosa cells are most responsive to FSH (lowest FSH threshold) becomes first in the cohort to secrete estrogen and inhibin. Increasing estrogen and inhibin levels send feedback to the hypothalamic–pituitary axis (HPA) and begin to suppress pituitary FSH secretion. Decreasing FSH concentrations are inadequate to maintain the growth of other follicles that have higher FSH threshold leading to the growth of a single follicle having the lowest threshold. Induction of LH receptors on the maturing follicle reduces its dependence solely on FSH. This follicle distinctively responds to both FSH and LH and continues to grow and secrete estrogen in spite of decreasing concentration of circulating FSH **(Flowchart 2)**.

Thus, both FSH and LH are essential for normal follicular growth. FSH plays a crucial part in recruitment, selection, and dominance, while LH contributes to dominance, final maturation, and ovulation. LH has a crucial role in steroidogenesis. So in hypogonadotropic hypogonadism, both FSH and LH supplementation are required to ensure normal follicular development.

Flowchart 2: Selection and growth of dominant follicle in a natural cycle.



(FSH: follicle-stimulating hormone; LH: luteinizing hormone)

In anovulatory polycystic ovary syndrome (PCOS), there is arrested development of follicle and failure to develop a single dominant follicle due to FSH levels below the required threshold.[18] Also LH at inappropriately high concentration leads to follicular atresia or prematurely luteinization.

Graafian/Preovulatory/Mature Follicle

Graafian follicle or preovulatory follicle is a stage after the completion of the first meiotic division but before the ovulation. It contains a 2N haploid secondary oocyte located eccentrically surrounded by zona pellucida, corona radiata, cumulus oophorus, large antral cavity, granulosa cells, basal lamina, and theca (interna and externa) cells. The preovulatory follicle is around 16–29 mm and grows at a rate of 1–4 mm/day.[2] A dominant follicle having least FSH threshold, increased aromatase activity, and LH receptors on granulosa cells produces >90% of estrogen in the preovulatory period.[24] The estradiol level on reaching 200 pg/mL for >48 hours stimulates LH surge by providing positive feedback signal to the hypothalamus and pituitary which is needed for inducing ovulation. After the preovulatory estradiol peak, the serum progesterone level starts rising indicating the onset of follicular luteinization.[2] This midcycle progesterone rise may be responsible for FSH surge prior to ovulation. The growth and development of dominant follicle is explained in **Flowchart 2**.

The remaining stages of development of oogenesis are described in the following text.

Secondary Oocyte

Just before the ovulation, the arrested primary oocyte resumes meiosis I and the division is completed by the formation of a haploid secondary oocyte and first polar body.

Maintenance of primary oocyte in meiotic arrest: Primary oocytes are arrested in meiosis I till the LH surge; after puberty, meiosis I resumes. As shown in **Figure 4**, granulosa cells produce cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), which reach the oocyte via gap junctions.[20] Protein kinase A (PkA) is activated by cAMP which inhibits oocyte maturation and maintains meiotic arrest.

Resumption of meiosis: LH peak and various autocrine and paracrine signals are involved in the resumption of meiosis as shown in **Figure 5**. LH peaking leads to dispersion of cumulus cells and thus disruption of gap junction. This causes a fall in intra-oocyte cAMP and reinitiation of meiosis I. Also, LH peak causes influx of calcium which activates protein kinase C (PkC) which help to initiate meiosis I. Immediately after meiosis I, the secondary oocyte begins meiosis II and again gets arrested in metaphase of meiosis II (*called MII oocyte*). Meiosis II is complete only if fertilization occurs.

Understanding the importance of LH surge, it is to be administered in stimulated cycles as a trigger for the final maturation. Human chorionic gonadotropin (hCG) which acts as a surrogate for LH by binding to the same receptor (i.e., LH/hCG receptor) or gonadotropin-releasing hormone (GnRH) agonists which release FSH and LH from the pituitary are the different triggers used in stimulated cycles.

Various cascades of events occurring in oogenesis and folliculogenesis are shown in **Figure 6**.

Oocyte Maturation

Oocyte maturation includes resumption of meiosis I and nuclear and cytoplasmic maturation of the oocyte. LH surge initiates resumption of meiosis I. Once the oocytes begin to mature, their nuclei (i.e., GV) break down and chromosome condenses [i.e., GV breakdown (GVBD)]. Chromosomes are then arranged in metaphase I (MI) stage which is followed by anaphase I to telophase I completing meiosis I. Then oocyte enters meiosis II and gets arrested in metaphase called MII oocytes.[25] Cytoplasmic maturity of an oocyte includes

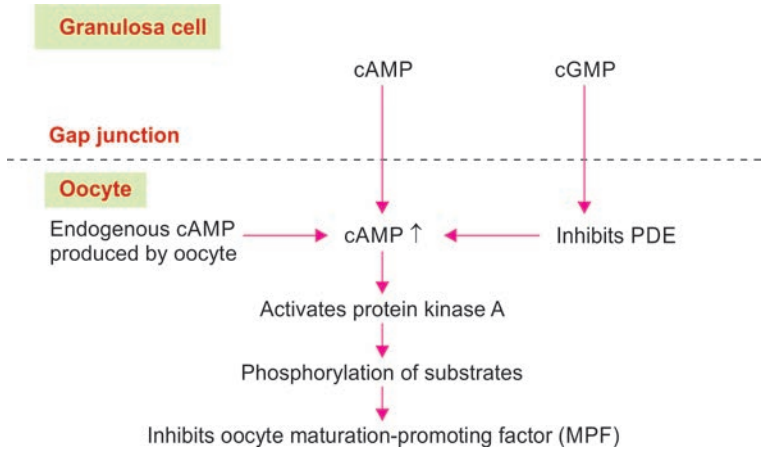


Fig. 4: Maintenance of primary oocyte in meiotic arrest.
(cAMP: cyclic adenosine monophosphate; cGMP: cyclic guanosine monophosphate; PDE: phosphodiesterase)

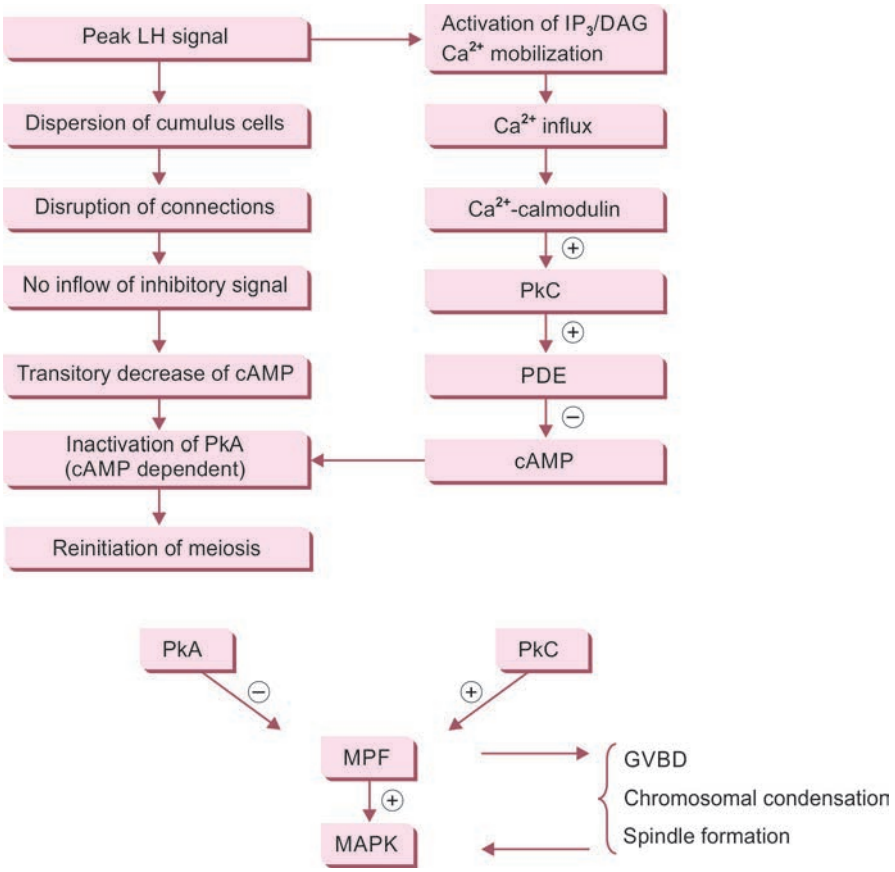

Fig. 5: Resumption of oocyte meiosis I.
(cAMP: cyclic adenosine monophosphate; DAG: diacylglycerol; GVBD: germinal vesicle breakdown; IP3: inositol-1,4,5-triphosphate; LH: luteinizing hormone; MAPK: mitogen-activated protein kinase; MPF: maturation-promoting factor; PDE: phosphodiesterase; PkA: protein kinase A; PkC: protein kinase C)

various events such as correct placement of organelles, post-translational modifications of mRNAs, synthesis of proteins, change in the number and morphology of mitochondria, ultrastructural modifications of Golgi complex, and accumulation of ribosomes. Then the mature oocyte is ovulated and is ready for fertilization.

Clinical implication: Retrieval of oocytes is done before ovulation in in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). These oocytes are not fully mature, although the first polar body is released and MII oocyte is seen.[26,27] There is asynchrony between the nuclear and cytoplasmic maturity in the stimulated cycles.[28,29] Thus cytoplasmic maturity may be induced by incubation of oocytes postretrieval, before IVF or ICSI, which eventually improves the fertilization and pregnancy rates.

Clinical significance of GV, MI, and MII oocytes: IVF or ICSI is performed on a fully mature MII oocyte. Collected GV or MI oocytes have to undergo in vitro maturation (IVM) before undergoing the IVF or ICSI procedure. The IVM procedure is beneficial and is indicated in a selected group of patients having polycystic ovaries, history of ovarian hyperstimulation, for fertility preservation (e.g., cancer patients), etc. In rare instances, there can be failure to complete meiosis in all the collected oocytes called oocyte maturation failure. Very few cases have been reported in the literature where all oocytes collected in GV or MI stage failed to resume meiosis when cultured in vitro.

Errors in meiosis: Gametes undergo meiosis for the maintenance of ploidy in the species. Meiotic dysfunctions are mistakes happening during meiosis.

- *Errors during DNA replication:* This occurs during DNA synthesis called S phase of meiosis. Errors while copying DNA cause alteration in the gene and can lead to mutations. Examples of diseases due to genetic mutation are sickle cell anemia, color blindness, etc.
- *Errors during recombination:* This occurs during meiosis I and II and can lead to alteration in the structure of chromosome. Mistakes while swapping of genetic material between paired chromosomes lead to errors such as duplication, deletion, inversion, and translocation (reciprocal and Robertsonian) of chromosome. Charcot–Marie–Tooth disease, Duchenne muscular dystrophy, hemophilia A, leukemia, etc., are examples of disorders caused due to recombination errors.

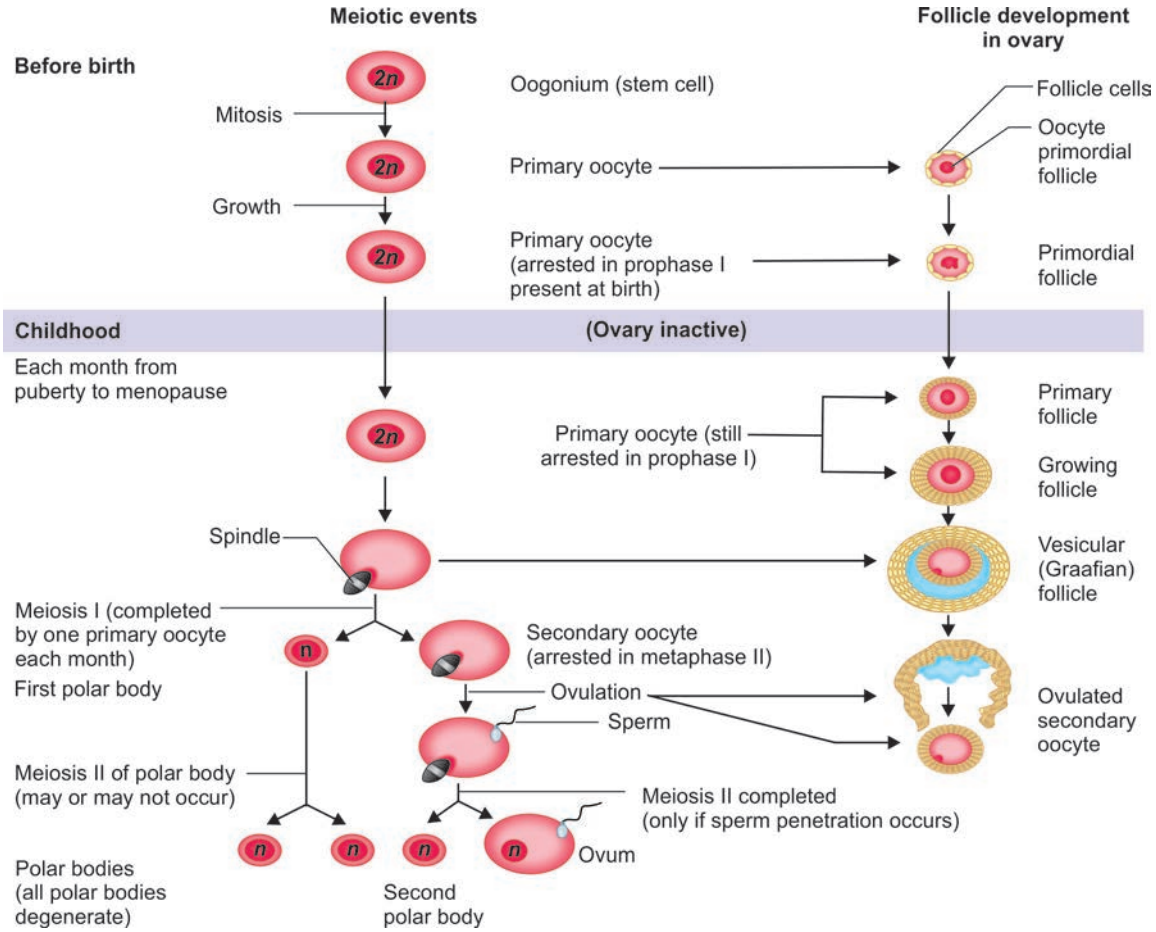

Fig. 6: Events occurring in oogenesis and folliculogenesis.

- *Errors during segregation:* This occurs during meiosis I and II due to nondisjunction of chromosomes. Prolonged arrest in the dictyate stage predisposes the oocytes for segregation errors resulting in aneuploid embryos leading to monosomies and trisomies (e.g., Turner and Down syndrome).

Ovulation

Ovulation is the process of release of female gamete from the ovary. It includes a series of changes occurring in the collagenous wall of the follicle to release the cumulus–oocyte complex. Ovulation occurs 10–12 hours after the LH peak and 24–36 hours after the estradiol peak. Roles of different hormones in ovulation are shown in **Figure 7**. All these hormones act together to breach the follicular wall and release the oocyte **(Fig. 8)**.

Cyclo-oxygenase (COX) inhibitors cause block in the synthesis of prostaglandins without an effect on LH-induced action on maturation and luteinization. Thus, nonsteroidal anti-inflammatory drugs (NSAIDs) taken near ovulation prevent rupture of follicle and may lead to luteinized unruptured follicle (LUF).

PREVENTION OF PREMATURE LUTEINIZATION

With continued cell proliferation and follicle growth, it is essential to prevent premature luteinization of growing follicles. Oocyte-derived BMP6, BMP15, and GDF9 prevent premature luteinization and control progesterone rise by suppressing gonadotropin-driven progesterone rise.[30] The effect of these luteinization inhibitors vanishes after ovulation, and luteinization will commence.

TWO-CELL, TWO-GONADOTROPIN THEORY

This theory explains the endocrine regulation of estrogen synthesis in a growing follicle. The gene *CYP17* encoding 17-hydroxylase/C-17-20-lyase activity is pivotal in androgen synthesis and is present only in theca cells. The role of FSH in a growing follicle is to increase FSH receptors on granulosa cells, LH receptors on theca cells, and granulosa cell aromatase activity. LH stimulates theca cells to produce androgens. Androstenedione produced by theca cells diffuse into granulosa cells and is converted to estradiol by aromatase (CYP19A1) activity **(Fig. 9)**. Androgens also play a role in follicle selection and dominance. Androgens

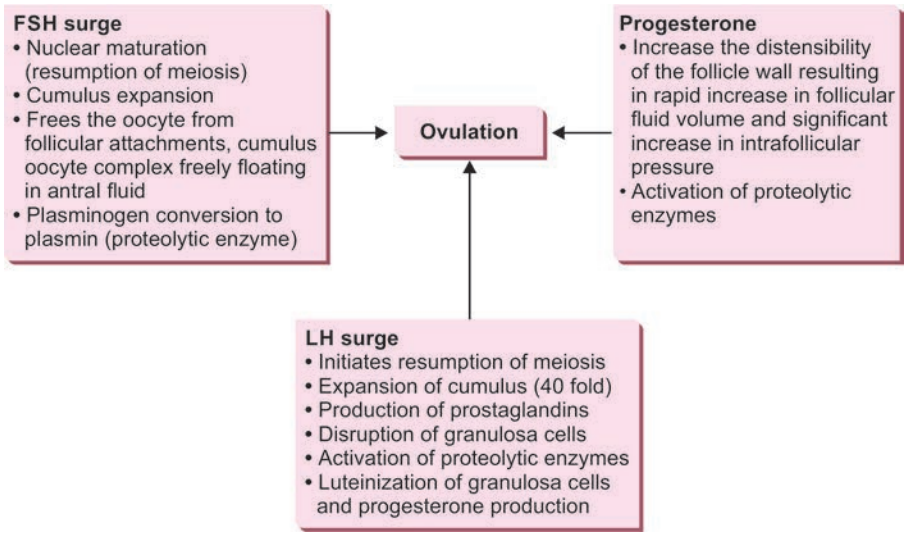

Fig. 7: Role of hormones in ovulation.
(FSH: follicle-stimulating hormone; LH: luteinizing hormone)

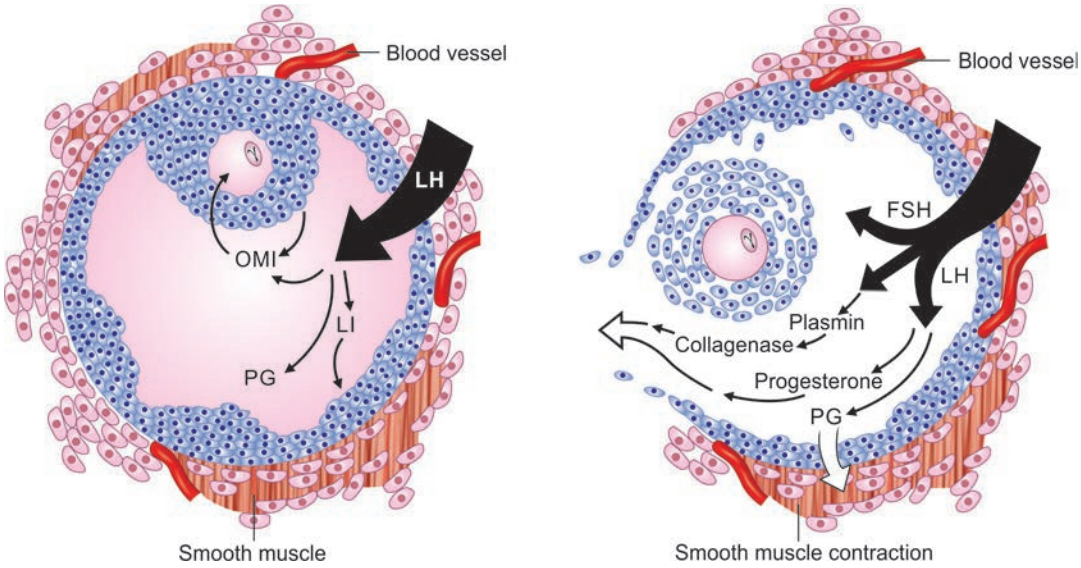

Fig. 8: Process of ovulation.
(FSH: follicle-stimulating hormone; LH: luteinizing hormone; LI; leukotriene; OMI: oocyte maturation inhibitor; PG: prostaglandin)

at low concentrations serve as a substrate for and enhance aromatase activity forming estrogen. At high concentration, androgens inhibit aromatase activity and FSH-induced LH receptor formation. Thus in hypothalamic hypogonadism, stimulation with FSH alone is not effective. Although it leads to the development of follicular size, estradiol production remains low and hence the occurrence of fertilization and pregnancy is low. These findings highlight the significance of both FSH and LH in follicle development **(Fig. 9)**.

CLINICAL IMPLICATIONS

Analysis of basics of oogenesis and folliculogenesis has important clinical implications.

- Multifollicular ovarian stimulation and development of different ovarian stimulation protocols
- Advancement of assisted reproductive techniques for the treatment of subfertile couples
- Preservation of fertility in individuals at risk of depleting ovarian reserve such as advancing age, any cancer, exposure to gonadotoxic agents, POF, and surgical menopause.

Understanding the basics has also answered some interesting queries like:

- *Does early menarche lead to early menopause*?
  All primordial follicles are destined to be subjected to apoptosis if not salvaged by FSH; thus, initial recruitment is responsible for follicular pool depletion rather than the cyclic recruitment. This indicates that even before the onset of puberty, follicles are lost from the pool by initial recruitment. Early menarche due to nutritional,

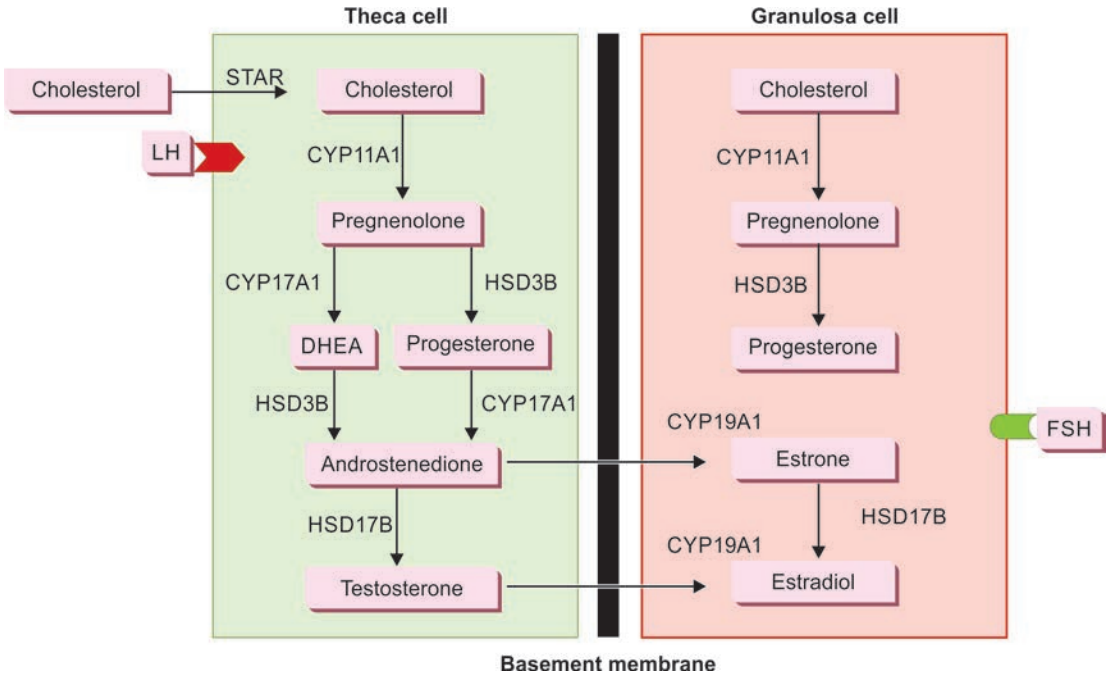

Fig. 9: Two-cell, two-gonadotropin theory. Cholesterol is internalized into the mitochondria via the steroidogenic acute regulatory protein (STAR). It is then converted to pregnenolone in the mitochondria via cytochrome-P450 cholesterol side-chain cleavage (CYP11A1). Pregnenolone then diffuses out of the mitochondria and is transported to the smooth endoplasmic reticulum where it is converted to progesterone or dehydroepiandrosterone (DHEA) via 3β-hydroxysteroid dehydrogenase (HSD3B) or 17α-hydroxylase-17,20-desmolase (CYP17A1), respectively. Progesterone and DHEA are then converted to the androgen androstenedione again via CYP17A1 or HSD3B, respectively. Androstenedione can then be converted to either testosterone or estrone via 17β-hydroxysteroid dehydrogenase (HSD17B) or aromatase (CYP19A1), respectively. Testosterone and estrone are then converted to the most potent estrogen, estradiol, via CYP19A1 (aromatase) or HSD17B, respectively.
(FSH: follicle-stimulating hormone; LH: luteinizing hormone)

environmental, or pathophysiological factors leads to early onset of cyclic recruitment, which should not affect the timing of follicle pool depletion and menopause.

- *Does unilateral ovariectomy or chemotherapy affect the age of menopause*?
  Unilateral ovariectomy or chemotherapy diminishes the pool of resting follicles, which is an important determining factor of ovarian aging. So it leads to early onset of menopause.
- *Does steroidal contraception delay menopause*?
  It mainly affects the surge of gonadotropins and thus prevents ovulation. It does not affect the initial or cyclic recruitment and so probably has no effect on age of menopause. But few epidemiological studies suggest that the age of menopause might be somewhat delayed; hence, more detailed studies are needed to prove its effects.
- *Whether increased parity delays menopause*?
  During pregnancy, progesterone in the circulation is elevated which might suppress initial follicular recruitment maintaining a greater follicle pool size. So, increased parity may lead to late onset of menopause.
- *Does repeated ovarian stimulation with gonadotropins lead to early onset of menopause*?
  Probably no, as the gonadotropins mainly act on antral follicles to promote cyclic recruitment. Gonadotropins may not have a role in initial recruitment, but it is uncertain whether repeated exogenous gonadotropin might increase follicle loss by an indirect action mediated through gonadotropin-responsive preantral follicles. Well-designed studies in egg donors need to be conducted to prove the effects of repeated ovarian stimulation on the age of menopause.

CONCLUSION

Remarkable progress is achieved in understanding the process of folliculogenesis and oogenesis, the gonadotropin-independent and -dependent phases, and various factors that act as stimulators and inhibitors in this process. Understanding the role of individual gonadotropins and the accessibility of recombinant preparations of FSH, LH, and hCG have opened the way to a more sophisticated and individualized approach to ovarian stimulation. Also, knowing the hormonal details of recruitment, follicular atresia, follicular maturation, and ovulation will facilitate to device new methods of contraception, to make improvements in culture conditions, and to treat subfertility associated with abnormal follicle development. May be in future we could

extend the female reproductive life span and delay the age of menopause if we are able to formulate regimens that will suppress the initial recruitment of the follicles.

CHAPTER 4

Spermatogenesis

Manishi Mittal

INTRODUCTION

The sperm is a unique cell produced in the mammalian male. Its specialized ability to move enables it to migrate through the female genital tract and fertilize the oocyte in vivo or in vitro. Its basic function is to carry the 23 male chromosomes to the egg at fertilization, and form the zygote. Also, the sperm centrosome provides the mechanism for cell division enabling mitosis and further development of the embryo.

GONADOGENESIS

The gonads develop in the gonadal ridge, by multiplication of primordial germ cells that originate in the extraembryonic mesoderm posterior to the primitive streak and thereafter cross the dorsal mesentery. This process is complete by 6 weeks of intrauterine life.[1] The developing gonad cannot be differentiated into male or female at this stage. Identification of gender starts after another 7–10 days.[2]

As opposed to females where oogenesis starts in utero; in males, meiosis is initiated with the onset of puberty. However, the foundation is laid during fetal development and any disturbance at this time may affect adult spermatogenesis.[3] The first cells to differentiate are the Sertoli cells (SC), which coordinate the development of the testis. The SC surround the germ cells (GC), which are further surrounded by the peritubular myoid cells to form the seminiferous cords which subsequently elongate to form the seminiferous tubules.[4]

THE SEMINIFEROUS TUBULES

The testis comprises an extensive tubular network which functions as the site for spermatogenesis. The tubules are lined by the seminiferous epithelium and contain a fluid-filled lumen, into which fully formed spermatozoa are released. Interstitial tissue lying between the tubules is formed of layers of myoid cells, fibrocyte-like adventitial cells, and collagen matrix. It contains blood vessels, lymphocytes, plasma cells, and Leydig cells. Peritubular myoid cells have properties similar to both fibroblasts and muscle cells. They provide support to the SC and drive testicular fluid, containing immotile spermatozoa, toward the *rete testis*. In addition, myoid cells help in paracrine control of SC function and preservation of the blood-testis barrier. It is believed that myoid cells secrete proinflammatory cytokines like tumor necrosis factor alpha (TNFα), escalation of which may cause peritubular wall remodeling and hence infertility.[5] Underneath the seminiferous tubules, there is a basement membrane, which lies on a connective tissue layer, the tunica propria.

Leydig cells are positioned in clusters between the blood vessels and seminiferous tubules. They are the main site of testosterone secretion in males. In humans, differentiation of these cells occurs in waves corresponding to the triphasic production of testosterone during fetal maturation. The first wave transpires between 8 and 18 weeks of gestation causing differentiation of male secondary sexual characteristics.[6] This is followed by the second wave in the first few months after birth, and the final wave during puberty.

The spermatogenic epithelium, including SC, is extremely susceptible to damage from toxins and ischemia. This damage may be partial, focal or complete, leading to abnormal sperm counts. The Leydig cells generally remain functional. Severe damage may cause complete destruction and hyalinization of the tubules, wherein they eventually get replaced by fibrous tissue.

Two main cell types are found in the seminiferous tubules:

1. *Sertoli cells:* They surround the GC and their cytoplasm extends through the entire height of the epithelium. Sertoli cells take up 17–20% of the adult spermatogenic epithelium and their number is directly proportional to the number of GC produced.[7] They are connected to each other by tight junctions. Structure of SC transforms continuously, helping in migration of developing GC toward the tubular lumen. One SC can sustain around 30–50 GCs at various points of differentiation.[8]

   Sertoli cells provide nutrition to the developing GC by transferring carbohydrates, amino acids, vitamins,

lipids, and metal ions. Furthermore, SC secrete numerous compounds that help in spermatogenesis, e.g., androgen-binding protein (ABP), proteases, vasoactive peptides, transferrin, vitamin transporters, lactate, acetate, extracellular matrix components, glial cell-derived neurotrophic factor (GNDF), TGF-a, TGF-b and interleukins.[9] They also deposit collagen and laminin along with forming junctions to maintain the seminiferous epithelium. Additionally, they provide immunoprotection and physical support. Alteration in any of these actions can cause infertility.

Sertoli cells multiply antenatally, in the neonatal period and just before attaining puberty. Different factors affect their growth; predominantly testosterone in the fetal and postnatal period and follicle-stimulating hormone (FSH) prior to puberty.[10] Multiplication of SC during any of these periods can be impaired by different environmental agents, thus limiting the production of GC leading to oligospermia. Functioning of SC is affected by presence of insulin, especially formation of lactate during carbohydrate metabolism. Moreover, lactate is a primary energy source for developing GC. Lactate production is decreased in absence of insulin, partly explaining adverse effect of diabetes on spermatogenesis.

2. *Germ cells:* They divide and migrate from the basement membrane vicinity, crossing the tight junctional complexes of adjacent SC to be ultimately discharged into the lumen as full-grown sperms. Any cross section of a normal seminiferous tubule shows four or five distinct generations of GC; earlier ones seen near the basement membrane, and the more mature ones toward the lumen **(Fig. 1)**. However, a single cross section does not simultaneously show all the stages.

The various GC seen in the cross section of seminiferous tubules (in ascending order of maturation) are as follows:[11]

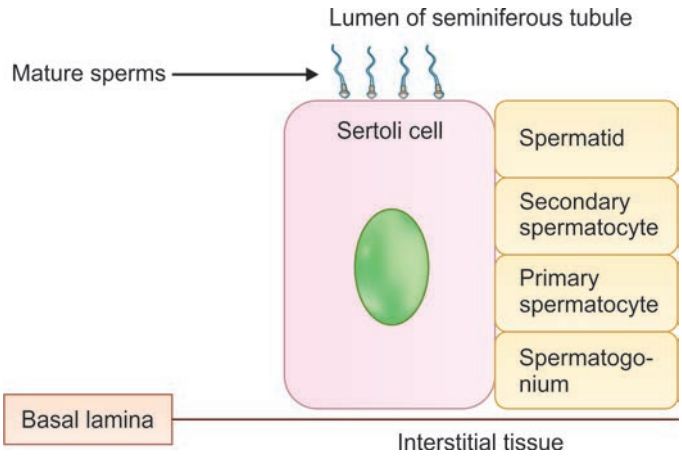

Fig. 1: Schematic of cross-section of seminiferous tubules showing various stages of spermatogenesis, with late spermatids in the lumen attached to tip of Sertoli cells.

- *Progenitor A dark (Ad)/A0 spermatogonia:* They provide a continuous supply of stem cells for spermatogenesis. They can divide into both type Ad and type Ap cells. They are located near the basement membrane.
- *Progenitor and committed A pale (Ap)/A1 spermatogonia:* Progenitor and committed cells have similar morphology but the committed ones go through repeated mitosis to form a clone of cells—type B spermatogonia. They are joined together by cytoplasmic bridges for synchronized development.
- *B spermatogonia:* Their division produces the first cell of the second phase, the diploid preleptotene spermatocyte, which crosses through the tight junctions between SC.
- Preleptotene (young primary spermatocytes), leptotene, zygotene, pachytene, and diplotene spermatocytes: These are the different stages seen during meiosis that progressively move toward the adluminal compartment.
- Secondary spermatocytes
- *Spermatids:* These are seen attached to the tip of SC. They are subdivided into Sa, Sb, Sc, Sd1, and Sd2 types.
- Spermatozoa.

SPERMATOGENESIS

Most mammals need 30–40 days to form mature spermatozoa, though in humans a mean interval of 74 days was observed between commitment of the Ap spermatogonium and extrusion of mature spermatozoon.[12] However, recent research has established a range of 42–76 days for total time required in formation of mature sperm in humans.[13] The number of sperms generated in a single male is thought to be approximately 150–275 million spermatozoa per day.[14] As opposed to the somewhat quiescent oocytes, spermatozoa are continuously produced by the testes and go through constant cell reproduction, meiosis, and spermiogenesis. Moreover, due to lack of recombination repair, male gametes are at a greater risk of damage to nuclear deoxyribonucleic acid (DNA).

Primordial GC form gonocytes, which stay in arrest in G0 phase till birth. Development of primordial GC and gonocytes is affected by products such as stem cell factor, stromal cell-derived factor 1, activator protein-2, growth and differentiation factor 3 (GDF3), estradiol, retinoic acid, and methylated DNA. Hence, these may be antecedent to various causes of infertility and some testicular tumors.[15] After birth, gonocytes develop into spermatogonia, which are inactive till 5–7 years age, subsequently undergoing mitosis. Ensuing puberty, further development starts.[16]

Spermatogenesis follows a rigid time scale. Ap spermatogonia simultaneously become committed at circumscribed areas within each seminiferous tubule. Hence, growing cells form clusters, which develop at intervals (16 days), specific for that location.[14] As a single spermatogonium develops, its progeny stay joined together

by cytoplasmic bridges until the late spermatid stage. The approximate number of spermatids developing from one spermatogonium is 512.[17] Multiple clusters are seen simultaneously, as the total duration of sperm formation is greater than the interim between commitment of spermatogonia at a particular position (74 vs. 16 days), forming *layers* or *generations*, with the earliest near the basement membrane. The multiple cohorts (six in humans) developing synchronously at a circumscribed area are called *cellular associations*.[12,14] Anomalous cellular associations may be seen in males with poor sperm formation, because of absent GC or mixing of different cohorts.

Spermatogenesis can be divided into four interdependent parts that are coordinated by factors emitted from the SC, peritubular cells, Leydig cells, and the vasculature:

1. Proliferation (spermatocytogenesis)
2. Meiosis
3. Differentiation (spermiogenesis)
4. Spermiation.

The phases of spermatogenesis transform with time as well as along the length of the tubular loop. The sequential change of cycle stage along the length is called the *wave* of the spermatogenic epithelium. The lesser stages are located near the middle of the loop and the advanced ones near the rete testis.[18]

Proliferation

The proliferation of the interphase GC begins at puberty. An estimated 500 spermatozoa per second are formed per gram of testis in the adult mammal.[19] Proliferation involves mitosis for regeneration of progenitor Ad and Ap spermatogonia, formation of B-spermatogonia from committed cells and their further development to preleptotene spermatocytes **(Flowchart 1)**. Any defect in proliferation can seriously affect the resulting sperm number.

Sertoli cells secrete factors that cause the spermatogonia to renew, differentiate or become apoptotic, a mechanism to control the SC/GC ratio. These factors include GNDF (promotes self-renewal), SCF, bone morphogenetic protein 4 (BMP4), retinoic acid, notch1/jagged 2 signaling system and many micro-RNAs.[20] The transition of Ad to Ap spermatogonia is regulated by pulses of retinoic acid which are staggered at regular intervals along the seminiferous tubules leading to asynchronous sperm formation. Any deviation in retinoic acid pulses may affect spermatogenesis.[21] Apoptosis is promoted by Bcl-2, Bax, and TNF-α acting thorough FaS/FaSL system. Any disruption in these mechanisms can cause infertility.

Inability of spermatogonia to evolve further causes eventual azoospermia. The pattern seen on histopathology is known as Sertoli cell only syndrome (SCO). SCO type 1 occurs due to abnormal migration of primordial GC from the yolk sac and is characterized by complete absence of GC. SCO type 2 occurs due to subsequent problems and shows occasional foci of spermatogenesis. In these cases, sperms may be retrieved with help of microdissection.

Meiosis

The primary spermatocytes are arrested in prophase of the first meiotic division until puberty (preleptotene spermatocytes). At puberty, these develop by meiosis into haploid secondary spermatocytes **(Flowchart 2)**. Prophase may last for nearly 3 weeks.[22] The pachytene stage is imperative to human evolution as it involves DNA recombination. Hence, there are many checkpoints during this stage as well as metaphase and anaphase. Recombination failure has been seen in around 10% of men with nonobstructive azoospermia (NOA),[23] and sperm aneuploidy may be the cause of 45% cases of recurrent miscarriage.[24] *TEX11* is a gene on the X chromosome that controls homologous chromosome

(n: set of chromosomes; 1n: haploid; 2n: diploid)

synapses and double-strand DNA break repair. Its mutation was seen in 2.4% of men with "idiopathic infertility".[25] Early maturation arrest, or arrest seen in meiosis affects around 10% of men with NOA. This is seen more often during meiosis 1 as quality control is more extensive in this stage. These men can have focal areas of normal spermatogenesis and show a 20–40% sperm retrieval rate with microdissection.[26]

Secondary spermatocytes have the shortest life span—1.1–1.7 days.[27] They undergo meiosis II, eventually forming haploid spermatids. The autosomes in the spermatid nucleus sustain production of small amounts of ribosomal and messenger RNA and proteins, so that they can enter into a protracted stage of terminal differentiation or spermiogenesis.

Differentiation

This process refers to the morphological differentiation of round spermatids to elongated cells with a species-specific shape. Duration of spermiogenesis is roughly 14 days in most species, wherein there are 16–18 delineated stages.[28]

There are three major modifications:

1. The nucleus elongates and chromatin condenses into a very dark staining structure, forming the head of the sperm.
2. The Golgi apparatus produces a lysosomal-like granule that spreads over the nucleus, with help of perinuclear theca, to form the future acrosome, which is rich in enzymes required for oocyte penetration and fertilization.
3. Reorganization of the cytoplasm leads to formation of the tail and the midpiece. The midpiece contains the mitochondria and related control mechanisms required for mobility.

The sperm cell needs to be compacted; therefore the DNA is condensed to below 10% of volume of a somatic cell. The solenoid structure is replaced by toroids which are further supercoiled into toroidal loops. Deoxyribonucleic acid is at first packaged with histones; subsequently, at secondary spermatocyte stage, histones are replaced by transition proteins followed by protamines. Compaction is achieved by disulfide bonding between DNA and protamines. Other factors helping to package sperm DNA include histone modifications, chromatin-binding proteins, and noncoding RNAs.[29] Protamines make up roughly 85%, and histones around 15% of proteins in mature sperm.[30] Underprotamination causes defective chromatin packaging, seen as presence of endogenous nicks in ejaculated spermatozoa.[31] The extent of protamine replacement reflects the fertilizing capacity of the sperm. Low H4 hyperacetylation has been associated with maturation arrest.[32] Remaining histone-bound DNA content is important for proper sperm function and early embryo evolution. Proportion of different protamine types also influences fertility. Males with lower P1/P2 ratio were seen to have higher DNA fragmentation index (DFI).[33]

Deoxyribonucleic acid packaging has multiple purposes, which are as follows:

- Reducing volume of the spermatozoa for easy travel through the genital tract.
- Attenuating exogenous damage before fertilization.
- Keeping the genome transcriptionally dormant.

Anomalous formation of acrosome affects the shape of sperm head, a condition known as globozoospermia. It is a rare ailment wherein round headed sperms are seen, which cannot penetrate or activate oocytes. Hence, to achieve good results in assisted reproduction techniques (ART), conventional ICSI needs to be combined with assisted oocyte activation.[34]

Reorganization of the cytoplasm causes elongation of the sperm. Extra cytoplasm is discarded as the cytoplasmic lobe that eventually gets phagocytosed by the SC as the residual body. Intercellular bridges connect residual bodies, resulting from incomplete division during spermatogenesis. Appearance of residual body indicates final maturation.[1] The mitochondria are organized around the microtubules in the tail and provide energy for motion. The mitochondria have been observed to perform indispensable function in the GC including energy production and apoptosis. Moreover, they are imperative for proliferation and mitotic regulation. Mutations in mitochondrial genome are recognized in infertile patients especially those with asthenospermia. Aging, obesity, and metabolic disorders affect mitochondrial action on fertility.[35]

When sperms are near the last stages of spermiogenesis, their ribosomes have almost disappeared, and the endoplasmic reticulum is absent. Since now, no mechanism remains for protein synthesis; hence, sperms have to acquire factors needed for further transport from external environment, or store them beforehand.

Six stages of differentiation are as follows:

1. *Sa1 and Sa2:* They contain well-differentiated Golgi complex and mitochondria. The acrosome vesicle, proximal centriole, and axial filaments appear. The chromatin body appears in one pole opposite to the acrosome vesicle.
2. *Sb1 and Sb2:* The formation of acrosome and intermediate piece is completed.
3. *Sc1 and Sc2:* Tail development is completed.

Arrest of spermiogenesis at the early spermatid phase (dark round nuclei) is known as late maturation arrest, which is less common then early maturation arrest (arrest at spermatogonia/spermatocyte stage). These sperms may still be used in ART after using microdissection techniques like microTESE. Better sperm retrieval rate is seen in late arrest (50–80%). Arrest during late spermiogeneisis (condensed

oval spermatids) is known as hypospermatogenesis and has best sperm retrieval rate (80–90%) among all causes of NOA.[36]

If the male pronucleus has obvious flaws such as compromised genomic integrity, aneuploidy, or misestablished epigenetic information, the effects may become obvious only after fertilization.[37] Apoptosis of defective GC helps to prevent transmission of such defects. On the other hand, increase in apoptosis by stimuli such as hormonal irregularity, ionizing radiation, chemotherapy, cell injury and cell stress, can lead to abnormal fall in number of GC.[7]

Intracytoplasmic sperm injection (ICSI) is a procedure that can use testicular sperms for the management of azoospermic males. However, these sperms may be defective and not yet have undergone apoptosis. These may fertilize the oocyte but the embryos would have poor reproductive outcome. Few studies have identified molecular markers that assess the protein and ribonucleic acid (RNA) content of spermatozoa prior to their use in assisted ART.[37] Further research in this area will help to improve results.

In spite of extensive defense systems, both developing and mature sperms can suffer DNA breakage, leading to subfertility. This damage is assessed with the help of DNA fragmentation index (DFI). A rise in sperm double-stranded DNA breaks has been seen with increasing age of the human male, along with a fall in regulatory sperm apoptosis. This indicates that the system of selection of healthy sperms declines with age.[38] High DFI is observed in diabetics, which can be attributed to increased oxidative stress because of advanced glycation end products.[39]

Spermiation

This process involves the extrusion of the elongated spermatid from the SC into the tubular lumen. Residual bodies remain embedded in the epithelium. The stalk connecting it to the spermatid breaks, resulting in formation of proximal cytoplasmic droplet in neck region of the spermatozoon. The embedded residual bodies are phagocytosed and protoplasm is recycled. Degenerated GC are also phagocytosed. Follicle-stimulating hormone and testosterone act synergistically to aid spermiation as seen by dysfunction in disengagement of spermatids from SC after suppression of both these hormones, in animal studies.[40]

Epigenetic State during Spermatogenesis

Epigenetic changes during spermatogenesis **(Fig. 2)** are significant as they aid in the following:

- Silencing of transposable elements
- Paternal imprinting
- Chromatin remodeling
- Sex chromosome inactivation
- DNA compaction.

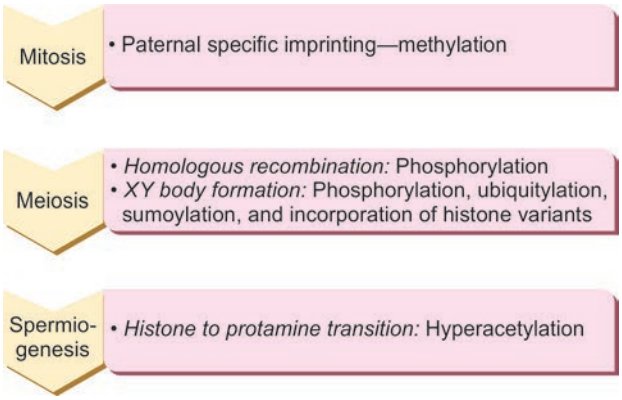

Fig. 2: Epigenetic changes during different stages of spermatogenesis.

Paternally imprinted genes are methylated, hence silenced in male GC so that expression is from maternal gene. Paternal imprinting starts in the gonocytes and is carried through remaining spermatogenesis.

Clinical implications include the following:

- Defective methylation may lead to oligospermia.[41]
  - Use of such sperm for intracytoplasmic sperm injection (ICSI) may cause transmission of epigenetic defects to subsequent generations.
- If genomic imprinting is not finished at the round spermatid stage, it could be completed after round spermatid enters the ooplasm, as DNA methylation has been demonstrated at the blastocyst stage and early embryonic development.[42]

Researchers have tried to generate elongated spermatids from surgically removed testicular spermatogenic GC, for use in ICSI for azoospermic men with maturation arrest.[43] However, it is not sure if imprinting can be successfully completed in vitro, hence leading to tumor susceptibility or other imprinting disorders after fertilization. Some conditions such as obesity and environmental exposure are postulated to affect spermatogenesis through epigenetic mechanisms, though further evidence is required in this field.[44]

Epididymal Maturation

Spermatozoa gain the ability to fertilize oocytes by various changes in the epididymis, collectively known as epididymal maturation, e.g., an increase in net negative charge of the sperm head, which facilitates attachment to the zona pellucida. Sperms undergo various complex biochemical, biophysical, and ultrastructural molecular changes, such as, loss of protein, cyclic adenosine monophosphate (cAMP), modification in energy metabolism, and changes in lipoprotein content, size, shape, and structure of acrosome. There are no obvious changes in the sperm tail though the cytoplasmic droplet seen around the neck is gradually lost.

Sperms aspirated from the distal corpus, after undergoing maturation process, are able to undergo capacitation and fertilization, hence preferred for ICSI.

The testis synthesizes many antigens required for binding to the oocyte and fertilization, which are activated when the sperms pass through the epididymis. A few examples are membrane-bound hyaluronidase (PH20/2B1), fertilin, proacrosin, 1, 4-galactosyl transferase (GalTase), and putative zona ligands sp56 and p95.[45]

Passage through the epididymis also provides motility to the sperm as evidenced by the fact that testicular spermatozoa are immotile even though flagellar morphological structures are acquired during spermiogenesis. Motility is possibly regulated at the level of the plasma membrane which alters progressively as sperm passes through the epididymis since the osmolality and chemical composition of the epididymal fluid differs in each segment.[46] During maturation, sperms use up the endogenous energy reserves and become dependent on external fructose.

In the human male, spermatozoa travel from the seminiferous tubules to the rete testis, further via the ductuli efferentia, finally into the caput epididymis. Testicular fluid gets resorbed in the proximal epididymis leading to concentration of the spermatozoa up to 10–100 times. Sperms negotiate the epididymis in 2–14 days and subsequently are stored in the cauda, vas, seminal vesicles, and ampullae before ejaculation. However, the viability of sperms is affected with increased duration of storage; therefore, for accurate semen analysis, sample should not be taken >5–7 days after ejaculation.

Abnormality at any of the stages of epididymal maturation may result in different pathologies, including azoospermia. The tubular lumen is highly sensitive to toxins and any damage results in altered sperm counts. Reactive oxygen species (ROS), in spite of being important for sperm capacitation, can themselves induce peroxidative damage and subsequently decreased sperm motility. Hence, supplementation with antioxidants helps to improve asthenospermia. However, care should be taken not to overload as even the normal action of reactive oxygen species (ROS) may be lost.

Blood–Testis Barrier

The testicular circulation is separated from the general circulation by a "blood-testis barrier" composed of tight junctions between adjacent SC **(Fig. 3)**. The main function of this barrier is to control passage of large molecules from the interstitial tissue and the basal compartment of the seminiferous tubule to the lumen and surrounding area. However, steroids can cross this barrier easily. Moreover, some proteins may also travel from SC to Leydig cells and vice versa in a paracrine manner.

Movement of developing GC from the basal compartment to the lumen is seen to occur without disruption of the barrier by progressive breakdown of the tight junctions above the GC, and concomitant formation of new tight junctions below them.

The blood–testis barrier is responsible for a particular composition of the luminal fluid of the tubule. The fluid is rich in androgens, estrogens, K^+, inositol, and glutamic and aspartic acids, with traces of protein and glucose. An osmotic gradient is created that promotes fluid entry into the lumen. Another important function of the barrier is to protect the developing spermatozoa from blood-borne toxins. It also prevents antigenic products of spermatogenesis from entering the circulation and generating an autoimmune

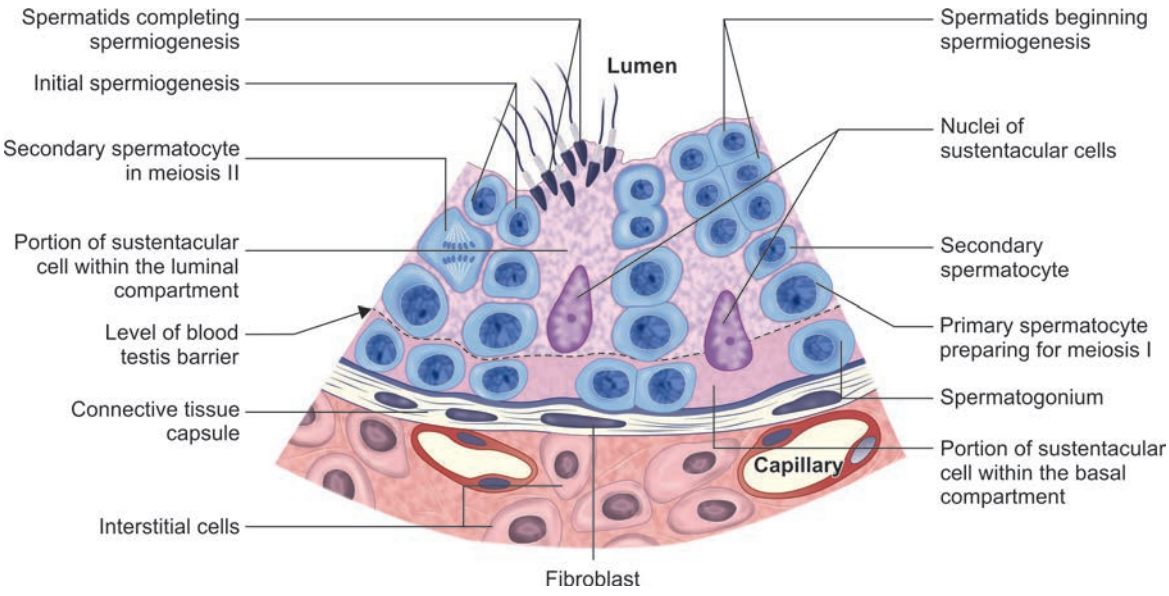

Fig. 3: Tight junctions between adjacent Sertoli cells form the blood-testis barrier.

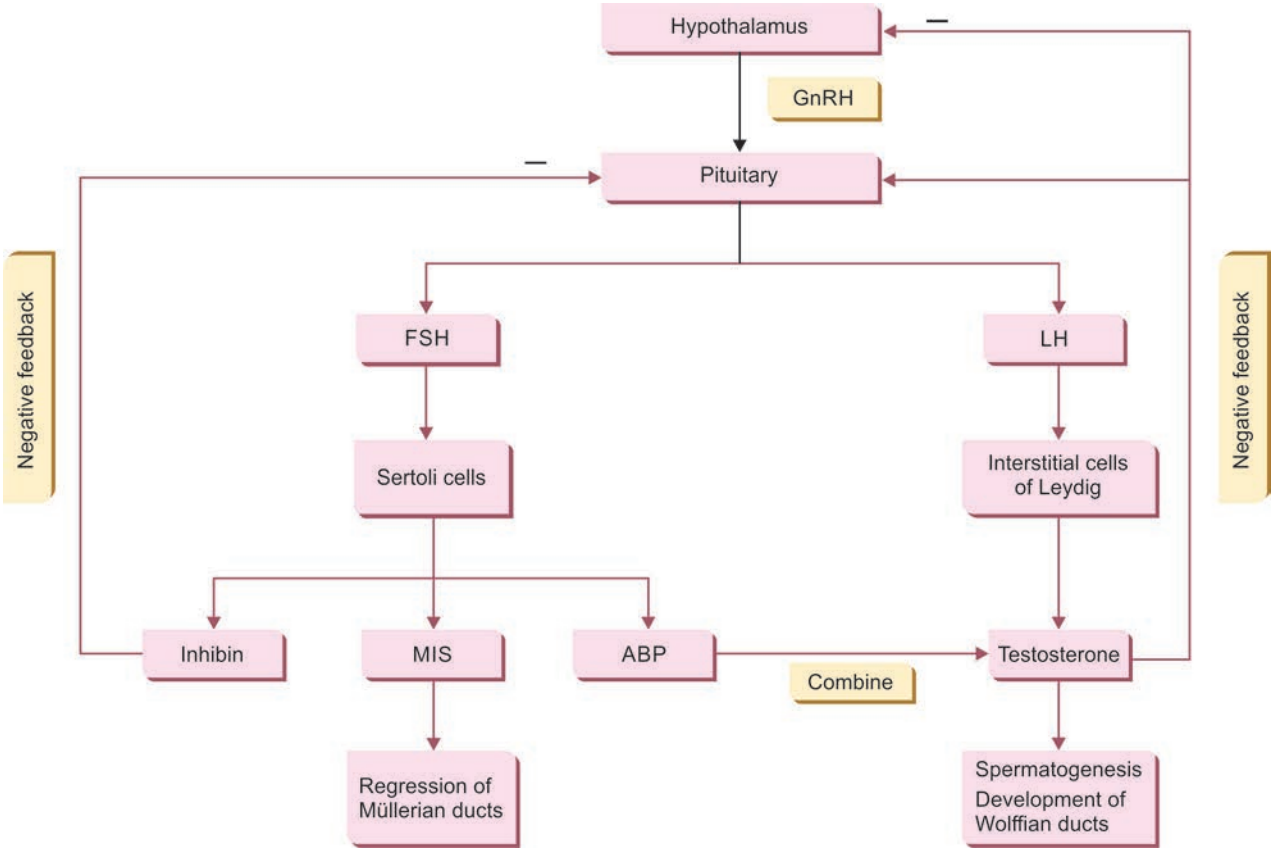
Flowchart 3: Endocrine control of spermatogenesis.



(GnRH: gonadotropin-releasing hormone; MIS: Müllerian inhibiting substance; ABP: androgen binding protein; LH: luteinizing hormone; FSH: follicle stimulating hormone)

response. Diseases like diabetes mellitus affect proper functioning of the blood–testis barrier causing male infertility.

Endocrine Control

The hypothalamic-pituitary-gonadal axis is a complex system of feedback and feed forward loops responsible for spermatogenesis and appearance of secondary sexual characteristics **(Flowchart 3)**. The hypothalamus releases various gonadotropin-releasing hormones that regulate the secretion of gonadotropins from the pituitary, which further act on the gonads. Therefore, hypothalamic disease leads to atrophy of the testes and loss of their function.

Gonadotropins released from the pituitary are FSH and luteinizing hormone (LH). FSH acts on the SC to produce ABP. LH stimulates the interstitial cells of Leydig to produce testosterone. Testosterone, in turn, combines with ABP in the seminiferous tubules, and controls LH secretion by negative feedback to the hypothalamus and pituitary. Interaction between these hormones is responsible for normal spermatogenesis. Novel research has shown that FSH may not be crucial for spermatogenesis as shown by the fact that spermatogenesis persisted in men with poor FSH production or FSH receptor mutation, though it was adversely affected.[47] Estimation of blood levels of FSH, LH, and testosterone is necessary to evaluate males with abnormal semen parameters as enumerated in **Table 1**.

TABLE 1: Endocrine profile in azoospermia.

Category	*Endocrine profile*			*Diagnosis*
	LH	*FSH*	*Testo*	
Eugonadotropic azoospermia	N	N	N	• Local factors—obstruction, maturation arrest • Sexual dysfunction
Hypergonadotropic azoospermia	↑	↑	↓	Testicular dysgenesis
Hypogonadotropic azoospermia	↓	↓	↓	Central defect—hypothalamus and pituitary

(FSH: follicle-stimulating hormone; LH: luteinizing hormone; Testo: testosterone; N: normal)

Androgen-binding protein (ABP) is responsible for sustaining high androgen concentration in testis and epididymis, by controlling their bioavailability, decreasing metabolism and improving their uptake.[48] High intratesticular testosterone is necessary for normal sperm

development; low levels cause spermatogonial apoptosis and defective spermiogenesis.

Different stages of spermatogenesis are under different endocrine control, for example, proliferation and meiosis appear to be androgen-independent. However, differentiation depends on androgens acting on the SC, where the developing spermatozoa are embedded. Final stages of spermatid maturation are expedited by FSH action on SC. Androgen receptors are located in the SC, Leydig cells, peritubular muscle cells, and vascular smooth muscle cells; but not in GC.[49] Testosterone regulates LH secretion by negative feedback on the hypothalamus and pituitary and Leydig cell action through an ultrashort loop negative feedback.[50]

Development of gonocytes is affected by activin A, follistatin, and inhibin. FSH promotes inhibin and follistatin secretion from SC, thus indirectly affecting gonocyte maturation.[51] Moreover, FSH decreases degeneration of spermatogonia and promotes their entry into meiosis along with testosterone. Inhibin B is a glycoprotein hormone that controls FSH secretion, and partly LH secretion, through negative feedback on the pituitary. The α subunit of inhibin B is located primarily in the SC, whereas, the β subunit is located predominantly in GC.[52] Hence, SC and GC must cooperate for formation of inhibin B, which further acts in a paracrine and autocrine manner to regulate SC and Leydig cell function. Damage to SC affects inhibin production, in turn raising serum FSH.

Exogenous use of androgenic steroids decreases secretion of LH from the pituitary. This decreases intratesticular testosterone, thereby inhibiting spermatogenesis. However, this suppression is temporary and is reversed after stopping steroid use.[53] This effect has been seen in athletes who take steroids; and is also used for male contraception.

Another important hormone required for development of male characteristics is the Müllerian inhibiting substance (MIS) or Müllerian regression factor. Secreted by SC, MIS reaches average plasma concentration of 48 ng/mL by the age of 1–2 years. Thereafter, it declines to low levels by puberty and remains at low but detectable levels throughout life. The interplay between MIS and testosterone is an important determinant for male sexual development. While these two hormones act unilaterally on the internal genitalia, the action on external genitalia is opposite. Main function of MIS is to promote regression of the Müllerian ducts by apoptosis, whereas, testosterone stimulates the development of the vas deferens and related structures from the Wolffian ducts. The testosterone metabolite dihydrotestosterone is responsible for formation of male external genitalia and secondary sex characteristics.

Sertoli cells do not synthesize androgens, but they contain aromatase (CYP19), that produce estrogen from androgens. The local interaction between androgens and estrogen is necessary to maintain normal spermatogenesis. It has been seen that low seminal testosterone/estradiol ratio and high seminal estradiol levels can be used to predict rate of surgical retrieval of sperms from testes of males with NOA.[54] Estrogen promotes germ cell functions such as movement and substrate metabolism. It also helps in vitro survival of sperms.[55] On the other hand, estrogens have a negative impact as they disturb development of interstitial cells antenatally. They also disrupt multiplication and differentiation of gonocytes and spermatogonia.[56] Extrinsic estrogen use causes apoptosis of GC. A useful function of the female hormone is seen in the rete testis where concentration of semen occurs. Here, the fluid has high estrogen levels, and the walls contain numerous ERα receptors. Defective working of the rete testis results in dilution of the semen entering the epididymis resulting in infertility.

Genetic Control

Thousands of genes have been identified as affecting sperm production. Abnormalities in any of these should affect spermatogenesis. Still, practically only a few have till now been identified as related to failure of spermatogenesis. Mutations in genes related to meiosis lead to either GC arrest or formation of abnormal gametes **(Table 2)**. Even though more and more genes are being identified as related to male infertility, their use as part of diagnostic workup is limited.

Normal spermatogenesis is under the control of azoospermia factor (AZF) region located on the euchromatin zone of long arm of Y chromosome. There are around 14 protein encoding genes divided into three groups—*AZFa*, *AZFb*, and *AZFc*.

- Microdeletions in any of these regions can lead to infertility though incidence and phenotype varies geographically and ethnically.[57]
- Microdeletions are seen in 10% of men with NOA and 5% of those with severe oligospermia.
- AZFc deletion is more frequently responsible.

Screening for Yq microdeletions is commonly used in males with severe oligospermia or azoospermia. Further analysis of the effects of genetic variants on sperm production is under research.

Klinefelter syndrome is the most common genetic cause of male infertility. The prevalence is 5% in severe oligospermia and 10% in NOA.[58] Though karyotype is

TABLE 2: Genetic abnormalities affecting spermatogenesis.[76]

Genetic abnormality	*Examples*
Numerical and structural chromosomal abnormalities	Klinefelter syndrome (XXY), reciprocal translocations, and pericentric inversions
Y chromosome deletions	AZFa, P5/proximal P1 (AZFb), P5/distal P1, b2/b4 (AZFc), and gr/gr deletions
Monogenic disorders	Endocrine defects, e.g., Kallmann syndrome and Noonan syndrome

mainly 47,XXY, around 20% show mosaic patterns such as 46,XY/47,XXY, 48XXXY, or 48 XXYY.[59] The process of inactivation of extra X chromosome is disturbed in Klinefelter syndrome affecting androgen production and spermatogenesis.

Micro-RNAs are short (20–23 nucleotides) single-stranded noncoding nucleotides. These are abundantly found in GC, many being stored in the chromatoid body. Newer studies have observed their effect on apoptosis, proliferation and differentiation. This post-transcriptional action is important because of silencing of GC during few stages of spermatogenesis. Anomalous expression of micro-RNA may adversely affect spermatogenesis leading to "idiopathic" infertility.[60]

Effect of Environment and Lifestyle (Flowchart 4)

Temperature

- Spermatogenesis requires the temperature of the testes to be lesser than in the interior of the body (about 32°C).[61]
- It is theorized that cooler conditions are due to air circulating around the scrotum and a countercurrent heat exchange between the spermatic vessels.
- Exposure to higher temperature can lead to degeneration of the spermatogenic epithelium, leading to infertility, for example, as seen in cryptorchidism.
- Evidence suggests that hot baths (43–45°C for 30 min/day) and insulated athletic supporters can reduce the sperm count, sometimes by 90%.[62]
- A seasonal effect has also been propounded, with higher sperm counts in winter regardless of the temperature to which the scrotum is exposed.
- Temperature can also be affected by viral fevers like influenza, or occupation like in bakers or foundry workers.
- High temperature can lead to hypoxia and oxidative stress in the developing sperms.
- Regarding this, much speculation has been made about the increasing use of laptops and smartphones. However, studies done on males who spend long time in sitting position or use laptops have not shown a direct correlation between time spent and poor semen parameters.[63] Still, they may exacerbate the action of other adverse environmental factors.
- Varicocele (dilated spermatic cord veins) affect spermatogenesis by raising the scrotal temperature. Moreover, it also causes oxidative stress through testicular hypoxia and disruption of blood-testis barrier.

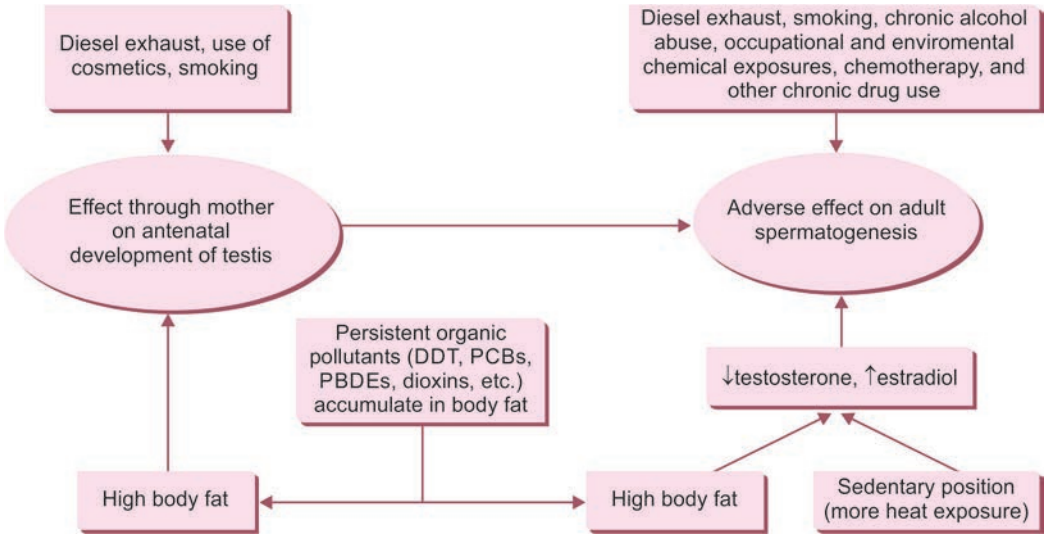
Obesity

- Obesity is related to both female and male infertility.
- High body mass index (BMI) (>25 kg/m^2) in males has been seen to decrease sperm count and motility by 25%.[64]
- Rise in BMI is directly proportional to fall in testosterone levels, affecting spermatogenesis.[65]
- Higher peripheral conversion to estrogens can alter T/E2 ratio.
- Fat may get deposited near scrotal vasculature affecting cooling.

Smoking and Alcohol

- Lifestyle problems such as smoking and chronic alcohol consumption affect sperm counts significantly, especially in combination.[3,66]
- Maternal smoking during pregnancy can impair spermatogenesis in male fetus.[67]
- Smoking causes hypoxic damage while alcoholism can lower testosterone values.

Flowchart 4: Environmental factors affecting spermatogenesis—at adult stage and during antenatal period.



(DDT: dichlorodiphenyltrichloroethane; PCBs: polychlorinated biphenyls; PBDEs: polybrominated diphenyl ethers)

Effect of Drugs

- Chemotherapy (cyclophosphamide, etc.)[68] and radiotherapy are well known to hamper spermatogenesis. Hence, before starting this treatment, any male desiring future fertility should be advised to freeze semen.
- Chronic use of some medicines can alter spermatogenesis and cause infertility, e.g., sulfasalazine (used in irritable bowel syndrome),[69] H1 receptor antagonists (for allergies), antiepileptics, antibiotics and H2 receptor antagonists (cimetidine).[70]

Occupational Exposure

- Few occupations have been associated with male infertility due to chemical exposure, such as dibromochloropropane (nematocide used on crops), glycol ethers (solvents in various procedures), heavy metals (lead, cadmium, and mercury), metal welding fumes and carbon disulphide.[3]
- Heavy metals like lead may also affect general population due to exposure from paints, petrol and diesel fumes, and consumption of fish in which metals get concentrated.
- Farmers in India are a high-risk group due to excessive use of pesticides without adequate protective gear. Chronic exposure to pesticides such as dichlorodiphenyltrichloroethane (DDT) and organophosphates is associated with poor semen parameters, altered hormonal status, and sperm chromatin damage, leading to infertility.[71] In vitro sperm quality is also decreased, affecting assisted reproductive technique success rates.[72] Use of multiple pesticides can have additive effect.
- Few pesticides persist in the crops, affecting the consumers.

Many environmental factors affecting the adult sperm producing capacity may affect a male fetus through maternal exposure too. They can exacerbate the effect on adult.[3] More research is necessary in environmental factors affecting spermatogenesis so that eliminating the exposures may decrease infertility incidence.

In Vitro Spermatogenesis

Researchers are experimenting with new approaches to improve fertility potential of men unable to produce functional sperm or for fertility preservation. Animal trials have been performed with autologous methods such as stem cell transplantation, de novo morphogenesis, and testicular tissue grafting. Xenografting and in vitro spermatogenesis are other methods.[73] All these approaches have shown some promise. The only method that has been tried in human males is autologous spermatogonial stem cell transplantation,[74] but the outcomes have not been reported, though the method has been successfully used in primates. Another possibility is autologous testicular tissue grafting which has been successfully used in primates, though no human trials have yet been done.[75]

In vitro spermatogenesis, if successfully replicated, will have an advantage in not risking malignant reintroduction or retroviral infection (as possible in testicular tissue grafting and xenografting). Complete in vitro spermatogenenesis has been performed in mice, but the results could not be reproduced in primates or humans. Human testicular tissue has been cultured up to haploid round spermatid stage but epigenetic/genetic normality and fertilization capacity is still elusive. Better appraisal of fertility potential of these cells in primates is necessary before human trials.

A better knowledge of basic human physiology will help us to improve ART procedures affecting the clinical outcome. Knowledge about factors affecting spermatogenesis is also important to improve reproductive health of males.

KEY POINTS

- Primordial germ cells arise just behind the primitive streak in the extraembryonic mesoderm. They migrate through the dorsal mesentery, and finally colonize the gonadal ridge.
- As opposed to females, where oogenesis starts in utero; in males, meiosis is initiated with the onset of puberty.
- The site for spermatogenesis is seminiferous tubules of testis.
- Sertoli cells are an important component of spermatogenesis. Their number is directly proportional to the number of GC produced.
- Germ cells divide and move from the basement membrane region, through tight junctional complexes of adjacent SC to be finally released into the lumen as mature sperms. The younger ones are at the basement membrane, and the more mature ones are located near the lumen.
- Mean interval of 74 days has been observed between commitment of the Ap spermatogonium and extrusion of mature spermatozoon.
- Spermatogenesis can be divided into four interdependent parts: proliferation (spermatocytogenesis), meiosis, differentiation (spermiogenesis), and spermiation.
- The sequential change of cycle stage along the length is called the wave of the seminiferous epithelium. The lesser stages are located near the middle of the loop and the advanced ones near the rete testis.
- Proliferation involves mitosis for renewal of progenitor Ad and Ap spermatogonia, formation of B-spermatogonia from committed cells, and their further division to preleptotene spermatocytes.
- The primary spermatocytes are arrested in prophase of the first meiotic division until puberty (preleptotene spermatocytes). At puberty these develop by meiosis into haploid secondary spermatocytes.

- *Differentiation:* Round spermatids are differentiated morphologically into elongated cells with a condensed nucleus and a flagellum.
- Epigenetic changes during spermatogenesis are significant as they aid in silencing of transposable elements, paternal imprinting, chromatin remodeling, sex chromosome inactivation, and DNA compaction.
- *Epididymal maturation:* Sperms undergo various complex biochemical, biophysical, and ultrastructural molecular changes such as loss of protein, cyclic adenosine monophosphate (cAMP), modification in energy metabolism, changes in lipoprotein content, size, shape, and structure of acrosome.
- Luteinizing hormone stimulates the interstitial cells of Leydig to produce testosterone.
- Testosterone combines with ABP in the seminiferous tubules, and controls LH secretion by negative feedback to the hypothalamus and pituitary.
- High intratesticular testosterone is necessary for normal spermatogenesis.
- Screening for Yq microdeletions remains the only genetic test commonly used in males with severe oligospermia or azoospermia.
- Various environmental factors such as high temperature, obesity, drugs, and occupational exposure have been seen to adversely affect spermatogenesis.
- In vitro spermatogenesis, if successfully replicated, will have an advantage in not risking malignant reintroduction or retroviral infection.

CHAPTER 5

Fertilization and Embryogenesis

Divya Sardana

INTRODUCTION

The spontaneous fusion of the sperm and the egg forms the zygote, the first cell of a baby through the process of fertilization. Fertilization is a complex sequence of coordinated molecular events beginning after the contact between a sperm and an oocyte. This is followed by intermingling of the parental chromosomes (of mother and father) and restoring the genetic constitution of the normal human being.[1] The zygote may die if there is any defect at any stage in the sequence of these events.

EGG TRANSPORT

The usual site of fertilization is the ampullary portion of the fallopian tube which is also the longest and the widest part.

At the time of ovulation, the secondary oocyte which is expelled from the ovarian follicle is swept into the funnel-shaped infundibulum of the fallopian tube. A picture of mature metaphase oocyte is shown in **Figure 1**.

This sweeping action is the result of the peristaltic movement of cilia on the mucosal cells of the fimbriae. With this movement, the oocyte reaches the ampulla of the tube.[2]

While the fertilization and dispersal of the cumulus cells occurs in the ampulla at its junction with the isthmus.

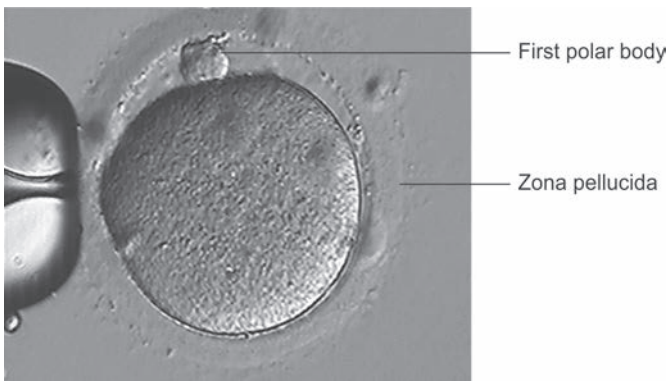

Fig. 1: Metaphase II oocyte (secondary oocyte) after denudation of the cumulus cells. The extruded first polar body can be seen at the top.

The transport of the fertilized oocyte through the tube requires about 3 days.[3] By this time, the endometrium becomes receptive for implantation.[4,5]

SPERM TRANSPORT

Following the deposition of semen through ejaculation, prostatic enzymes in the semen cause liquefaction. This takes around 20–30 minutes.

There is a transient protection of sperm from the acidic pH of vagina due to the alkaline pH of semen. The motile sperm enters into the cervical folds. Those that remain in vagina are immobilized within 2 hours.[6] The entry of the sperm into the cervical mucus is also aided by the contractions of the female reproductive tract. Cervix acts as a reservoir, and can provide sperm supply for up to 3 days. The sperms actively push their way through the cervical mucus.[7] This is enabled in part by the interaction between properties of the sperm head and the mucus.[8] Abnormal morphology of the sperm head can also result in poor penetration of cervical mucus.[9,10] The cervical mucus in turn has a filtering action on the less motile and less capable sperm.[11]

Throughout the sperm transport from vagina to the fallopian tube, there is substantial reduction in the number of sperms. The sperms are lost in vagina with semen expulsion from the introitus, digested by vaginal enzymes and by phagocytosis during the journey through the uterine cavity.

VIABILITY OF GAMETES

The human oocyte is known to survive for 12–24 hours after ovulation. After 24 hours, it degenerates whereas human sperms probably survive for 48 hours in the female genital tract. Some sperms remain in the cervical mucosal folds and are gradually released into the uterus up to 72 hours of coitus. Hence, there are maximum chances of conception when coitus happens within the 3-day-interval just before ovulation.[12,13]

CAPACITATION

Sperms which are freshly ejaculated cannot fertilize oocytes. They must undergo some cellular changes in the female reproductive tract, collectively called capacitation or physiological priming, to be able to fertilize the oocyte. This includes:

- The ability for acrosomal reaction
- Binding ability to the zona pellucida
- Hypermotility (hyperactivated motility).

In this capacitation, the seminal proteins and the glycoproteins are removed from the acrosome of the sperm and their surface charge is altered. Bicarbonate ion ($HCO3^-$) is present in various secretions of female reproductive tract. Bicarbonate influx in sperm leads to increased intracellular pH which causes plasma membrane collapse. Further, albumin present in female reproductive tract secretions causes cholesterol efflux from sperm plasma membrane making it more fluidic which in turn facilitates acrosome reaction. This process takes around 7 hours and happens in the uterus or tubes by substances secreted by these parts of the female reproductive tract.

When such sperms reach near the oocyte or follicular fluid, there is a breakdown of these plasma membrane and outer acrosomal membrane which is called the *acrosomal reaction*.[14] With the breakdown of the outer acrosomal membrane, there is release of the acrosomal enzymes namely—hyaluronidase, neuraminidase-like factor, cumulus-dispensing enzyme, and acrosin which probably play role in sperm penetration through the investments of the egg and digestion of zona pellucida.

Moreover, the capacitation results in increased velocity of the sperm and increased flagellar beat amplitude (hyperactivity) which helps in the penetration of zona pellucida. This process of capacitation is the result of influx of calcium ions in the sperm, in turn induced by progesterone. Increased intracellular calcium causes redox reactions in the sperm cell and the resulting changes in the sperm membrane.[15,16]

PROCESS OF FERTILIZATION

The sequence of events in the process of fertilization involves:

- *Sperm penetration through the corona radiata:* The capacitated sperms are guided to the oocyte by the chemical signals (attractants), secreted by the oocyte and the surrounding follicular cells. Oocyte factors especially growth differentiation factor 9 (GDF-9) and bone morphogenetic protein 15 (BMP-15) are important for cumulus differentiation and expansion. Preovulatory expansion of cumulus oophorus increases the chances of encounter with the sperm. The follicular cells are dispersed from the oocyte by the action of enzyme hyaluronidase from the sperm acrosome and also possibly by the enzymes from tubal mucosa.[17] Abnormal secretion of oocyte factors may impair sperm transit or sperm capacitation.
- *Penetration of zona pellucida:* This is an important step in fertilization. Zona pellucida is a glycoprotein layer that surrounds the oocyte and is made up of four proteins namely, ZP1, ZP2, ZP3, and ZP4. The acellular zona surrounding the egg is penetrated by the sperm with the help of acrosomal enzymes mainly—acrosin, esterase, and neuraminidase, as well as by sperm motility.[18,19]

  The zona pellucida has species-specific receptors for the sperm. The zona pellucida glycoprotein-3 (ZP3) is the main sperm ligand.[20] Once the sperm binds to ZP3, the acrosome reaction is triggered. This requires receptors on the sperm head also, e.g., tyrosine kinase, protein kinase C, and G-protein signaling system.[21-25] Once activated, there is:
  - Calcium influx
  - Efflux of hydrogen ions
  - Increase in pH
  - Fusion of sperm plasma membrane with outer acrosomal membrane leading to exocytosis of enzymes on the inner acrosomal membrane.
- Zona pellucida glycoprotein binding to sperm occurs after the acrosome reaction and this triggers *zona reaction* in which zona pellucida becomes impermeable to other sperms once the fertilizing sperm penetrates it. This is a protective mechanism to prevent polyploidy.[26] This zona reaction is a result of the action of lysosomal enzymes released by cortical granules near oocyte plasma membrane. When these granules discharge these enzymes into the perivitelline space, changes in the plasma membrane occur (rapid depolarization, hardening by cross-linking structural proteins, and inactivation of sperm ligands) which makes it impermeable to sperms.[27]
- *Fusion of plasma membranes of oocyte and sperm:* Sperm enters perivitelline space at an angle and then there is fusion of egg and sperm membranes. This is again mediated by specific proteins (ligands) on sperm head—PH-20 binds with zona pellucida; PH-30 (fertilin), and vitronectin help in fusion with oocyte.[28-30] Oolemma microvilli, CD-9-associated proteins, and glycosylphosphatidylinositol (GPI) proteins are thought to play role in fusion. The sperm nucleus enters the cytoplasm of the oocyte while the plasma membrane remains behind.
- *Completion of second meiotic division of oocyte and formation of female pronucleus (PN):* Human oocytes remain arrested at the metaphase stage of second meiotic division. This arrest is released and the development proceeds by a process called *"oocyte activation"*. This activation involves:
  - Release from meiotic arrest (after approximately 3 hours)[31]

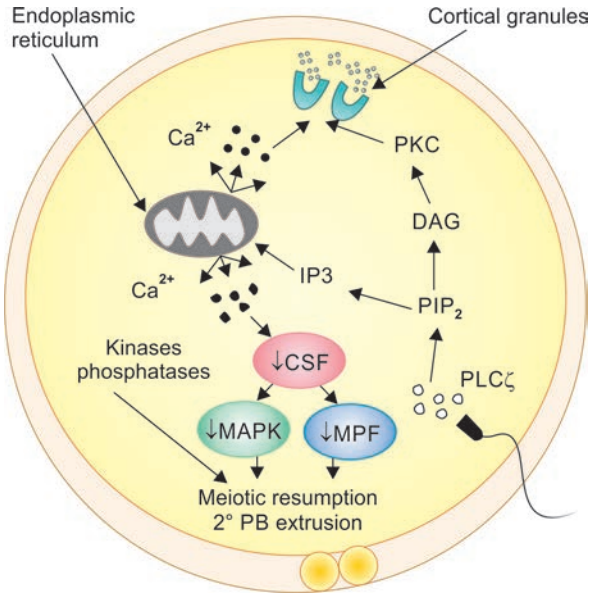

Fig. 2: Molecular mechanism of oocyte activation.
(CSF: cytostatic factor; DAG: diacylglycerol; PB: polar body; MAPK: mitogen-activated protein kinase; MPF: maturation-promoting factor; PKC: protein kinase C; PLCζ: phospholipase C zeta)

- Extrusion of second polar body
- Exocytosis of cortical granules
- Formation of female PN.[32-36]

This is the result of repeated oscillations of free cytosolic calcium. Though the precise mechanism of these oscillations is unclear, it is now widely believed to be the result of a soluble "sperm factor",[37-41] namely phospholipase C zeta (PLCζ)[42] localized to the equatorial region of the sperm head **(Fig. 2)**.[43]

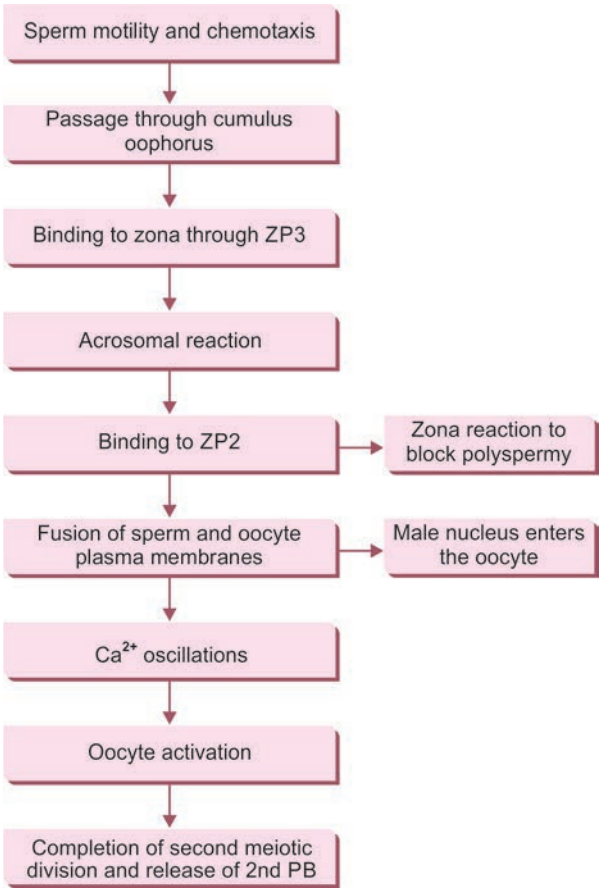
The major cause of fertilization failure, or abnormally low fertilization after intracytoplasmic sperm injection (ICSI) is a deficiency in the process of oocyte activation during the process of *in vitro* fertilization (IVF).[44,45]

- *Formation of male pronucleus:* Nucleus of the sperm enlarges to form male PN within the oocyte cytoplasm. Tail of the sperm degenerates. Male PN forms slightly earlier or simultaneously with female PN (which forms adjacent to second polar body). This is the stage of fertilized egg (oocyte containing two haploid pronuclei) **(Fig. 3)**.
- *Zygote formation:* The pronuclei migrate toward each other via sperm aster microtubules, their opposing membranes break down, and their chromosomes get arranged on a spindle. There is restoration of the normal diploid number of chromosomes (46) in the zygote. Crossing over of chromosomes shuffles the genes and produces a unique recombination of the maternal and paternal genes.[46]

The sex of the embryo is determined by the genetic kind of sperm (X or Y) that fertilizes the oocyte. Fertilization by X-bearing sperm produces 46, XX zygote and by Y-bearing sperm produces XY zygote which develops into a female.

Fig. 3: Two pronuclei stage where pronuclei from male and female gametes are closely opposed. Second polar body can also be seen at the top.

Flowchart 1: Sequence of events during the process of fertilization.



(PB: polar body; ZP3: zona pellucida glycoprotein-3)

This sequence of steps in the process of fertilization is shown in **Flowchart 1**.

EMBRYOGENESIS

The thick zona pellucida is present around the zygote during cleavage. Zygote starts dividing into blastomeres about 30 hours after fertilization, first forming the two-cell stage

Fig. 4: Two-cell stage of the embryo (after the first cleavage of the zygote).

Fig. 5: Four-cell stage of the embryo.

(Fig. 4), and then the four-cell **(Fig. 5)**, and the eight-cell stage **(Fig. 6)**.

The zygote undergoes repeated mitotic divisions and there is a rapid increase in number of cells. The embryonic cells (blastomeres) gradually become smaller with each division.

There is a marked increase in ribonucleic acid (RNA) and protein synthesis, and change in patterns of phospholipid synthesis. These blastomeres which were originally round and loosely adherent, begin to flatten, increase cell-to-cell contact and align themselves tightly against each other to form a compact ball of cells. This process of compaction is mediated by cell surface adhesion glycoproteins. This allows greater cell-to-cell interaction and is important for segregation of internal cells that form inner cell mass (ICM) or embryoblast of future blastocyst.

Fig. 6: Eight-cell stage of the embryo.

GENOME ACTIVATION

During its development, the oocyte accumulates reserves of messenger RNA (mRNA), proteins, organelles, etc. to support the early development. The zygote initially depends on stored maternal mRNA during its first cleavage divisions. Then there is critical transition to zygotic genomic activation during the four-to eight-cell stage in humans. Maternal mRNA rapidly disappears and further development is directed by the new embryonic genome. The mammalian embryo fails to develop further if the zygotic genome activation does not occur. There is modification in protein synthesis and nucleolar organizing region (NOR) also.

The compacted stage with 12–32 blastomeres is called a morula; this forms about 3 days after fertilization **(Fig. 7)**. The boundaries between membranes are not clearly distinguishable.

Cleavage of zygote and morula formation occurs during the passage of the dividing zygote through the fallopian tube. The spherical morula enters the uterus and blastocyst formation generally occurs in the uterus.

In spite of the increase in number of cells, there is no increase in size of developing embryo until the zona pellucida degenerates.[47]

BLASTOCYST FORMATION

About 4 days after fertilization, the embryo at the stage of morula enters the uterus and a fluid-filled space called blastocele appears inside it. This is the effect of activation of Na-K-ATPase system resulting in energy-dependent active transport of Na into the center of embryo, followed by osmotically driven movement of water inside.

Gradually, the fluid increases and it separates the blastomeres into an outer thin layer called the trophoblast and the central blastomere collection called the ICM

Fig. 7: Stage of morula with compacted cluster of cells formed by repeated division of the zygote. Till this stage the embryo travels through the fallopian tube.

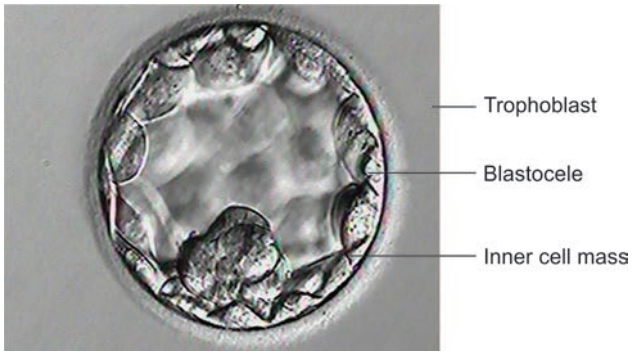


Fig. 8: Blastocyst stage with degenerating zona pellucida. The size of the blastocyst has increased and the cavity is filled with fluid (blastocele) separating the blastomeres into outer trophoblast and the inner cell mass. This generally develops in the uterine cavity.

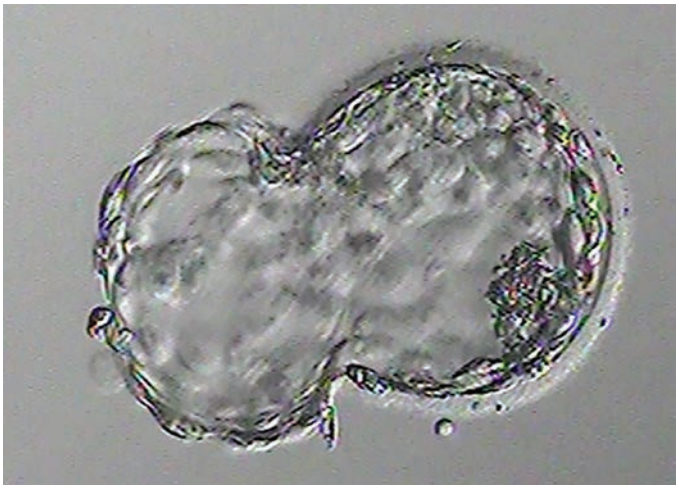

Fig. 9: The hatching blastocyst stage. Zona pellucida has degenerated and the embryo is escaping out.

(*see* Fig. 8). While the blastomeres at previous stages are totipotent, at compaction the cells polarize radially and divide into the following:

- Outer polar cells with surface microvilli and these cells form trophectoderm
- Inner apolar cells with tight junctions having basal nuclei, which then form ICM.

The trophoblast later forms the placenta while the ICM forms the embryo proper (hence called the embryoblast).[47,48] At this stage, the conceptus is called the blastocyst. Initially, there is no increase in size (day 4/5) but subsequently blastocyst expands over next 1 or 2 days (day 5/6) by more fluid accumulation inside.

After 2 days, the zona pellucida gradually thins out and the blastocyst "hatches" **(*see* Fig. 9)**. This zona shedding allows the hatched blastocyst to rapidly increase in its size. This blastocyst then attaches to the endometrium, generally adjacent to the embryonic pole. At that time, the trophoblast rapidly divides and differentiates into outer syncytiotrophoblast (multinucleated mass with no cell boundaries) and inner cytotrophoblast. At about 6 days after fertilization (around day 20 of a 28-day cycle), syncytiotrophoblast extends its finger-like processes into the connective tissue beneath the endometrium.

Blastocyst thus, superficially implants in the endometrium by the end of the first week. The complete process of "implantation" is dealt with separately in another chapter.

CLINICAL APPLICATION IN ASSISTED REPRODUCTIVE TECHNOLOGY

- *Intracytoplasmic sperm injection:* It is an advanced assisted reproductive technology especially for male infertility, where the entire spermatozoon is inserted into the oocyte with the help of a fine injection pipette under micromanipulator (ICSI machine). It is different from natural fertilization as normally sperm plasma membrane and acrosomal contents never enter the oocyte, but in ICSI, the whole of the sperm and a small amount of extracellular medium are deposited in the oocyte.
- *Total fertilization failure (TFF):* This refers to failure of fertilization in all the mature oocytes. TFF is seen in 5–10% of IVF cycles and 1–3% of ICSI cycles.[49,50] TFF can happen due to failure of sperm penetration of cumulus, acrosome reaction, zona binding, gamete fusion, or oocyte activation. Assisted oocyte activation using strontium chloride, calcium ionophores, or electrical stimulus can be useful in certain cases of TFF.
- *Blastocyst culture:* Success rate of IVF has considerably improved with blastocyst transfer than transfer of day 2 or day 3 embryos as it is more in synchronization with the physiology that embryo reaches uterus at blastocyst

stage and then implants there. This allows the possibility of single embryo transfer also with decent success rate in IVF and avoids the complications of multiple pregnancies.

CHAPTER 6

Implantation

Nisha Singh, Divyashree PS

INTRODUCTION

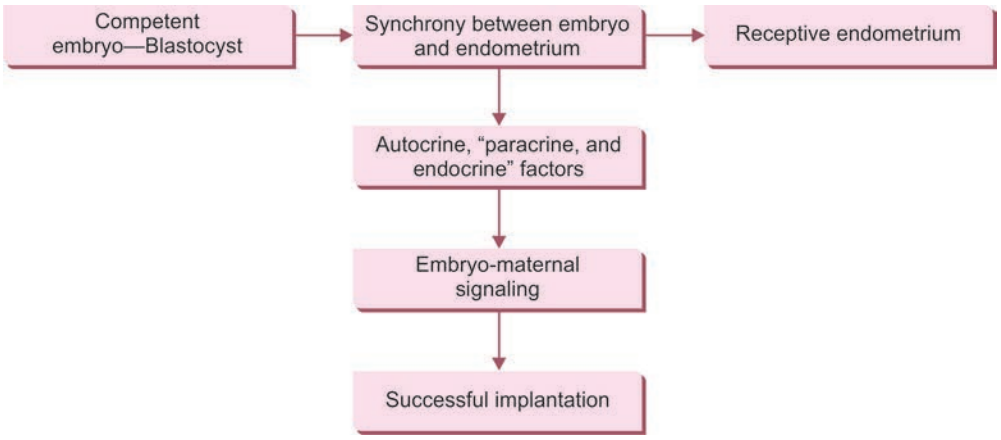
Implantation is the process by which the blastocyst comes into intimate physical and physiological contact with the uterine endometrium. It requires:

- Competent embryo
- Receptive endometrium
- Synchrony between development of embryo and conditioning of the uterus **(Flowchart 1)**
- Factors involved in regulation of blastocyst implantation are incompletely understood. Human chorionic gonadotropin (hCG), growth factors and cytokines, steroid hormones, and other mediators produced either by the embryo, by the mother, or by both, during the periimplantation period dictate changes in the endometrium, in the immunological system of the mother, and in embryo metabolism which enables the embryo to implant.
- Successful implantation requires a synchronous development of a blastocyst competent to implant and an endometrium able to respond to the signals from the blastocyst.[1] Implantation is a complex process involving spatiotemporally regulated endocrine, paracrine, autocrine, and juxtacrine modulators that span cell–cell and cell–matrix interactions.[2]
- Despite experimental success in initiating embryonic development outside the uterus and in identifying numerous molecules involved in the embryo–uterine dialogue, there is a yet to be filled significant knowledge gap in understanding the in vivo events of implantation. Furthermore, the implantation process varies among species, thus precluding the formulation of a unified theme. In addition, ethical restrictions and experimental difficulties prevent direct analysis of embryo–uterine interactions during human implantation. This chapter is focused on the mechanisms of implantation, embryo–maternal cross talk, and immunotolerance of the fetus to accomplish implantation.

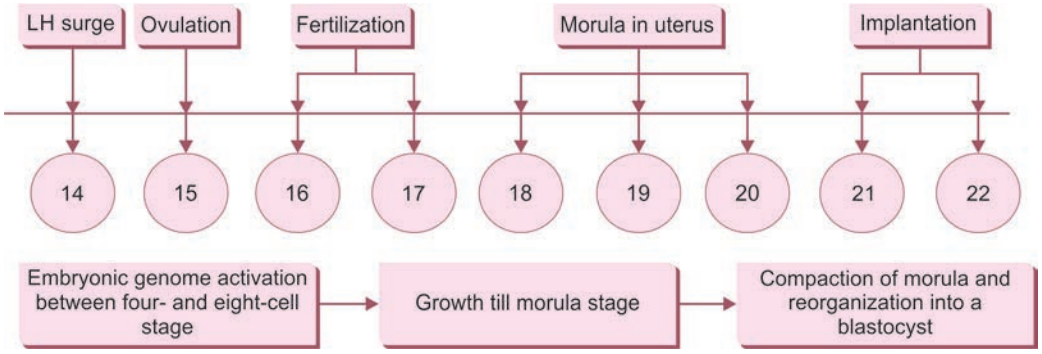
PREIMPLANTATION EMBRYO DEVELOPMENT AND GENOMIC ACTIVATION

Following successful fertilization, in most mammals the zygote starts a 4–5-day journey from the ampulla portion of the fallopian tube toward the uterus, developing to the morula stage by an increase in cell number. Whereas the

Flowchart 1: Contributors of implantation.



Flowchart 2: Preimplantation events.



(LH: luteinizing hormone)

overall amount of cytoplasm in the embryo remains constant, the number of nuclei and the amount of deoxyribonucleic acid (DNA) increase exponentially. During this period, messenger ribonucleic acid (mRNA) and proteins are maternally driven and embryonic genome is transcriptionally activated only at later cell cycles.[3]

Timeline for Implantation

The maternal zygotic transition occurs at four- to eight-cell stage in humans.[3] Embryo enters into the uterine cavity, on average 3 days postovulation, the morula undergoes reorganization processes at the cellular level, compaction, and becomes "activated" to progress to the blastocyst stage **(Flowchart 2)**. This activation involves the expression and transcription of over 500 dormant genes. However, this embryonic (gene) activation might be delayed during which the embryo remains in a state, what is known as diapause, which causes delayed implantation.[4,5]

During the transition from eight-cell to blastocyst, several genes have been identified that are crucial for lineage segregations; some of the important ones include *OCT4*, *SOX2*, *NANOG*, *CDX*, *LEFTY*, and eomesodermin (*EOMES*) **(Fig. 1 and Table 1)**.[6]

The appearance of the inner cavity within the mass of cells is a sign of initiation of the formation of the blastocyst. The differentiated and expanded blastocyst is composed of two distinct types of cells: (1) The outer cell mass, also called the trophectoderm (TE) and (2) the inner cell mass (ICM).

Trophectoderm gives rise to trophoblast and extra-embryonic structures such as placenta, while ICM gives rise to the embryo.[14] On entry into the uterine cavity, the embryo will be relatively inactive for the embryo–maternal interaction until it hatches from its zona pellucida at 6 days postovulation.[15] This coincides with and may even induce the window of implantation (WOI). Preimplantation embryo development normally occurs within the zona pellucida. However, zona removal by various experimental manipulations does not deter embryonic development in vitro suggesting that this glycoprotein barrier is not essential for development to progress. The nonadhesive nature of the zona pellucida probably preventing implantation within the oviduct is thought to facilitate the journey of embryos through oviduct to uterus.[15]

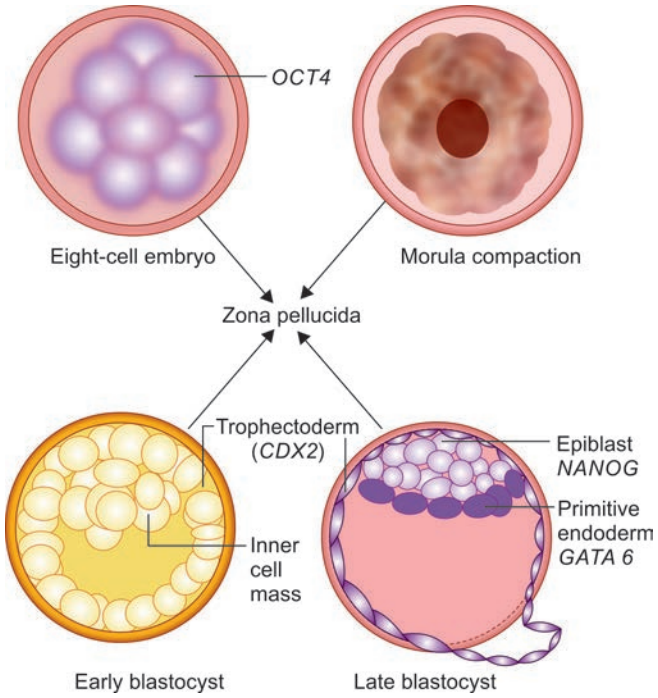


Fig. 1: Lineage differentiation during eight-cell to blastocyst transition and gene expression patterns during blastocyst formation. *OCT4* is expressed throughout the embryo before late morula and is crucial for the formation of inner cell mass. The expression of *NANOG* is induced in the inside cells of late morula. *CDX2* is expressed in trophectoderm. *GATA6* is expressed in the primitive endoderm of the late blastocyst.
Source: Adapted from Guzeloglu-Kayisli O et al.[13]

HATCHING OF BLASTOCYST

Hatching occurs in vitro as well, suggesting this process does not need a uterine environment,[16] albeit at lower rates than in vivo. Sathananthan has described electron

TABLE 1: Function of transcription factors known to be important for the fate of trophectoderm (TE) and the inner cell mass (ICM).

Gene	*Function*	*Reference*
OCT4	Restricted to ICM upon blastocyst formation, preventing TE formation	Kirchhof et al.[7]
SOX2	Similar to *OCT4*, prevents trophoblast specification	Avilion et al.[8]
NANOG	Sustaining the self-renewal capacity of embryonal stem cells and inhibiting their differentiation, ICM formation, and visceral parietal endoderm formation	Mitsui et al.[9]
CDX2	Segregating ICM and TE lineages, by suppressing *OCT4* and *SOX2*	Niwa et al.[10]
EOMES	Required for TE proliferation and differentiation at the blastocyst stage	Simmons and Cross[11]
LEFTY	Determining left–right axis in mouse embryos	Takaoka et al.[12]

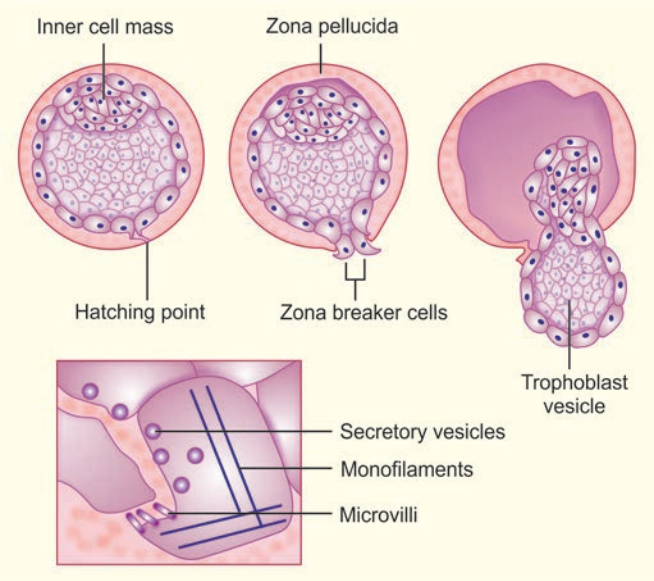

Fig. 2: Hatching of blastocyst.
Source: Adapted from Hoozemans DA et al.[48]

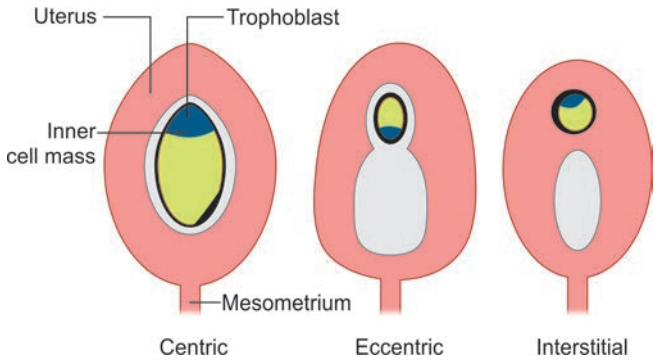

Fig. 3: Types of implantation.

microscopical observations in the hatching process wherein both mechanical and chemical factors seem to be involved.[15] Hatching usually occurs on the opposite site of the embryonic pole. Specialized trophoblast cells called "zona breaker" cells have secretory vesicles that seem to facilitate opening the zona pellucida at the hatching point. Possibly the vesicles contain proteolytic enzymes, which help in the dissolution of the zona. Microvilli and contractile monofilaments make the embryo hatch out *mechanically* **(Fig. 2)**.[15]

Hatching failure in assisted reproduction possibly derives from hardening of the zona pellucida or general blastocystic inactivity.[15] To treat this hatching failure, assisted hatching procedures by means of laser, enzymes, or zona drilling have been attempted to rescue blastocysts.[17] The hatching of the blastocyst from its zona pellucida occurs approximately 72 hours after entry into the uterus.

The hatching process exposes the trophoblast cells, which express different molecules on their cell surface such as leukemia inhibitory factor (LIF), colony-stimulating factor (CSF), heparin-binding epidermal growth factor (HB-EGF) receptors, L-selectin and integrins, and releases chemical messengers such as interleukin-1β (IL-1β). With the exposure of the trophoblast cells, their signal, and attachment molecules to the uterine environment, implantation begins approximately 7 days postovulation. The initial apposition of the hatched (and chromosomally normal) embryo has to take place at this time, since the WOI is open only for a limited period of 48 hours.

Based on the different types of blastocyst uterine cell interactions, implantation has been classified into three broad categories: (1) Centric, (2) eccentric, and (3) interstitial (Wimsatt, 1975) **(Fig. 3)**.

1. *Centric implantation* occurs when the blastocyst is able to grow large and form ample surface contact to fuse with the luminal epithelium without penetrating through it. Rabbits, dogs, domestic animals (cows, pigs, and sheep), and many marsupials have centric implantation.
2. In *eccentric implantation*, the luminal epithelium forms an invagination to surround the trophoblast. Mice, rats, and hamsters have eccentric implantation.
3. The third type of implantation is *interstitial*, in which the trophoblast passes through the luminal epithelium to invade the endometrial stroma and become embedded in the wall of the uterus. Implantation in humans and guinea pigs has been classified into this category (Wimsatt, 1975).[127,18]

EMBRYO-ENDOMETRIAL INTERACTION DURING IMPLANTATION

Embryo-endometrial interaction during implantation takes place through three ways:

1. Molecules and pathways known to initiate embryo apposition and attachment
2. Embryo invasion into stroma and mechanisms that safeguard quality implantation
3. Blastocyst regulation of implantation

Molecules and Pathways known to Initiate Embryo Apposition and Attachment

Enders and Schlafke have classified the process of implantation into three stages:[19]

1. Apposition and rolling
2. Adhesion (attachment)
3. Penetration (invasion) **(Table 2)**

Molecules Involved in Implantation

Molecules involved in implantation are discussed in **Table 3**.

Comparative model:
Embryonic implantation versus leukocyte transendothelial migration ***(Flowchart 3)****:* A parallelism between the different steps in human embryo-endometrial apposition/adhesion/invasion and leukocyte (LK) endothelium rolling/adhesion/extravasation has been observed.[39] A cascade of multiple events that take place during both processes show similarities, although some details with respect to time scale, size of cells, identity of involved molecules, and others are different **(Fig. 7 and Flowchart 3)**.

Once the blastocyst enters the uterine cavity, free-floating sphere "rolls" on the surface and encounters the epithelial glycocalyx. The trophoectoderm of hatched human blastocyst expresses L-selectin, which recognizes specific sialylated or sulfated sugars, which are carried by certain mucins such as Mucin 1 (MUC-1) on apical surface of the endometrium. This initial weak adhesion locates embryo to a specific site and activates other molecules to establish further attachment. The ability of attaching embryo to remove the mucin barrier is the health test on the embryo.[46]

Human endometrium undergoes a complex series of organized proliferative and secretory changes in each menstrual cycle.[47] When implantation does not occur, there is a deliberate and timely destruction of the fully developed endometrium, which leads to menstruation, only for the same cycle of events to be repeated once again to prepare for the next-generation blastocyst.[47]

Embryo Invasion into Stroma and Mechanisms that Safeguard Quality Implantation

Factors Influencing Implantation[48-50]

- *Ovarian hormones*:
  - Estrogen
  - Progesterone
  - Relaxin
- *Endometrium*:
  - *Cytokines*: LIF, CSF, and IL-1
  - *Growth factors*: Insulin-like growth factor-1 (IGF-1), HB-EGF, transforming growth factor-beta (TGF-β) (inhibins and activins), and vascular endothelial growth factor (VEGF)
  - *Genes*: *HOXA10* and *HOXA11*, *BMP2*, and *WNT4*
  - *Proteins*: Glycodelin, matrix metalloproteinase-2 (MMP-2), and MMP-9, signal transducer, and activator of transcription 3 (STAT3) protein
- *Embryo*:
  - IL-1
  - VEGF
  - IGF-2
  - Chorionic gonadotropin (CG)
- *Peripheral*: Cyclooxygenase-2 (COX-2) signaling
- *Endocrine*:
  - Corticotropin-releasing hormone (CRH)
  - Leptin

Ovarian hormones and endometrium:
Estrogen and progesterone: Ovarian steroids, estrogen, and progesterone are the major factors that prepare the uterus for implantation. They initiate a cascade of paracrine and autocrine signal transduction which, via cell adhesion processes, will lead to attachment and the subsequent invasion of the embryo into the endometrium.

Estrogen causes:
- Upregulation of P4 receptors
- Also upregulates VEGF, IGF-1, L-selectin, and HB-EGF. Progesterone receptor is upregulated by estrogen.

Therefore, the highest concentration of progesterone receptors is found in the periovulatory region, and maturation disorders in the secretory phase might also have their origin in an inadequate proliferative phase. After ovulation, estrogen receptors and progesterone type B receptor vanish from the stroma.

Progesterone causes:
- Morphological changes in the endometrium
- Upregulates pinopode formation
- Upregulates CSF, LIF, IL-1, prostaglandin (PG), VEGF, glycodelin, fibronectin, MUC-1, and L-selectin
- Downregulation of LIF and beta3 integrin
- Downregulation of estrogen receptors

Relaxin: Relaxin is an ovarian peptide hormone of the IGF family. Its receptors are expressed in the endometrium spatiotemporally.
- Increases the production of glycodelin and VEGF secretion[51]

TABLE 2: Morphological steps of implantation.

S. No.	*Stages*	*Physiology*	*Mediators involved*	*Figure*
1.	Apposition (unstable adhesion of blastocyst to endometrial surface) **(Figs. 4A to C)**	• Once embryo reaches uterus via tapis roulant of mucin (MUC) flow, which is continuous toward cervix • Apposition is progressively increasing intimacy of contact between trophoblast and uterine epithelium • Characterized by: – Enlargement of embryo – Edema of endometrium – Decrease in uterine fluid volume – Obliteration of uterine lumen by closer apposition of apical end of endometrial and trophoblastic cells – Appearance of pinopodes	• MUC-1 • Chemokines: – Alpha (CXC chemokines) – Beta (CC chemokines)	 **Fig. 4A**
2.	Rolling over	Blastocyst enters the uterus and roll over the endometrium freely **(Figs. 4B and 5)**	L-selectin	 **Fig. 4B**
3.	Adhesion **(Fig. 4C)**	• Direct contact occurs between the maternal endometrial epithelium cell (EEC) and the embryonic trophectoderm (TE) • The first sign of attachment reaction occurs on days 20–21 in humans and coincides with a localized increase in the stromal vascular permeability at the site of blastocyst attachment[20,21] • Endometrium and embryo now express extracellular matrix (ECM) component which helps to mediate adhesion through adhesion molecules, e.g., integrins and selectin	• Cellular adhesion molecules: – Integrins – Heparin-binding epidermal growth factor (HB-EGF) – Cadherins – Immunoglobulin – Fibronectin and laminin	 **Fig. 4C**
4.	Invasion	• Finally, in the invasion phase, the embryonic trophoblast breaches the basement membrane and invades the endometrial stroma up to the uterine vessels **(Fig. 4D)**. Three types of interaction occur between implanting trophoblast and uterine epithelium: • Trophectoderm cells from the blastocyst migrate between the epithelial cells, displacing them and penetrating as far as the basement membrane[21] • Epithelial cells lift off the basement membranes, an action that allows trophoblast to insinuate underneath the epithelium • Fusion of trophoblast with uterine epithelial cells	• Chemokines • Matrix metalloproteinase-2 (MMP-2)/MMP-9 • Vascular endothelial growth factor (VEGF) • Collagenases • Plasminogen activators • Selectins • Integrins	 **Fig. 4D**

TABLE 3: Molecules involved in implantation.

Molecule	*Function*	*Relation to fertility*
Mucin-1 (MUC-1)	• Glycoprotein which is found on luminal surface of the epithelium • Mainly MUC-1, MUC-6 • First molecule that blastocyst encounters on the endometrial wall before implantation • Expression is highest in luteal phase and implantation period[22] • When highly expressed on a cell surface, MUC-1 produces a steric hindrance phenomenon interfering with cellular adhesion • Cell–cell and cell–matrix adhesions are inhibited in direct correlation to the length of the MUC-1 ectodomain • It repels and guides the blastocyst to find the correct place for implantation • There is a local loss of MUC-1 at the site of embryo attachment and in the immediate vicinity, whereas its expression is increased at a distance farther away from the implantation site[23,24] • Tumor necrosis factor-alpha (TNF-α) (proinflammatory cytokine) and sheddases[25] bring proteolysis of MUC-1 at the site of implantation	In women with recurrent implantation failure (RIF) and recurrent pregnancy loss (RPL), studies have shown reduced midsecretory phase levels of MUC-1 and its epitopes[26,27]
Chemokines	• Chemokines (short for chemoattractant cytokines) are a family of small polypeptides (70–80 amino acids) specialized in the attraction of specific leukocytes (LKs) • Interleukin-8 (IL-8) (α-chemokine) is a potent chemoattractant and activator of neutrophils and T lymphocytes	Chemokines act on a range of LK subsets, which in turn release proteases and mediators, which facilitate embryo apposition and invasion
	• Monocyte chemoattractant protein-1 (MCP-1), β-chemokine subfamily, is a potent chemoattractant and activator of monocytes, macrophages, T cells, basophils, mast cells, and natural killer (NK) cells • The β-chemokine regulated upon activation of normal T cell expressed and secreted (RANTES) is a chemoattractant of monocytes, eosinophils, and basophils, and is localized in eutopic endometrium and ectopic endometriotic implants • Chemokine receptors are G protein-coupled receptors (GPCRs) and are localized in the plasma membrane and trigger chemotactic response in many immune cells • During the apposition phase, there is a specific LK subset infiltration into the endometrium from blood vessels and neighboring tissues • Immunohistochemical localization demonstrated that IL-8, MCP-1, and the three receptors *CXCR1*, *CCR2B*, and *CCR5* were mainly expressed in glandular and luminal epithelium and endothelial cells, whereas RANTES staining was localized mainly in the stromal and perivascular cells of blood vessels[28] • After previous estradiol priming, progesterone upregulates endometrial epithelium cell (EEC) IL-8 and MCP1 messenger ribonucleic acid (mRNA) in the secretory phase of the menstrual cycle • The human embryo does not secrete IL-8, MCP-1, or RANTES, but curiously, it expresses some of these chemokine receptors, CCR2B (MCP-1 receptor) and CCR5 (RANTES receptor)	
Selectins	• *Most important:* L-selectin • Tether and rollover mechanism over the endometrial surface • L-selectin is expressed by the hatched embryo and selectin oligosaccharide-based ligand, MECA-79, is upregulated during the window of implantation (WOI) **(Fig. 5)** • Embryo is slowed down by integrin interactions • It facilitates the apposition of blastocyst to the endometrial epithelium[29]	It has been shown that lack of expression of the L-selectin ligand MECA-79 in midluteal endometrial biopsies were indicative of low or no chances of pregnancy[30]
Integrins	• Family of transmembrane glycoproteins • Formed by the interaction of two different, noncovalently linked alpha and beta subunits[25] • They establish a firmer adhesion after the appositioning process is initiated by selectins **(Fig. 5)** • They are expressed both by the endometrium and blastocyst • Alpha 5 beta 3 (αvβ3) integrin and its ligand osteopontin first interact with trophoblast • The expression of the αvβ3 integrin in the endometrial stroma has been shown to be stimulated by IL-α, IL-β, and tumor necrosis factor-α (TNF-α) • Integrins have been proposed as markers for endometrial receptivity, particularly the αvβ3 glycoprotein	• Blockage of αvβ3 integrin lowers the implantation rates in mice[31] • In humans, lower or absent concentrations of integrins (mainly αvβ3) in midluteal endometrial biopsy have been observed in unexplained infertility, polycystic ovarian syndrome (PCOS), and endometriosis[32-35]

Contd...

Contd...

Molecule	***Function***	***Relation to fertility***
Cadherins	• Cadherins are a group of glycoproteins responsible for calcium-dependent cell-to-cell adhesion through homotypic binding • In regard to implantation, E-cadherin represents the most studied subclass	• Genetic variants on the E-cadherin gene may be involved in endometriosis-related infertility • Potential role of *HOXA10* and E-cadherin in the implantation processes and altered expression in women with reproductive failure
	• E-cadherin possesses a dual function. In the preliminary phases, its expression at the cell surface is required to ensure adhesiveness. Subsequently in the luteal phase, E-cadherin may be downregulated to enable epithelial cells dissociation and blastocyst invasion. Interestingly, calcitonin (CT) expression is induced by progesterone leading to increased intracellular calcium which then suppresses E-cadherin expression **(Figs. 6A and B)**[36] • Calcitonin receptors have been identified in embryos between the eight-cell and blastocyst stage	
Immunoglobulins	• Among the cell adhesion molecules (CAMs) family, the immunoglobulins superfamily is the most extensive • Intercellular adhesion molecule-1 (ICAM1) or CD54 is a transmembrane glycoprotein, which is constitutively expressed on the cell surface of a variety of cell types, such as fibroblasts, LKs, macrophages, T lymphocytes, granulocytes, and endothelial and epithelial cells of the endometrium • This molecule is upregulated at the transcriptional level by both inflammatory and noninflammatory cytokines	• ICAM1 adhesive interactions are essential for the transendothelial migration of LKs and for various immunological functions • Decreased expression in women with implantation failures
Fibronectin and laminin	• They are ECM proteins abundantly secreted by decidualized endometrial stroma and are under progesterone control. They interact with integrins as signal-transducing ligands resulting in changes in the trophoblast invasiveness • Laminin expression is higher in the secretory phase of the menstrual cycle and increases with implantation and in early pregnancy37 • Laminin facilitates trophoblast invasion, probably via lowering of insulin-like growth factor-binding protein-1 (IGFBP-1) and prolactin, which are the two major secretory proteins of decidualized stromal cells • Fibronectin interacts with integrins expressed by trophoblast, and this integration inhibits trophoblast invasiveness	Fibronectin is increased in patients with fetal growth retardation and hypertensive disorders in comparison with controls. Total plasma fibronectin concentrations might predict the maternal restraint on the invading trophoblast before and during implantation and placentation[38]

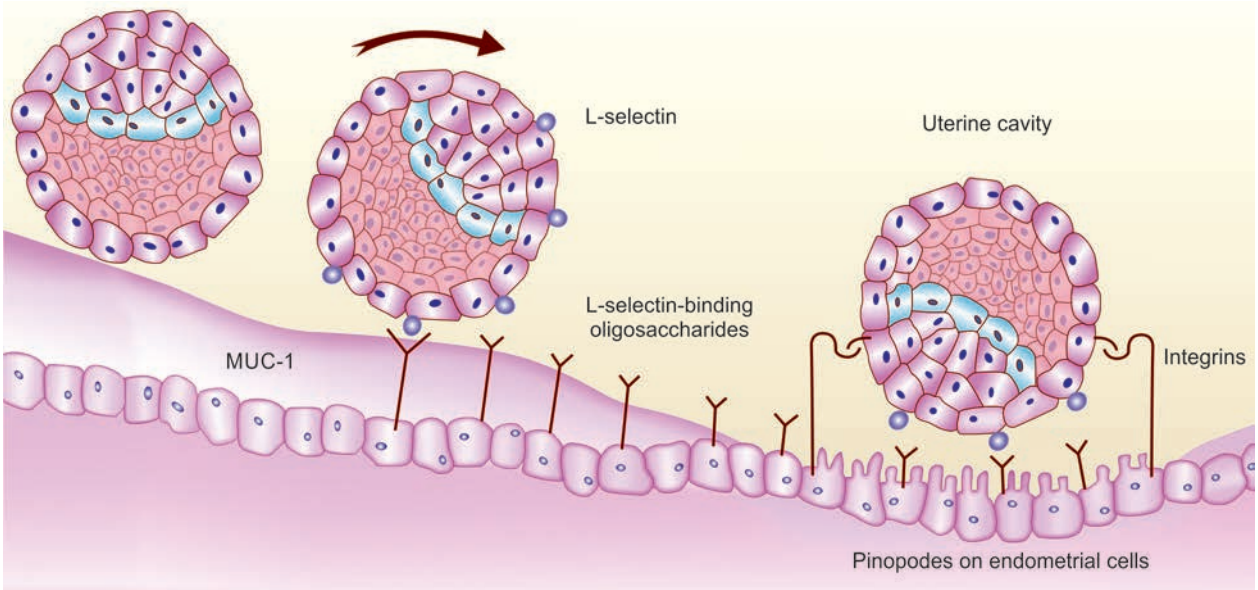

Fig. 5: The embryo at the implantation site via a "tapis roulant" of mucin flow. It is captured by L-selectin-ligand interaction; integrin attachment molecules provide adhesion at the implantation site. (MUC-1: Mucin-1)
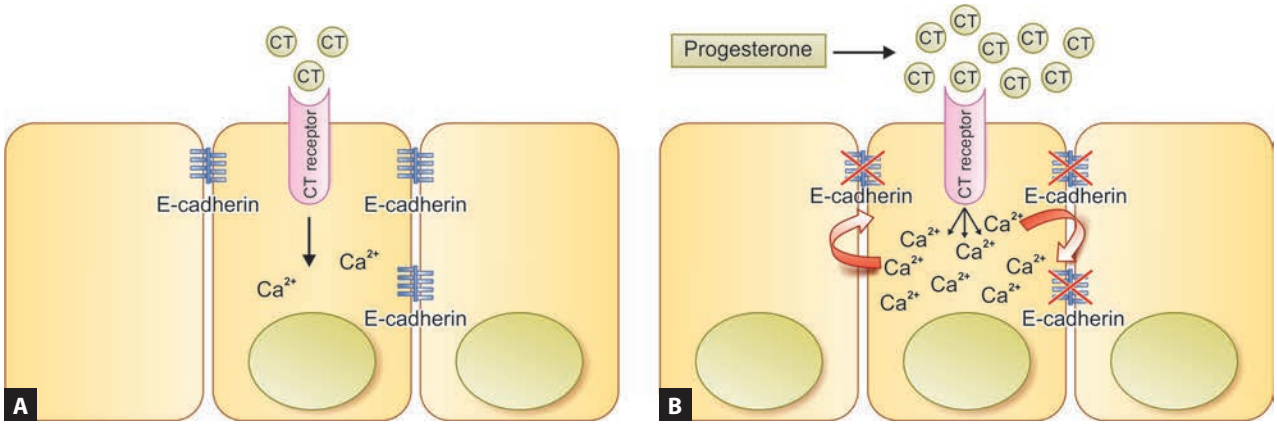
Source: Adapted from Chaouat G et al.[20]



Figs. 6A and B: (A) Epithelial cell adhesiveness by E-cadherin is controlled by intracellular calcium; (B) Rising progesterone levels induce calcitonin (CT) expression and thus increase the concentration of intracellular calcium, which then suppresses E-cadherin expression at cellular contact sites facilitating blastocyst invasion.
Source: Adapted from Kumar S et al.[36]

Flowchart 3: Comparative model: Embryonic implantation versus leukocyte transendothelial migration.

Human embryo		LK model
• Tapis roulant of MUC-1 flow makes embryo reach implantation site[40] • L-selectin by hatched embryo (TE) interacts with uterine oligosaccharide, expressed by endometrium during WOI[29,41] • Blastocyst express chemokine receptors (ccr5, ccr2) and adhere to chemokine ligands on endometrial surface	Apposition	• LKs express L-selectin, slows down LK through transient contact between LK and endothelial monolayer • Chemokines bind to GPCRs, cause activation of in situ integrin at LK, and cause polarization of cell
Adhesion molecules such as integrin and cadherins facilitate embryo adhesion	Adhesion	Adhesion molecules such as integrin facilitate LK adhesion
• Size of blastocyst prevents its migration between EEC. Blastocyst adheres to EEC and induces a paracrine apoptotic reaction mediated by Fas–Fas ligand. Bastocyst breaches the epithelial barrier, and then the trophoblast advances through the stroma, expressing different metalloproteinases such as MMP-2 and 9.[42] Blastocyst upregulates β3 integrin in the endometrium through the embryonic IL-1 system.[43]	Invasion/diapedesis	• LK integrins establish heterotypic interaction with JAM (junctional adhesion molecules) • Once the LK has traversed the monolayer, they are replaced by JAM homotypic interactions thus restoring initial situation[44,45] **(Fig. 7)**

(EEC: endometrial epithelium cell; GPCR: G protein-coupled receptor; IL-1: interleukin-1; LK: leukocyte; MMP: matrix metalloproteinase; MUC-1: Mucin-1; TE: trophectoderm; WOI: window of implantation)

- There is cycle-dependent concentration of relaxin in the serum with a peak at the WOI, which demonstrates its role in endometrial receptivity.[52]

Patients with an ongoing pregnancy show an accelerated rise in serum relaxin concentrations on the day that hCG is first detected in their serum, compared with patients with abortion.[53]

Endometrium:

- *Cytokines*:
  - LIF
  - CSF
  - IL-1
- *Growth factors*:
  - TGF-β (inhibins and activins)
  - IGF-1
  - HB-EGF
  - VEGF
- *Genes*:
  - HOXA
  - BMP
  - WNT4

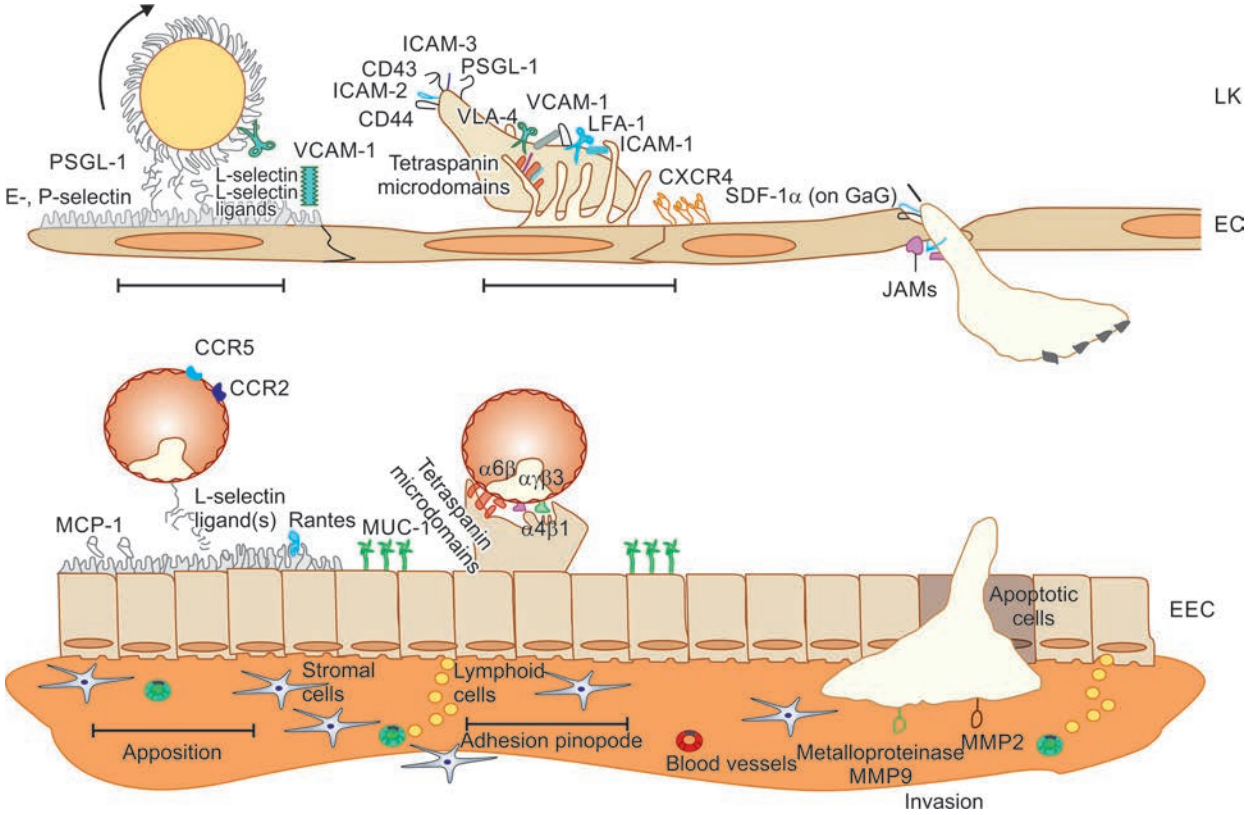


Fig. 7: Comparison of the sequential adhesion steps involved in LK transmigration and embryonic implantation and their molecular players. LK rolling, via the interaction of selectins with their carbohydrate ligands, slows down the LK and facilitates the binding of chemokines to their G protein-coupled receptors (GPCRs). Chemokines induce the high-affinity conformation of LK integrins, which bind to intercellular adhesion molecule-1 (ICAM-1) and vascular cellular adhesion molecule-1 (VCAM-1), included into tetraspanin microdomains and anchored to the cortical actin cytoskeleton on the apical surface of endothelial cells. Upon LK adhesion, endothelial cells develop a three-dimensional docking structure that prevents the detachment of the adhered LK, allowing it to proceed to diapedesis. During diapedesis, LK integrins interact with endothelial junctional adhesion molecules (JAMs) that reseal the junction by homophilic interactions once the LK has traversed the monolayer. In embryonic implantation, chemokines are implicated in embryonic apposition. Blastocyst presents CCR5 and CCR2 receptors on its surface, whereas chemokine ligands adhere to glycosaminoglycans in the endometrial epithelium. In the final invasion phase, the blastocyst breaches the epithelial barrier and advances through the stroma, expressing the metalloproteinases.[39] (EC: endothelial cell; EEC: endometrial epithelium cell; LFA-1: lymphocyte function-associated antigen-1; LK: leukocyte; MCP-1: monocyte chemoattractant protein-1; MMP: matrix metalloproteinase; MUC-1: Mucin-1; PSGL-1: P-selectin glycoprotein ligand-1)

- *Protein signaling pathways*:
  - Glycodelin
  - MMP
  - Janus kinase (JAK)-STAT signaling

Leukemia inhibitory factor: LIF, a member of IL-6 type family, behaves as a pleotropic glycoprotein. LIF seems to be regulated by progesterone and some locally produced factors. LIF acts on cells by interacting with LIF receptor (LIFR), which exists as LIFR and gp130 and is expressed on TE and luminal and glandular epithelium.

Roles in implantation are as follows:

- In humans, LIF acts on cytotrophoblast (CTB), causing them to differentiate into anchoring phenotype, which is achieved by increased synthesis of fibronectin and decreased production of hCG protein, while inducing secretion of oncofetal fibronectin.
- In human endometrium, LIF is expressed in a cycle-dependent manner as well with secretory endometrium showing the maximum expression, more precisely in the WOI. In the endometrium of fertile women, LIF mRNA is expressed on days 18–28 of the menstrual cycle, suggesting a role in uterine receptivity.[54]

In a proven LIF-producing endometrial coculture, embryo quality and development are significantly higher compared with conventional media and a trend was seen in the subsequent pregnancy rates.[55] Being more assessable clinically, was also traced in endometrial cultures of women with unexplained infertility. Recently, recombinant human LIF has been developed for clinical use in assisted reproduction.

Colony-stimulating factor: CSF-1 or macrophage CSF is a hematopoietic growth factor inducing the proliferation and differentiation of cells belonging to mononuclear

phagocytic lineage. Increased production of CSF-1 is found at fetomaternal interface during conception and pregnancy. Pollard et al.[56] was the first to describe the role of macrophages in the production of cytokines that regulate the process of implantation.

Roles in implantation are as follows:

- It has a trophic effect on trophoblast cells.
- Responsible for decidual function and placental growth. Progesterone regulates CSF production and CSF enhances macrophage growth and development. Production of CSF-1 in humans takes place in endometrial glands from the mid-proliferative phase to the mid-secretory phase.

There is no direct evidence to correlate the role of CSF in human implantation and pregnancy maintenance. Although low CSF-1 concentration is described in both preconception and conception in women with unexplained recurrent abortions, thereby promoting embryo implantation and substitution of CSF-1 in women with recurrent abortion seem to have a beneficial effect.[57]

Interleukin-1 and others: IL-1α, IL-1β, IL-1 receptor antagonist, and signal transduction receptor comprise the IL-1 family. IL-1, a known product of monocytes and macrophages, fine-tunes cell proliferation and differentiation, and is also present in both endometrium and embryo. Endometrial levels of IL-1α and IL-1β are under progesterone control. Only the type 1 receptor is functional in human endometrium. IL-1 and its receptors are localized on human oocyte and embryo. Embryo is the major source for IL-1β.

Role in implantation is as follows:

- IL-1β produced from embryo acts on IL-1RT-1 (receptor type-1) on the endometrium and upregulates integrin (alpha 5 beta 3) cascade and plays a role in adhesion **(Fig. 8)**.

Growth factors: Endometrium growth factors are presented in **Table 4**.

Genes:

- *HOXA (homeobox genes)*: They are transcription factors and regulators of embryonic morphogenesis and differentiation (Krumlauf, 1994).[66]
  HOXA10 and *HOXA11* are upregulated during WOI, and play a role in implantation. Also responsible for the upregulation of IGF-binding protein-1 (IGFBP-1), pinopodes, and beta3 integrin.[67] There is a reduced expression in hydrosalpinx, endometriosis, and polycystic ovarian syndrome (PCOS) leading to reduced implantation.[68]
- *WNT4 gene*: Once WNT protein binds to its ligands, *WNT* gene is activated and leads to transcription of target genes by either beta-catenin signaling or beta-catenin-independent pathway (noncanonical). WNT/β-catenin signaling is transiently and strictly induced at the prospective site of embryo attachment immediately before implantation.[69] It plays a role in:
  - Cell–cell adhesion in apposition phase
  - Morula to blastocyst transition
    - Embryo spacing via induction of evenly spaced bands in smooth muscle of uterus
    - Decidualization of uterus
  - *BMP2 gene: BMP2* is a major player in decidualization, the levels of which increase during WOI.[70]

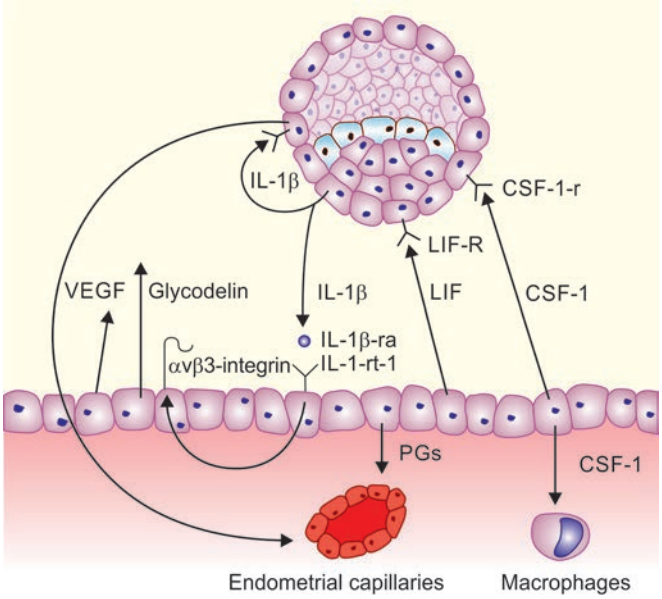

Fig. 8: Embryo–maternal dialogue—IL-1beta from the embryo acts on IL-1 receptor on the endometrium, leading to upregulation of alpha 5 beta 3 (αvβ3) integrin system. Various players in the implantation orchestra: Vascular endothelial growth factor (VEGF), glycodelin, αvβ3-integrin, interleukin-1β (IL-1β), interleukin-1β-receptor-antagonist (IL-1β-ra), interleukin-1-receptor-type-1 (IL-1-rt-1), prostaglandins (PG), leukemia inhibitory factor (LIF), LIF-receptor (LIF-R), and colony-stimulating factor type 1 (CSF-1).
Source: Hoozemans DA et al.[48]

Proteins:

Glycodelin: Glycodelin-A, also known as placental protein 14 (PP-14) or progesterone-associated endometrial protein (PEP), is the most abundantly secreted and consistently upregulated glycoprotein in late secretory endometrium and gestational decidua.[71]

Roles in implantation are as follows:

- Glycodelin has immunosuppressive role, suppresses the activity of natural killer (NK) cells, and protects the embryo from maternal immune rejection,[72] thus opens the WOI for developing blastocyst. Progesterone, hCG, and relaxin seem to be the regulatory pathways for glycodelin production.
- Glycodelin concentrations from cycle day 18 reach maximum in luteal phase and increases if conception occurs. Concentrations in uterine flushing (and not in

TABLE 4: Endometrium growth factors and their roles in implantation.

	Growth factor	*Role in implantation*	*Evidences*
1	HB-EGF	• Maximal expression during late secretory phase, at the sites of active blastocyst displaying ErbB4 • This induction is followed by expression of betacellulin, epiregulin, neuregulin-1, and COX2 at the time of attachment	Das et al.[58]
2	IGF	• Insulin-like growth factor system comprises IGF-1 and IGF-2 • All IGF participate in regulation of cellular growth and differentiation and have metabolic, antiapoptotic, and angiogenic effects, via increase in VEGF • In cycling human endometrium, IGF expression is restricted to stromal cells • IGF-2 dominates in secretory endometrium, expressed by trophoblast, while IGFBP is mainly by decidual cells • IGFBP-1 regulates the invading trophoblast, by modulating MMP-2 and MMP-9 levels • High IGFBP-1 levels in the decidua prevent deeper invasion and can lead to defective placentation • Within the EEM, IGFBP-3 binds IGF, but IGFBP-3 has a low affinity toward IGF, so making it available around EEM, to provide a free supply for embryo	Larsen et al.[59]
3	TGF-beta	• Inhibin and activin belong to TGF-beta subfamily[60] • Inhibin A and activin A levels increase during WOI[61] • Modulates maternal immune tolerance during implantation • TGF-beta signaling is associated with the onset of uterine receptivity and embryo-attachment reaction, whereas it diminishes when trophoblast invasion starts • Serum concentrations in the first trimester of pregnancy can possibly discriminate between a viable pregnancy and an abortion. This is mainly due to rescue of corpus luteal function by inhibin A[62]	Leung et al. [60]
4	VEGF	• VEGF is a major modulator of vascular growth and remodeling and it increases vascular permeability in the endometrium • It increases vascular permeability in the endometrium at implantation site, making it receptive to implantation	Risau[63] and Smith et al.[64,65]

(EEM: extraembryonic matrix; HB-EGF: heparin-binding epidermal growth factor; IGF: insulin-like growth factor; IGFBP: insulin-like growth factor-binding protein; MMP: matrix metalloproteinase; TGF-β: transforming growth factor-beta; VEGF: vascular endothelial growth factor; WOI: window of implantation)

serum), on the contrary, are higher in fertile patients than in patients with recurrent abortion.

Matrix metalloproteinase-2 and -9: Tissue remodeling and angiogenesis are hallmark events during implantation and decidualization. MMP and tissue inhibitors of metalloproteinase (TIMP) are thought to be key mediators for matrix degradation during implantation. There is evidence that a balance between a select set of MMP and TIMP is important for implantation.

Progesterone, growth factors, and cytokines including the EGF and TGF-β family members and LIF have been shown to modulate MMP and TIMP.[73]

Janus kinase-signal transducers and activators of transcription: In human endometrial stromal cells, STAT3 protein production is regulated by progesterone, LIF, and IL-11.[74] Furthermore, a role of STAT3 activity in trophoblast invasiveness has also been proposed.[75]

Blastocyst Regulation of Implantation

Embryo

Interleukin-1: Interleukin-1β is the major form produced by the preimplantation embryo. It acts on IL-1 receptor on the maternal side (epithelial and stromal) and causes endometrial transformation via integrin cascade, which is known to initiate NK cell differentiation.[76]

Interleukin-1 regulates the expression of several molecules in the endometrium, including IL-6, IL-8, LIF, CSF tumor necrosis factor alpha (TNF-α), COX-2, prostaglandin E2 (PGE2), prostaglandin F2-alpha (PGF2-alpha), MMP-1 and -9, and TIMP-1 and -3.

Vascular endothelial growth factor: In the developing embryo, release of IL-1β upregulates VEGF production from embryo **(Fig. 9)**. Both VEGF and its functional receptor are expressed by the trophoblast, most notably by the invasive first-trimester extravillous cytotrophoblast, suggesting that VEGF participates in regulating the proliferation, migration/invasion, and metabolic activity of the trophoblast in an autocrine fashion.[77]

The VEGF-A is the dominant subtype in the endometrium and VEGF-R1 and VEGF-R2 have been described as the main subtypes involved in implantation.

Insulin-like growth factor-2:

- Insulin-like growth factor-2 dominates in secretory endometrium, released by trophoblast, while IGFBP-1 is secreted by decidua.

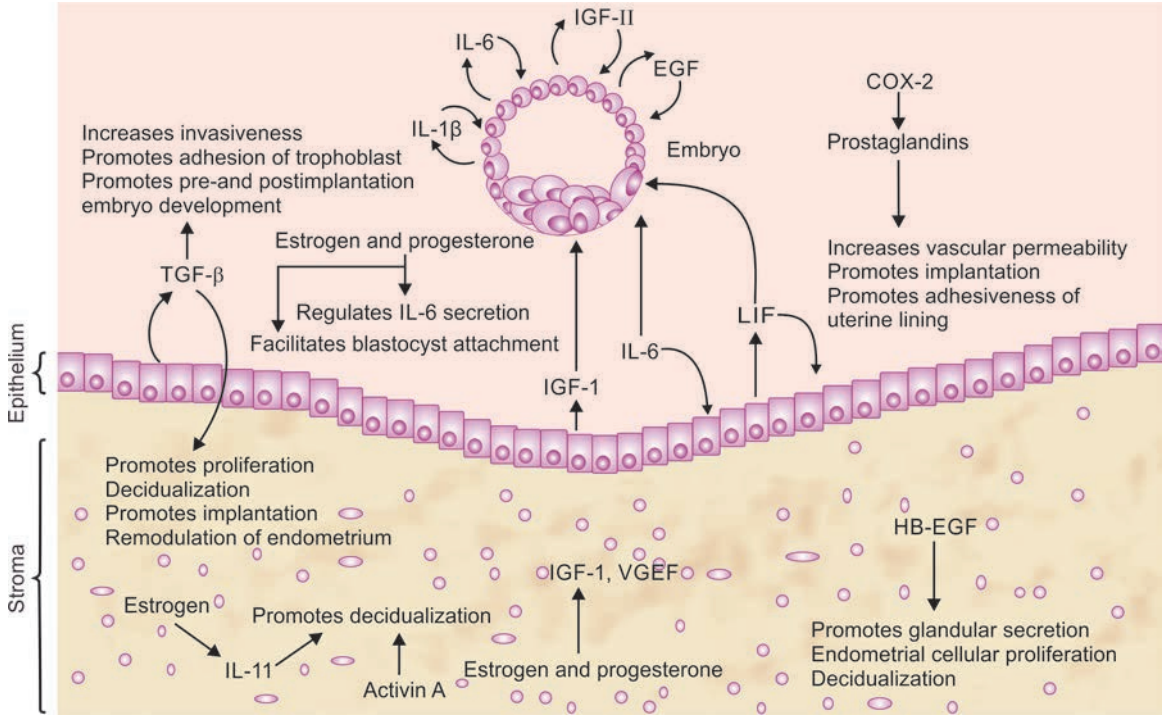

Fig. 9: Various players are ovarian hormones (E2 and P4): PR beta receptors in postovulation facilitate pinopode formation, upregulate MUC-1, L-selectin, LIF-CSF, IL-1, IL-6, PG, VEGF, IGF-II, and CRH. Embryo: Secretes IL-1beta (levels high during WOI), acts on IL-1-rt-1 on endometrium, plays a role in paracrine signaling via upregulation of integrin cascade. IL-1beta upregulates VEGF levels, which causes CTB proliferation, migration/invasion of trophoblast, and angiogenesis. IGF-II is secreted by trophoblast and mediates angiogenic effects via increase in VEGF. IGFBP-1 regulates trophoblast invasion, while IGFBP-3 makes more IGF-II available. Endometrium: IL-1 regulates the expression of several molecules in the endometrium, including IL-6, IL-8, LIF, CSF TNF alpha, COX-2, PGE2, PGF2 alpha, MMP-1 and -9, and TIMP-1 and-3. LIF makes CTB anchoring phenotype, and CSF helps in implantation. TGF-beta acts on both embryo and endometrium and helps in implantation and decidualization. Others: PG promotes vascular permeability and adhesiveness of uterus at site of implantation, HOXA, WNT4, and BMP-2 all are markers of receptivity. (CRH: corticotropin-releasing hormone; CTB: cytotrophoblast; E2: estradiol; IGF-II: insulin-like growth factor-II; IGFBP-1: insulin-like growth factor binding protein-1; IL: interleukin; IL-1-rt-1: interleukin-1-receptor-type-1; LIF-CSF: leukemia inhibitory factor-colony-stimulating factor; MUC-1: Mucin-1; P4: progesterone; PG: prostaglandin; TGF-beta: transforming growth factor-beta; TNF: tumor necrosis factor, VEGF: vascular endothelial growth factor; WOI: window of implantation)
Source: Adapted from Hoozemans DA et al.[48]

- All IGFs participate in the regulation of cellular growth and differentiation and have metabolic, antiapoptotic, and angiogenic effects, via increase in VEGF.
- Within the extraembryonic matrix (EEM), IGFBP-3 binds IGF, but IGFBP-3 has a low affinity toward IGF, so making it available around EEM to provide a free supply for embryo.

Chorionic gonadotropin: See in embryo maternal signaling section.

Peripheral: Cyclooxygenase-2 signaling: Progesterone influences the PG level in the human menstrual cycle. PGE2 and PGF2-alpha peak in midluteal phase, where WOI is situated, helps in implantation by increasing vascular permeability and bringing decidualization of the endometrium. In early pregnancy, two processes concerning PG take place. They are thought to be initiated by embryo, and the extent of endometrial reaction is due to endocrine effect (either progesterone or hCG by embryo).

1. The decidual PG levels drop remarkably low as compared to nonpregnant levels.
2. Increased local production of PG at the implantation site

The implanting embryo seems to be capable of triggering this mechanism as well, possibly by its own PG production.

Endocrine signals

Corticotropin-releasing hormone: Corticotropin-releasing hormone has been localized in endometrial glands and decidual stroma as well as trophoblast. Progesterone upregulates CRH production, which causes decidualization.[78] Also upregulates IL-1, IL-6, and PGE2.[79-81]

Corticotropin-releasing hormone participates in local inflammatory phenomena, which takes place at the implantation site, rendering the endometrial surface adhesive for the implanting blastocyst.[79] Indeed, CRH induces the synthesis of proapoptotic Fas ligand (FasL) on human invasive extravillous trophoblast and maternal decidual cells. Therefore, it potentiates the ability of these cells to induce apoptosis of surrounding activated maternal T cells bearing the Fas receptor (FasR) on their surface and facilitating trophoblast invasion.[82]

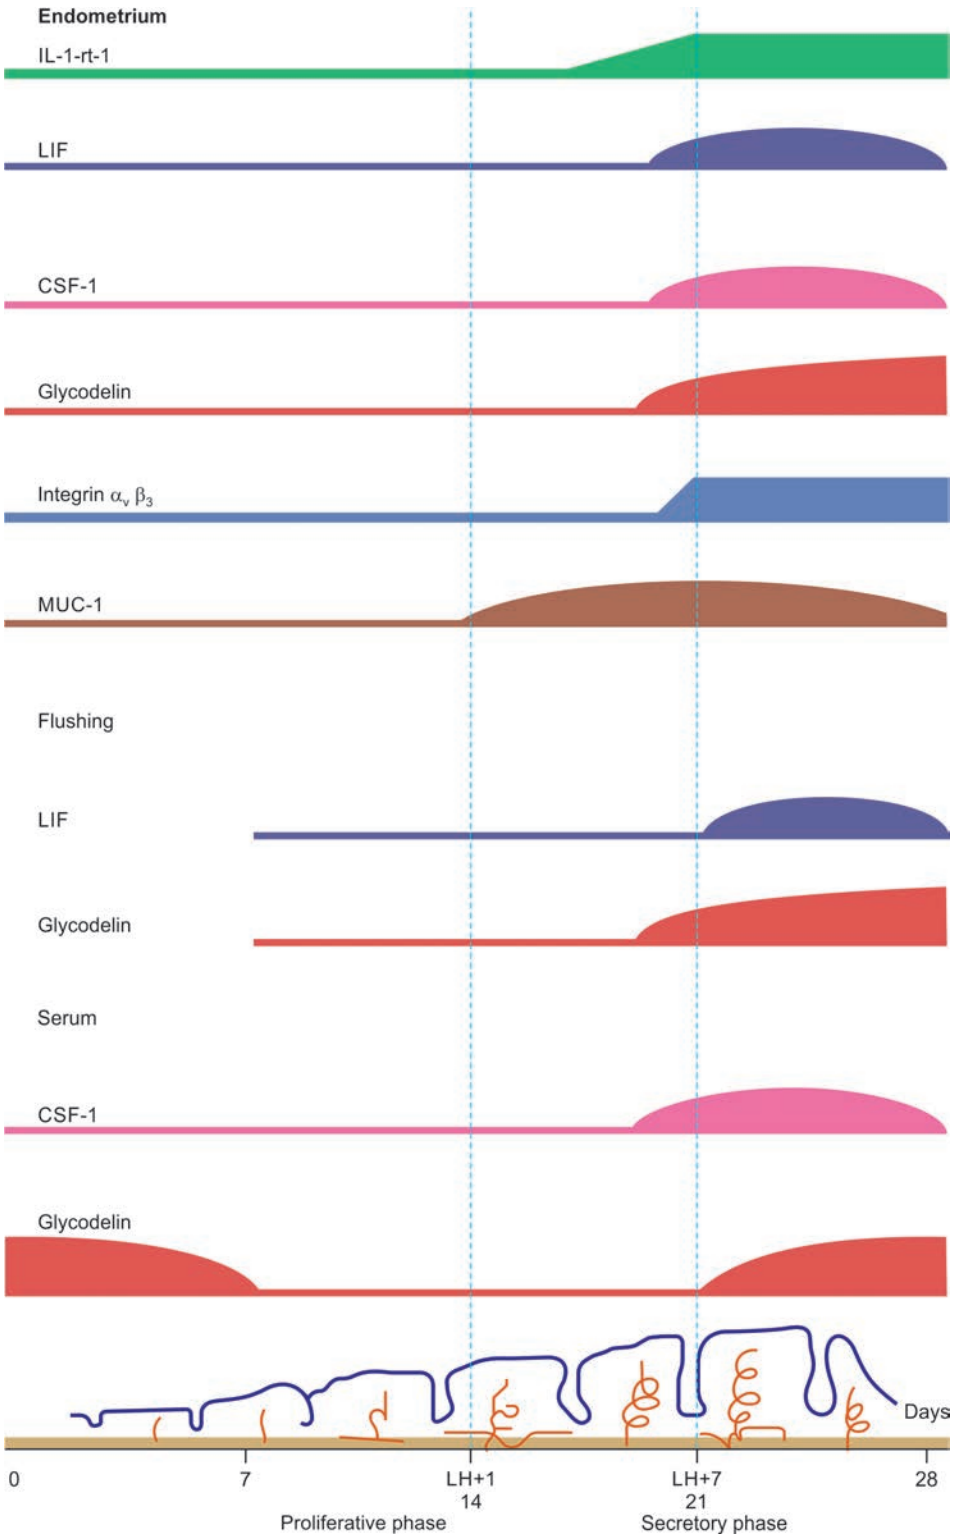

Fig. 10: Profiles across the menstrual cycle of factors of importance to the interaction between human blastocyst and endometrium. (CSF-1: colony-stimulating factor-1; IL: interleukin; IL-1-rt-1: interleukin-1-receptor-type-1; LH: luteinizing hormone; LIF: leukemia inhibitory factor; MUC-1: Mucin-1)

Leptin: Leptin is a product of the *OB* gene. Its receptors are found in the endometrium with maximal expression in the late luteal phase.[29] Additionally, leptin has also been shown to increase integrin β3 expression, which is essential for endometrial receptivity and implantation.[83]

Summary of Players in Implantation Orchestra

Summary of players in implantation orchestra has been shown in **Figures 9 and 10**.

EMBRYO–MATERNAL CROSS-DIALOGUE

As we have seen through the above-mentioned facts that both partners, the mother and the embryo, play equal roles in the embryo–maternal dialogue. For successful achievement of pregnancy, both the processes of implantation and trophoblast invasion play a crucial rule.

The EEM and zona pellucida represents the interface between the mother and embryo. The start of full embryo–maternal signaling can be expected to occur at around day 6 following the luteinizing hormone (LH) peak and have to pass this matrix to reach their destination, since the human embryo does not hatch till day 6. Hence, EEM of preimplantation embryos acts as a mailbox, through which signals traverse from embryo to mother or vice versa **(Fig. 11)**.

Herrler et al.[84] noticed through their animal experiments, investigating rabbit (rab) and horse embryos, which, like human embryos, remain surrounded by their EEM until shortly before adhesion to the endometrium.

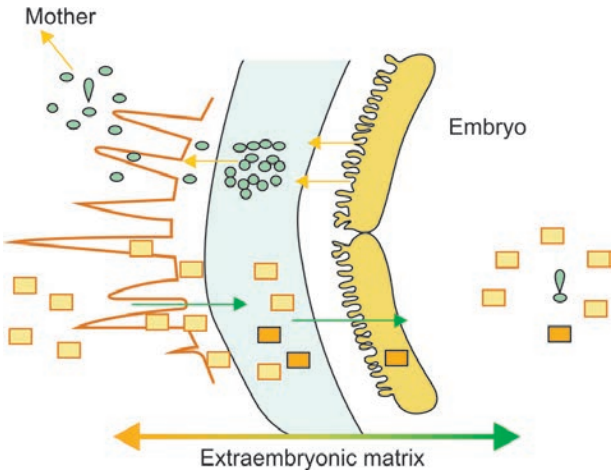

Fig. 11: Extraembryonic matrices surround most embryos until shortly before implantation. Maternal (from the left) as well as embryonic signals (from the right) have to pass them to reach their destination. However, these molecular messages are stored and modulated as generally in other extracellular matrices. Such extraembryonic matrices may serve as a mailbox in embryo maternal signaling before implantation.[82]

Only a few embryonic signals, which are clearly directed toward the mother during the preimplantation period are known; the most well-known is hCG.

Human Chorionic Gonadotropin: Classical Signal (Flowchart 4)

Like other gonadotropins, its secretion is regulated by gonadotropin-releasing hormone (GnRH), synthesized by the early blastocyst itself.[85] hCG mRNA is detectable as early as in the two-cell stage and detectable concentrations of hCG are already produced before implantation.[86,87] The critical days of the establishment of pregnancy are days 6–10 after the LH peak, which relates to the time of increasing hCG plasma concentrations.[88]

Preimplantation embryos of primates release CG under the control of GnRH from blastocyst, as the studies by Seshagiri et al.[85] have shown.

Sherwin et al.[89] concentrate on CG, which has long been thought to be secreted by the early blast, playing a major role in rescue of corpus luteum, moved to more attention in the role of CG in embryo implantation.

Embryonic action via hCG on the endometrium is through two effects:

1. An indirect, endocrine effect via rescue of the corpus luteum and subsequent progesterone release
2. A direct, paracrine effect on the *endometrium* **(Fig. 12)**. The luteotrophic activity of hCG is well documented. Progesterone controls endometrial function by increasing LIF secretion, mediated via IL-4, which originates from T cells.[90,91]

Chorionic Gonadotropin Receptor and Signal Transduction Pathways

Multiple mRNA transcripts for CG/LH receptor (CG/LH-R) have been detected in human gonadal tissues. In the human ovary, 8.0-, 7.0-, and 4.5-kb transcripts were seen with the 4.5-kb being predominant.[92] Extragonadal CG/LH-R expression has been reported in reproductive

(uterus, placenta, and decidua) and several nonreproductive organs.

The existence of these LH/CG receptors within the endometrium is still debatable. However, these receptors are functional based on in vivo experiments in baboons[93] and in vitro studies with human endometrial cell lines.[94] CG/LH-R is a member of the subfamily of glycoprotein hormone receptors within the superfamily of G protein-coupled/seven transmembrane domain receptors (GPCR).

So, CG has a unique signal transduction pathway in the endometrium. Extracellular signal-regulated kinase 1/2 (ERK1/2) may be an important signal regulating these CG-mediated events in the endometrium.[95] The human endometrium exhibits high basal adenylyl cyclase (AC) activity and it possesses the capacity for cyclic adenosine monophosphate (cAMP) production in response to PGE2, PGF2, forskolin, and isoproterenol. In addition, endometrial AC has been shown to be upregulated by ovarian steroids.[96] Although evidence for a direct action of CG on uterine tissues is strong, characterization of the various isoforms of the CG/LH-R and their role in activating alternate signal transduction pathways remain to be elucidated.

Human CG directly causes endometrial differentiation, decidualization, and embryo invasion by **(Fig. 13)**:

- Modulating the endometrial activity through several proteins such as LIF, VEGF, IGFBP-1, monocyte CSF (MCSF), and MMP-9.[97] These paracrine factors are known to be associated with decidualization, angiogenesis, immunomodulation, and matrix remodeling, thereby promoting embryonic implantation.
- hCG interaction in synergy with IL-1β to induce IGFBP is well known. hCG inhibits apoptosis in steroid-treated stromal cells and enhances differentiation by IGFBP-1 expression.
- Srisuparp noticed through his studies on baboons, the observation of decidual plaque reaction and increase of glandular secretion following CG. The primary effect of CG on stromal fibroblast is induction of alpha-smooth muscle actin,[95,98] as a consequence of integrin upregulation by CG binding to extracellular matrix (ECM) proteins.[98] This leads to transformation of glandular epithelium and appearance of pinopodes.
- It has been shown that in vitro, hCG can stimulate monocytes to promote embryo invasion.[99]

IMMUNE ACCEPTANCE OF PREGNANCY

Fetal–Maternal Contact

Placenta plays a crucial role in establishing intimate contact of fetus with maternal uterine tissue. Since the trophoblast cells are the most important fetal cells coming in contact with maternal cells, and three different trophoblast populations that are exposed to different maternal elements can be distinguished.

1. *Villous cytotrophoblast*: Actively dividing trophoblast cells in the villi

Flowchart 5: Immunological paradox of pregnancy.

2. *Syncytiotrophoblast:* Float in the maternal blood
3. *Extravillous cytotrophoblast*: These are proliferating precursor trophoblast that migrate into decidua and myometrium.

As half of the fetal genes are derived from the father, the developing embryo and placenta must be considered a semiallograft. Clearly, during pregnancy, when the mother must accept a semiallogeneic fetus, immune responses also play a very important role.

This was first recognized by Medawar in 1953, when the concept of the fetal allograft was presented in order to explain the immunological relationship between mother and fetus.[100] He suggested that the fetus escapes rejection because the immunological interaction between the mother and fetus is suppressed. Medawar proposed that this was due to a lack of fetal antigen expression, resulting from an anatomical separation between the mother and the fetus, or from a functional suppression of maternal lymphocytes.

Immune Paradox of Pregnancy

To understand the concept of immunological paradox of pregnancy, we need to focus on two processes as mentioned in **Flowchart 5**.

Effect of Pregnancy on Immune System

Peripheral Immune System

- T cells
- Peripheral NK cells
- Monocytes, granulocytes, and dendritic cells (DCs)

Immune System in Decidua

- Uterine NK (uNK) cells
- Decidual T cells
- Macrophages

Mechanism to Escape Rejection by Fetus

- Major histocompatibility complex (MHC) expression by trophoblast
- *Uterine modulators*:
  - Haptoglobin
  - Uteroglobin
- *Downregulation of T-cell activity*:
  - Induction of T-cell anergy
  - Fas–Fas ligand

How Pregnancy Affects Immune System?

Peripheral Immune System

Villous syncytiotrophoblast is floating in maternal blood and is therefore in close contact with maternal peripheral LKs. Hence, it can be expected that the peripheral immune response is adapted to the presence of the semiallogeneic syncytiotrophoblast cells. Increase in the peripheral white blood cell (WBC) count is the first recognized change to occur in the peripheral maternal immune system during pregnancy. The following changes are noted in:

- *T cells:* This shift away from type 1 cytokine production during pregnancy is beneficial for pregnancy, since type 1 cytokines [e.g., interferon gamma (IFNγ) and TNF-α) are harmful for pregnancy because they inhibit embryonic and fetal development **(Flowchart 6)**.[101] Uterine immune response is adjusted so that T-helper type 1/T-helper type 2 (Th1/Th2) homeostasis creates an optimal environment fostering implantation **(Flowchart 7)**.
- *Peripheral natural killer cells*: The number of peripheral NK cells is decreased in pregnant women as compared with nonpregnant women. These changes in NK cell number and activity during pregnancy are also consistent with a shift from a cellular to a humoral immune response during pregnancy.
- *Monocytes and granulocytes and dendritic cells*: Sacks et al. in 1998 noticed the activation of innate immune response in pregnancy. The main factors for activation are the pregnancy hormones as well as the soluble mediators of placenta, which are released into maternal circulation. DCs may be involved in the regulation of type 1/type 2 cytokine balance.[102]

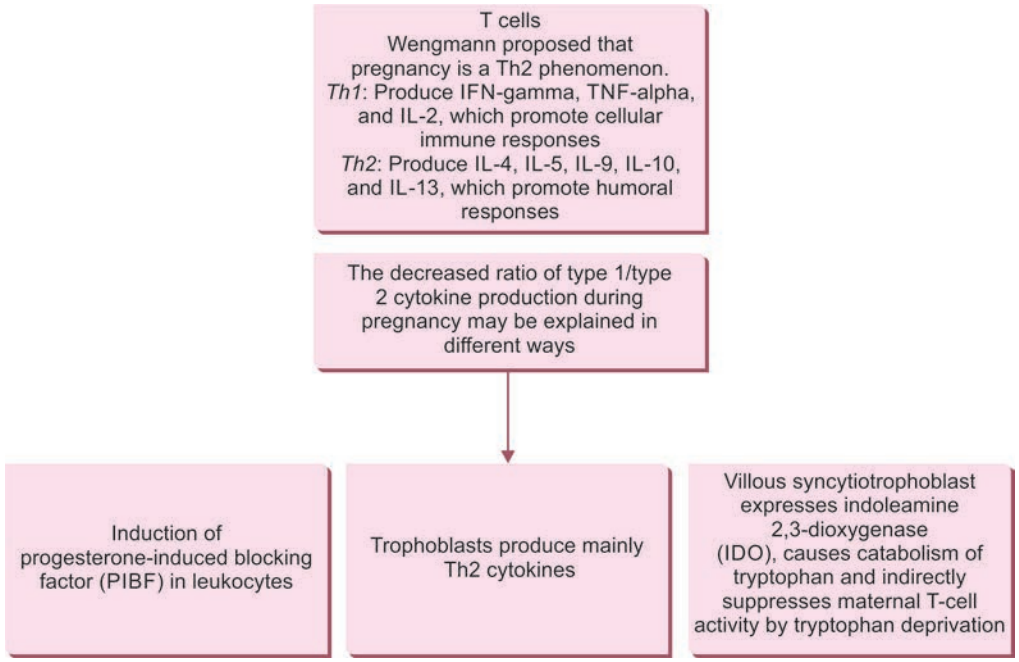
Immune System in the Decidua

The decidua is the maternal part of the placenta in which there is a close contact between maternal and fetal cells. Consequently, the decidual cells may play an important role in acceptance of the fetus and the control of trophoblast invasion. Hence, the decidua contains a diverse population of cells, including decidualized stroma cells, lymphocytes, uNK cells, monocytes, and epithelial cells. Bulmer et al. found that the proportion of LKs in the decidua is cycle dependent, from <10% in early proliferative phase to 20% in the late secretory, to >40% in early pregnancy. This is mainly due to increase in uNK cells, which comprise 60% of LKs.[103]

Uterine natural killer cells: The uNK cells have an NK cell-like function, but they are specific for the uterus. The presence of uNK cells in the decidua may be explained by two mechanisms.

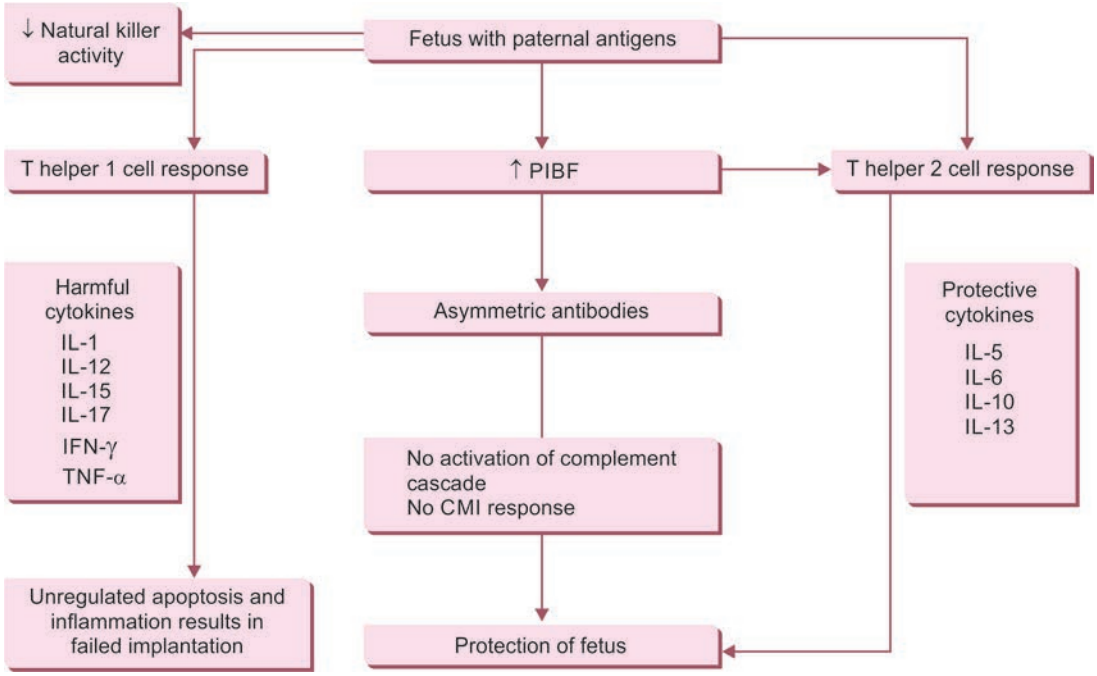
1. The *first mechanism* is that peripheral blood uNK cells are selectively homing to the uterine mucosa, because they

Flowchart 6: Role of T cells in immune regulation.



(IFN: interferon; IL: interleukin; Th2: T-helper type 2; Th1: T-helper type 1; TNF: tumor necrosis factor)

Flowchart 7: Immunomodulation during pregnancy.



(CMI: cell-mediated immunity; IFN-γ: interferon-γ; IL: interleukin; PIBF: progesterone-induced blocking factor; TNF-α: tumor necrosis factor-α)

can interact with adhesion molecules on the decidual blood vessels.

2. *Second mechanism* is that uNK cells are actively dividing. Their proliferation can be stimulated either by cytokines produced by other decidual cells or by (steroid) hormones.

Uterine NK cells are different to mature circulating NK cells, yet phenotypically resemble the smaller unique NK cell subset, which is CD56/CD16/CD3 and has low direct cytotoxicity. Since they do not share all the membrane expression markers, it is not clear whether these cell types have same function.

Natural killer cells have been shown to be essential for implantation, as NK cell-deficient mice repeatedly have pregnancy failures.[104] Their uNK cell-derived cytokines, e.g., granulocyte-CSF (G-CSF), M-CSF, GC-MSF, and LIF are crucial for normal implantation.[105]

Proliferation of uNK cells is through the production of IL-15 by placental macrophages, expression of IL-15 receptor on $CD56^+$ uNK cells, and embryonic signals such as hCG.[106]

These $CD56^+$ NK cells and $CD8^+$ T cells accumulate at the decidua parietalis and trophoblast invasion front[107] and facilitate deep invasion of cytotrophoblasts into the myometrial segments thereby promoting spiral artery remodeling and angiogenesis.

Although the uNK cells are present in the decidua in large amounts, they do not attack the semiallogeneic nonvillous cytotrophoblast. This is due to the fact that uNK cells express inhibitory receptors. These receptors bind to the MHC-Ia and b [human leukocyte antigen-C (HLA-C), HLA-E, and HLA-G)] on trophoblast, by binding to these MHC-I antigens, the inhibitory receptors inhibit the lytic activity of the uNK cells. The types of inhibitory receptors on uNK cells are namely immunoglobulin (Ig)-like killer cell inhibitory receptor (KIR) (e.g., KIR2D, KIR2DL4) and lectin-like KIRs (CD94/NKG2A). But interaction with killer activating receptor (KAR) stimulates the production of trophic cytokines and angiogenic factors.[20,84]

Also consistent with a role for uNK cells in implantation and placentation were the findings that high preconceptional NK activity was associated with significantly higher rates of miscarriage[108] and infertility,[109] since these cells through Th1 cytokines can damage trophoblast and can cause fetal death.

Decidual T lymphocytes: Similar to the peripheral blood, the most accepted theory is the dominance of Th2 response over Th1. Th2 cells, placental (mostly), and decidual cells secrete Th2 cytokines (IL-5, IL-6, IL-10, and IL-13), which controls the Th1 responses, promote allograft tolerance, and may improve fetal survival.[110]

Macrophages (Flowchart 8)

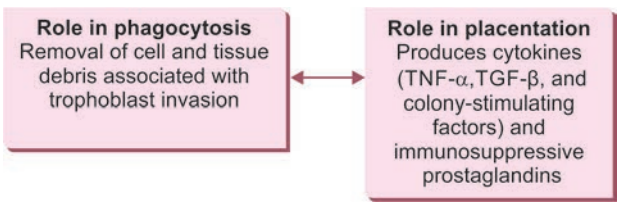
In humans, macrophages are spread through the pregnant uterus, including the decidua[111] and are also associated with trophoblast cells of the placenta and extraplacental membranes.[103] In the decidua, macrophages constitute about 20–30% of all LKs. Factors responsible for increased invasion of macrophages into decidua are:

- *Pregnancy hormones*: Estrogen[112]
- *Cytotrophoblast*: Can attract macrophages into the decidua by producing monocytes inflammatory protein-1 alpha[113]

However, the number of uterine macrophages must be tightly controlled, since in preimplantation endometrium of patients with recurrent miscarriage significantly more macrophages were seen than in patients without these miscarriages.[114]

The present observations suggest that at the maternal and fetal interface, a balanced production of cytokines by various immune cells (T lymphocytes, uNK cells, and macrophages) is needed for a successful pregnancy, which in turn suggests the existence of a complex fine-tuning system for cytokine production.[115]

Flowchart 8: Role of macrophages.



(TNF-α: tumor necrosis factor-α; TGF-β: transforming growth factor-β)

MECHANISMS AT THE TROPHOBLAST TO ESCAPE IMMUNE ATTACK

Human embryos are able to modulate the LK subtype composition and in consequence the corresponding cytokine pattern within the invaded decidual tissue. This results in modulation of maternal immunotolerance, allowing trophoblast invasion, while at the invasion front activated T cells control the depth of implantation **(Flowchart 9)**.

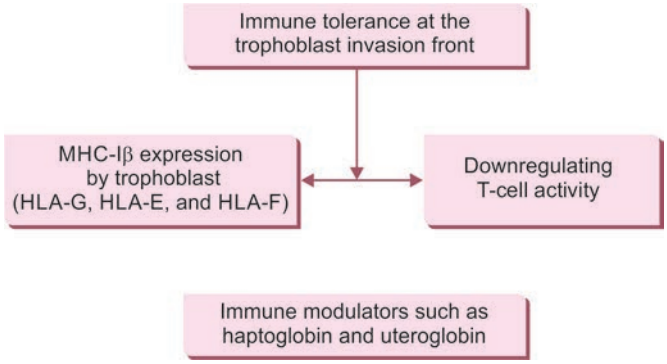
Major Histocompatibility Complex Expression by Trophoblast[116]

It is clear from the previous sections that immune cells are in close contact with the trophoblast cells but do not attack it, despite being activated. The highly polymorphic MHC is responsible for the distinction of the immune system between self and nonself. The MHC can be divided into three classes:

1. Class Ia (HLA-A, HLA-B, and HLA-C)
2. Class II (HLA-DP, HLA-DQ, and HLA-DR)
3. Class Ib (HLA-E, HLA-F, and HLA-G)

Major histocompatibility complex class Ia is expressed on all nucleated cells—present antigen to cytotoxic T cells,

Flowchart 9: Mechanism to evade maternal immune response.



(HLA: human leukocyte antigen; MHC: major histocompatibility complex)

and play a role in the inhibition and activation of NK cells via inhibitory NK-cell receptors (KIR) and activating NK-cell receptors (KAR). Foreign cells, expressing nonself MHC-Ia, can be directly recognized by T-cell lymphocytes and killed.

Major histocompatibility complex class II expressed by B lymphocytes, antigen-presenting cell (APC), and present antigen to T-helper cells. MHC class Ib have a role in immunoacceptance of fetus.

Major histocompatibility complex-Ia is not expressed in trophoblasts. However, some authors have demonstrated the expression of HLA-C, which belongs to the MHC-Ia molecules, by nonvillous cytotrophoblast.

The trophoblast cells express a unique pattern of MHC nonclassic class I molecules, namely HA-Ib (HLA-G and HLA-E). Since they lack expression of most MHC-Ia molecules; they cannot be recognized as foreign by maternal T cells, though this lack of MHC-Ia may place the nonvillous trophoblast at risk of lysis by uNK cells, which dominate in the decidua. Therefore, nonvillous cytotrophoblast cells express MHC-Ib molecules such as HLA-G and HLA-E, both of which may be important at the maternal fetal interface by inhibiting lysis of nonvillous cytotrophoblast by uNK cells, via direct binding with inhibitory receptors on the uNK cells. Maternal T cells recognize placental MHC class I and secrete cytokines mostly CSF, IL-3, and MCSF, which act as growth factors on trophoblast.[106]

Haptoglobin and Uteroglobin as Immune Modulators

Haptoglobin

Haptoglobin is widely known as an "acute phase" protein, strongly binding to hemoglobin. The embryo does not express haptoglobin mRNA. In contrast, embryos accumulate considerable amounts of maternal haptoglobin within the embryonic coats and blastocyst fluid. Its secretion increases during the midluteal phase and peaks at the implantation window.[117]

Since it is concentrated within the embryonic coats, it is known to reduce LK activity by competitive binding to CD11b/CD18[118,119] and serve as early protection against maternal immune cells. Haptoglobin continuously released during trophoblast invasion may further induce immunological tolerance. This is in agreement with the recent findings of Bottini et al.,[120] who have shown that women carrying the haptoglobin alpha 1, alpha 1 isoform have slightly higher natural fertility than women with alpha 2 isoforms. In concordance with this, haptoglobin alpha1 has a significantly higher antiadhesion activity.

Uteroglobin

Another maternal protein taken up and accumulated within the blastocyst fluid is uteroglobin. Its secretion increases during the midluteal phase and peaks at the "implantation window."[117]

Embryo takes up the maternal uteroglobin and releases it following hatching, directed toward the endometrium and acts on maternal immune cells. It also reduces NK cell adhesion/invasion to ECMs.[121]

Another blastocyst fluid component, PGE, has been shown to decrease cytotoxic NK cell activity.[122]

Downregulation of T-cell Activity

As it has been shown in the above-mentioned text that immune competent cells play an important part in the embryo–maternal dialogue. Embryonic signals like hCG, through induction of MMP and IGFBP-1 via LIF, trigger monocyte capability to promote embryonic invasion.

Also, NK cells, the predominant intrauterine LK subpopulation, have been shown to be essential for regular implantation, as NK cell-deficient mice repeatedly have pregnancy failures. These NK cells as well as T cells accumulate at the trophoblast invasion front.[107] Therefore, it can be suggested that the invading trophoblast cells modulate the LK pattern in the invaded tissue as a result of the embryo–maternal dialogue. The physiological lack of NK cells in the endosalpinx and consequently the lack of their cytokines may be a significant reason for the pathological trophoblast over invasion of the tubal wall in tubal pregnancy. At the site of implantation front, specific pattern of LK subtypes within different areas of decidual tissue gets expressed, which regulate cytotoxic T-cell activity.

There are different pathways to downregulate T-cell activity, which are as follows:

- *Induction of anergy*: NK cells activate T cells and monocytes as well as induce trophoblast apoptosis via IFNγ at the invasion front. Afterward, macrophages present peptides from phagocytosed apoptotic trophoblast cells to Th1 cells.[123,124] This induces anergy of the T cells, as the costimulation signal CD86 is missing.[125,126]
- *Fas ligand system-induced apoptosis*: Another mechanism by which the trophoblast may escape attack by maternal immune cells is via the expression of apoptosis-inducing ligands. Induction of apoptosis by FasL in invading lymphocytes acts as a mechanism of immune privilege and is important in graft rejection. Increased FasR expression leads to increased susceptibility of the T cells for induction of apoptosis, called "activation-induced cell death (AICD)." Apoptosis may be induced either by FasL expressing LKs or by FasL-positive invading trophoblast cells **(Figs. 14 and 15)**.[81]
- Consequently, the precise balance between cytotoxic T-cell activity, controlling the amount of trophoblast invasion, and AICD or anergy induction of T cells, supporting trophoblast invasion via their cytokines, is necessary for an implantation process which is beneficial

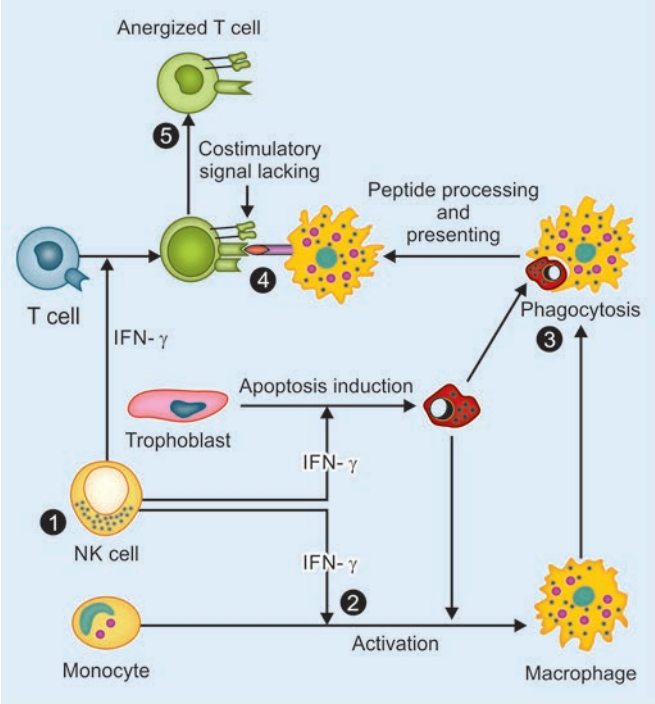


Fig. 14: Induction of T-cell anergy. (1) NK cells recognize trophoblast cells as "nonself" and induce apoptosis; (2) via IFN-γ secretion, NK cells activate macrophages and T cells; (3) phagocytosis of apoptotic bodies by macrophages leads to peptide presentation without (4) costimulatory signal; and (5) if this signal is missing, T cells which recognize the presented peptide are anergized. (NK: natural killer; IFN-γ: interferon-γ)

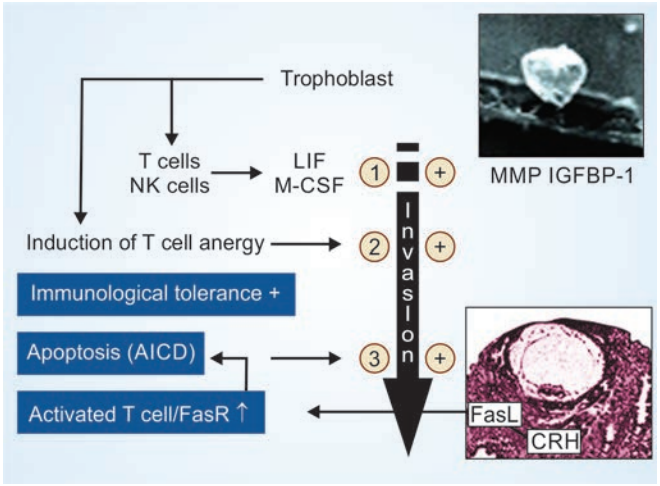

Fig. 15: Synopsis of immune tolerance at the trophoblast invasion front.
(AICD: activation-induced cell death; CRH: corticotropin-releasing hormone; FasL: Fas ligand; FasR: Fas receptor; IGFBP-1: insulin-like growth factor-binding protein-1; LIF: leukemia inhibitory factor; M-CSF: macrophage colony-stimulating factor; MMP: matrix metalloproteinase; NK: natural killer)

for the embryo and not detrimental to the mother. These data provide evidence for a tight interaction between embryo and maternal cells to establish a maternal immunological status that allows adequate trophoblast invasion.

However, addressing the establishment of pregnancy merely as a Th2 phenomenon is an oversimplification, because NK cells and inflammatory cytokines also seem to be important in this complex regulation.

CONCLUSION

Embryonic implantation thus involves the following:

- Anchoring of the conceptus in the maternal uterine wall
- Embryo maternal cross talk involving various growth factors, cytokines, and hormones
- Trophoblast migration and differentiation
- Establishment of vascular supply
- LK influx and activation
- Promotion of tolerance of fetal alloantigens encoded by paternal gene

KEY POINTS

- Blastocyst implantation requires a competent embryo and its ability to cross talk with a receptive endometrium, and the dialogue must talk about immunity and angiogenesis.
- The uterus is tailored to tolerate the fetal allograft and to allow controlled invasiveness of trophoblast only during the WOI, ensuring the success of the intricate cascade of implantation. It still remains an enigmatic process with many unknown factors and interactions.
- The embryonic metabolome is a source of multiple factors that may influence implantation.
- The data also suggest that measurement of blastocyst-derived factors, including micro-RNA, may be useful to identify blastocyst destined to implant and may also serve as useful targets to regulate their implantation.
- A better understanding of the process will improve not only the pregnancy rate of assisted reproductive technologies, but also will assist the understanding of several other pathophysiological processes such as tumor development, angiogenesis, and tumor metastasis. Future research should focus on further evaluation of this process.

CHAPTER 7

Embryo-Endometrial Crosstalk and Endometrial Receptivity

Nalini Mahajan, Anshu Dhar

INTRODUCTION

The endometrium undergoes cyclical changes in response to ovarian hormones in its preparation for embryo implantation. During the window of implantation (WOI), many processes occur simultaneously and sequentially within the endometrium to allow changes at a morphological and molecular level for successful implantation. Some of the important transformations are cell cycle regulation, immune modulation of implantation, angiogenesis, growth factor actions, steroid hormone action and metabolism, production of extracellular matrix proteins, cell surface glycoproteins, and a variety of transcription factors.[1] Recent advances in genome sequencing which include the introduction of next-generation sequencing and bioinformatics analyses have made it possible to understand the omics involved in endometrial maturation and embryo-endometrial crosstalk. This information allows a better understanding of implantation failure and may help to improve infertility management.

IMPLANTATION

The process by which the blastocyst trophectoderm adheres to the endometrium of the uterus is called implantation. The three phases of implantation—apposition, adhesion, and invasion involve an intricate interplay of hormones, genes, and cytokine expression. During apposition and adhesion, the blastocyst establishes a firm contact with the epithelial lining, while invasion encompasses penetration of the endometrium by trophectoderm cells. The trophectoderm invades by displacing the endometrial cells in its attempt to establish contact with blood vessels and this process is aided by genes involved in tissue remodeling.[2] In response to this invasion, the endometrial stromal cells and extracellular matrix undergo decidualization essential for the sustainability of the pregnancy. The endometrial epithelial cells (EECs) undergo specific structural and functional changes. At a morphological level, there are changes in the plasma membrane and cytoskeleton (Murphy, 2000; Martın et al. 2000) leading to the formation of pinopods also known as uterodomes which are proposed to aid embryo adhesion by their various functions including endocytosis, exocytosis, and expression of adhesion molecules.[3] A delicate balance between trophoblastic invasion and decidual resistance ensures proper placentation. The prime players in the implantation process include a viable embryo, an endometrium that has undergone the necessary molecular and structural changes to accept the embryo, and the host immune system which must protect this semi-allograft. Embryo-endometrial crosstalk is a prerequisite for successful implantation. Though significant progress has been made in the identification of the molecular mechanisms involved, intricate details of the process still elude us. Implantation failure thus remains a major bottleneck in the success of assisted reproduction technologies.

Endometrial Receptivity

Endometrial receptivity (ER) defines the short window of time within which a zona-free blastocyst must attach, invade, and derive sustenance from the endometrium. Progesterone secretion is integral to this process as it brings about the necessary secretory changes in an estrogen-primed endometrium. It is also essential for the maintenance of pregnancy. The WOI or window of ER opens 4–5 days after progesterone secretion and lasts 30–36 hours depending on the patient. It occurs at luteinizing hormone (LH) + 6 to LH + 9 in natural cycles or P + 4 to P + 9 in hormone replacement therapy (HRT) cycles.[4] ER is a dynamic process that involves a series of changes within the endometrium at the morphological, biochemical, molecular, and immunological level in response to embryonic signaling. The systemic and local alterations that occur constitute is termed as "the maternal recognition of pregnancy".[5] Progesterone and estrogen are considered the key modulators of endometrial maturation and have a multifaceted role. Hormonal activity depends not only on the levels of progesterone, estrogen,

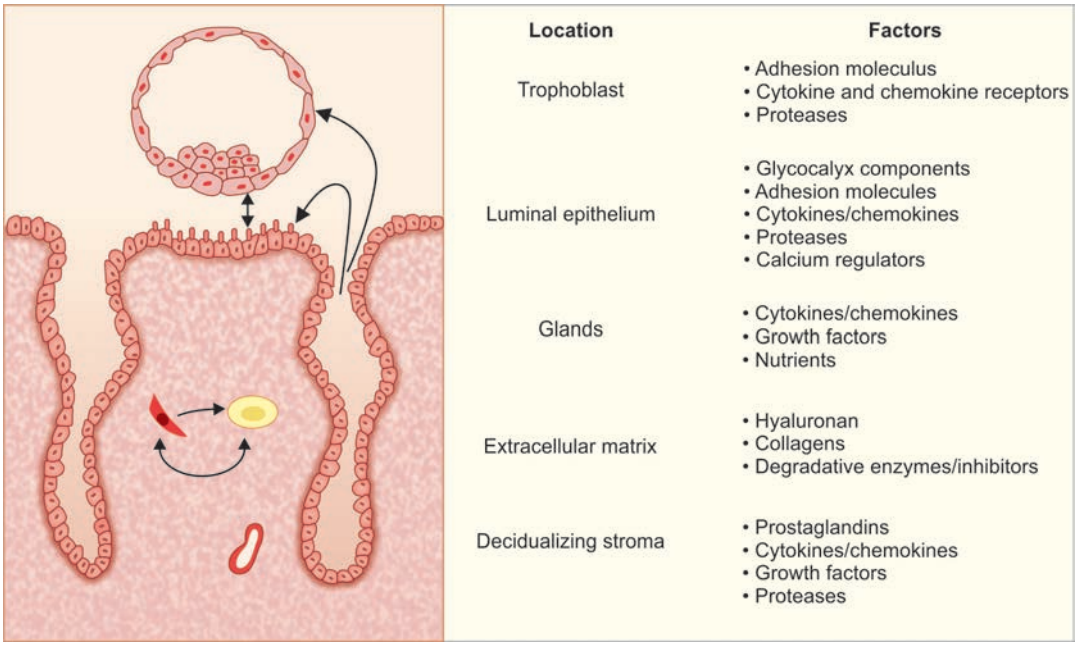

Fig. 1: Factors involved in endometrial maturation.
(*Source:* Diedrich K, Fauser BC, Devroey P, Griesinger G, Evian Annual Reproduction (EVAR) Workshop Group. The role of the endometrium and embryo in human implantation. Hum Reprod Update. 2007;13(4):365-77).

and their receptors, but is also influenced by the coactivators, repressors, and paracrine signaling **(Fig. 1)**.[6]

Endometrium during "the Window of Implantation"

Changes in the endometrium occurring during this phase result from a well-coordinated action between autocrine, paracrine, and endocrine factors. At a *histological level*, increasing progesterone levels herald a secretory transformation—subnuclear vacuolation, stromal edema, increase in glands, and capillary permeability in the endometrium.[7,8] Pinopods or cytoplasmic projections of the luminal epithelium that facilitate blastocyst adhesion appear 6 days after ovulation and are retained for approximately 24 hours **(Box 1)**.[9,10]

Steroid Receptors during Window of Implantation

During the WOI, progesterone (P) acts more via paracrine and autocrine factors, this transition from direct or endocrine action to an indirect one is important for successful implantation. Epithelial estrogen receptor-alpha (ESR1) is downregulated and there is a shift of progesterone receptors (PR) from the epithelium to the stromal compartment. The persistence of ESR1 and PR in the glandular epithelium is associated with infertility and implantation defects. The action of estrogen (E) is also limited by progesterone (P) through induction of 17β-hydroxysteroid dehydrogenase type 2 (HSD17β2) in the endometrium that converts E2 to the less active estrone.[11]

Molecular Changes

At the molecular level, the pre-receptive early secretory phase is characterized by increased metabolic activity in preparation for implantation. This leads to a predominance of cellular metabolic products (fatty acids, eicosanoids, amino alcohols, and lipids), greater expression of transporters of biological molecules, and facilitation of sperm migration.[12] There is an inhibition of mitosis during this phase as suggested by the downregulation of several growth factors. In the receptive phase, there is an upregulation of gene expression. Apart from increased metabolic and secretory activity, there is an upregulation of genes involved in the activation of the immune response.[13] During the late secretory phase, the WOI closes and in this phase genes related to immune response—both cellular and humoral, blood coagulation, steroid biosynthesis, and prostaglandin metabolism are regulated.[14]

Estrogen, progesterone, and embryonic chorionic gonadotropin regulate the secretion of growth factors and cytokines which are the mediators of the embryo-maternal dialogue and initiation of decidualization.[15,16] A large number of molecular mediators that are important for ER have been identified. The ones extensively researched are integrins, leukemia inhibitory factor (LIF), homeobox A10,

- Key findings in a receptive endometrium:
  - Luminal epithelial pinopods formation
  - Expression of adhesion molecules
  - Novel cytokines profile
  - Immune protection
  - Appropriate gene expression

mucin 1, calcitonin, and cyclooxygenase 2.[17] *Integrins* are cell adhesion molecules that are involved in cell-to-cell and cell to extracellular matrix interaction facilitating signal transduction. The co-expression of αVβ3 and α4β1 during the WOI has been well-documented.[18-20] *Mucin 1* (MUC1), a glycoprotein and an antiadhesive molecule is localized to the luminal surface epithelium but is excluded from cells with pinopods allowing the blastocyst to preferentially attach to these specialized structures on the apical surface.[15] *Cytokines* are glycoproteins produced by the trophoblastic and endometrial cells that act via specific cell surface receptors. They are involved in intercellular signaling and regulate the embryo-maternal interactions. Their production is interlinked with the arrival of the blastocyst into the endometrial cavity. *LIF* expressed during the WOI appears to be important for the embryo-endometrial crosstalk.[21] It has been hypothesized that LIF plays a role in the adhesive and invasive phases of implantation because of its anchoring effect on the trophoblast.[22] Other factors such as the heparin-binding growth factor, epidermal growth factor, and insulin-like growth factor also seem to have a role in implantation as their expression is found during the WOI. *HOX* genes are upregulated by estrogen and progesterone and are essential for endometrial growth, differentiation, and receptivity. HOXA10 and HOXA11 messenger ribonucleic acid (mRNA) are expressed in endometrial epithelial and stromal cells, their expression being higher in the mid-and late secretory phase and decidua of early pregnancy.[23-25] *HOX* genes regulate many molecular and morphological markers specific to the WOI, e.g., pinopods, β3 integrin, and insulin-like growth factor-binding protein-1 (IGFBP-1). Women having decreased expression of HOXA10 or 11 during the secretory phase have been seen to have lower implantation rates. Expression of these genes is reduced in disorders such as endometriosis, polycystic ovary syndrome (PCOS), hydrosalpinx, and fibroids.[26,27] Calcitonin, L-selectin, and L-selectin ligand are also secreted by the EECs during the mid-secretory phase of the menstrual cycle. Prostaglandins and aromatase play an essential role in implantation. Ion channels in the endometrium are also emerging as important players in regulating ER and embryo implantation. Abnormal expression or function of ion channels in the endometrium may lead to impaired ER and/or implantation failure.[28]

Immunological Response

The maternal immune response is intricately linked to successful implantation though the exact mechanism is unclear. The results from transcriptome studies during the preimplantation phase suggest that instead of general suppression of the maternal immune system, there is a fine-tuned regulation of immune cells.[29] Immune cells in blood circulation regulate corpus luteum function and endometrial differentiation to promote subsequent embryo implantation.[30]

The balance between T-helper 1 and T-helper 2 cytokines: An existing paradigm suggests that for successful implantation, a balance between *T-helper 1 (Th1) and T-helper 2 (Th2) produced cytokines* is mandatory. A shift in the ratio toward Th1 cells leads to increased production of proinflammatory cytokines such as interferon-gamma (IFN-γ), interleukin-2 (IL-2), and tumor necrosis factor-alpha (TNF-α) resulting in a cytotoxic cell-mediated immune response and increased phagocytosis and inflammation. In contrast, Th2 cells produce a range of interleukins involved in the humoral immune response and inhibit several functions of phagocytosis which together represent an anti-inflammatory response. Several observational studies have reported an increased expression of proinflammatory cytokines in women with a history of recurrent pregnancy loss.

Natural killer cells: Despite the tremendous progress in the field of immunology, the origin of uterine natural killer (uNK) cells is still not clear. It has been hypothesized that hematopoietic precursor cells (HPCs), hosting in endometrium differentiate into uNK cells.[31] On the other hand, another hypothesis suggests that uNK cells are derived from differentiated peripheral blood NK cells, that are attracted to the endometrium by locally secreted cytokines and chemokines.

A disrupted population of *peripheral and/or uNK* cells has been implicated in implantation failure and early pregnancy loss. After ovulation, uNK cells become the dominant immune cells accounting for >30% of immune cells. In early gestation, the uNK cells expand in number and are thought to play an important role in maintaining a balance between the normal and excessive invasion of the trophoblast accounting for as much as 70% of the leukocyte population. As opposed to the peripheral NK cells, uNK cells express a unique pattern of surface markers being $CD45^{+}$ $CD56^{bright}$, $CD16^{+}$, and $CD9^{+}$ cells. They are characterized by a lower level of cytotoxic activity but produce abundant cytokines which are responsible for their varied actions. It is believed that during implantation, these cells communicate with the extravillous trophoblast cells (EVTs), recognizing the human leukocyte antigens G (HLA-G) via the killer cell immunoglobulin-like receptors (KIRs). These interactions cause immunological acceptance of the semi-allogeneic fetus, by the mother and trigger uNK cells to secrete several cytokines and growth hormones that promote trophoblast invasion. In addition, uNK cells secrete several matrix metalloproteinases (MMPs) and angiogenic factors, such as vascular endothelial growth factor (VEGF), that contribute to the remodeling of the spiral arteries. Successful orchestration of these events is essential to ensure invasion, acceptance, and further growth of fetus and maintenance of pregnancy.[32] Peripheral blood NK cells play an important part in the innate immune system and are not thought to play a role

in endometrial function. *Human leukocyte antigen (HLA)* dissimilarity is crucial at early implantation and the similarity of HLA in the partners may interfere with implantation.[33]

The prognostic value of uNK cells is however unclear due to a lack of standardization in the techniques of measurement and defined cut-off values; as concluded by various systematic reviews.[34,35] The lack of good quality studies elucidating the role of the same also contributes to the confusion. At present, the testing for uNK cells and the provision of immunotherapy for correction of the same should be considered only within the realm of experimental medicine.

Role of human chorionic gonadotropin: Studies on mice suggest that the maternal immune system undergoes functional changes by recognizing the developing embryos in a stepwise manner from before fertilization to after embryo implantation. A novel concept has been proposed by Fujiwara et al. in 2016.[36] They hypothesize that immune cells receive information about the presence of a developing embryo in the female genital tract via the human chorionic gonadotropin (hCG) secreted by the embryo and transmit this information through blood circulation to the uterus. This induces endometrial changes that further facilitate embryo implantation. hCG has several immunological properties regulating not only the number of local immune cells but also making these cells adopt a unique phenotype to support and protect the fetus. It is also believed to upregulate the number of endometrial NK cells via the mannose receptor thereby positively influencing embryo implantation.[37]

Global profiling of genes in the endometrium, decidua, and trophoblast-decidual interface has provided significant insight into endometrial maturation and implantation.[38,39] Microarray technology has revealed an upregulation of >200 genes in the WOI and downregulation of 60.[40] Microarrays are now being replaced by next-generation sequencing.

Role of endometrial microbiota: The recognition of the existence of endometrial microbiota, as opposed to the previously believed concept of a sterile endometrial cavity, has opened a new field for research and analysis. In the study by Moreno et al, it was shown that the presence of non-*Lactobacillus* dominated microbiota, defined as the presence of *Lactobacillus* spp. <90% determined by next-generation sequencing of endometrial fluid samples was associated with a negative impact on endometrial function and has been considered as an emerging cause of implantation failure. Also, it was demonstrated that the levels of microbiota remain stable throughout the cycle, independent of hormonal regulation.[41] The mechanism for implantation failures associated with the same has been implicated to be the endometrial inflammation caused by the bacteria. Some other mechanisms associated with the direct production of microbial metabolites and/or enzymes, producing relevant substances that can induce key cellular pathways in the endometrium have also been considered. The commercially available tests Endometrial Microbiome Metagenomic Analysis (EMMA®) and Analysis of Infectious Chronic Endometritis (ALICE®) analyze the endometrial microbiome to help identify abnormalities associated with a poor reproductive prognosis. EMMA indicates the endometrial microbiome balance, providing information on the proportions of all endometrial bacteria, including those linked to higher pregnancy rates (PRs). EMMA also includes ALICE, which detects pathogenic bacteria that can cause chronic endometritis.

Markers of Endometrial Receptivity

Over the years, attempts have been made to develop tests for ER, especially in the context of improving in vitro fertilization (IVF) results. The markers of ER include:

- *Histological markers:* Histological dating of endometrial using the Noyes criteria is no longer considered a valid method for the diagnosis of luteal phase deficiency nor can it guide clinical management of infertility. Improvement in histological diagnosis of ER was sought by the use of electron microscopy which identified the formation of pinopods considered to be an important histological change that heralds implantation. However, apart from not having universal availability, pinopods are no longer considered to be accurate makers of ER.
- *Ultrasound:* It is the only clinically applicable marker of ER. Endometrial pattern, thickness, and blood flow have been used to determine ER. Unfortunately, these parameters are prognostic and not confirmatory.
- *Biochemical and molecular:* Assessment of many of the cytokines and growth factors evaluated (Integrins, LIF, VEGF, and interleukins) have not yielded definitive results.

Endometrial Transcriptomics

Transcriptomics is the study of "transcriptome", i.e., the complete set of RNA transcripts produced by the genome under specific circumstances or in a specific cell using high throughput methods. The use of microarray technology has now given way to evaluation using next-generation sequencing. Molecular studies have identified the endometrial transcriptomic signature of the WOI allowing identification of the displaced WOI which may contribute to recurrent implantation failure (RIF). It is believed that in approximately 30% of IVF cycles, the WOI may be displaced leading to embryo-endometrial desynchrony. Two such tests—endometrial receptivity array (ERA) and integrity are commercially available. ERA analyzes the expression levels of 238 genes linked to the status of ER using RNA sequencing taken from the endometrial tissue. Following analysis, a specific computational predictor classifies the samples according to their expression profile as receptive or nonreceptive (NR). The NR endometrium is further classified

as pre- or post-receptive meaning that the endometrium has not reached the receptive phase yet or has passed it, respectively.[42,43]

In a recent randomized controlled trial, which is also the first of its kind, the authors concluded that the ERA test did not show any benefit in the intention to treat analysis, other than a statistically significant increase in clinical pregnancy rate (CPR) when compared to frozen embryo transfer (FET) and fresh embryo transfer. However, the per-protocol analysis showed a significant increase in PRs at the first and cumulative PRs up to 12 months, and implantation rates at the first attempt highlighting the potential usefulness of ERA. Hence, the authors emphasized the need to confirm the findings in larger controlled trials.[44]

Concept of Selectivity and Receptivity

Endometrial receptivity suggests that the endometrial changes in the mid-luteal phase ensure adequate embryo-endometrial crosstalk ensuring implantation and growth of the embryo. A new concept of selectivity suggests a key role for the decidua in directing the maternal response to the implanting embryo. If *selectivity of the endometrium is suboptimal and receptivity is increased*, then the biosensor function may be disrupted allowing implantation of poorly viable embryos to establish a clinical pregnancy which may end up in miscarriage. On the other hand, *excessive selectivity or reduced receptivity of the endometrium* would decrease the likelihood of implantation or may lead to RIF after IVF.[45]

FACTORS AFFECTING IMPLANTATION

The major factors affecting implantation are listed in **Figure 2**.

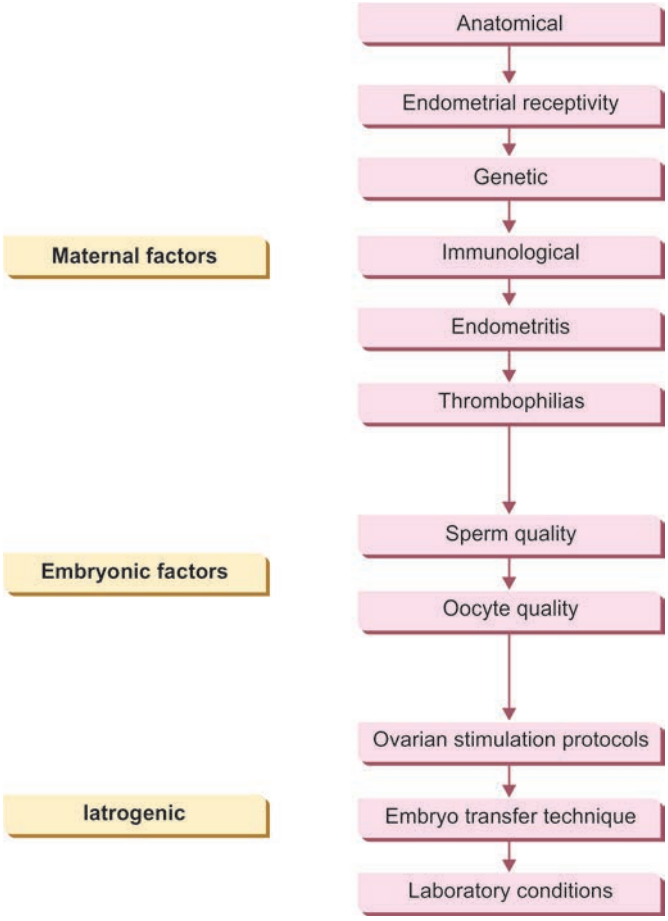

Fig. 2: Factors affecting implantation.

Anatomical Factors

Congenital uterine anomalies—result mainly from fusion or canalization defects of the Müllerian ducts. Mutations of *HOXA10* and *HOXA11* genes that regulate Müllerian duct development have been implicated[46] in the adverse reproductive outcomes as the same genes are known to play an important role in decidualization and implantation.[47] The most common anomaly that leads to adverse reproductive outcomes is the septate uterus. It is suggested that it may also contribute to RIF and improvement in pregnancy outcome is seen after surgical correction.[48] Practice Committee of the American Society for Reproductive Medicine (ASRM) suggests that hysteroscopic septum excision might be associated with improved CPRs in women with infertility.[49]

Acquired Uterine Conditions

Fibroids, polyps, intrauterine adhesions, adenomyosis, and hydrosalpinx have all been considered as potential causes of implantation failure. These disorders lead to a mechanical obstruction, increased contractility, impaired vascularity, or altered ER. Most of them are easy to investigate and amenable to treatment. Studies in patients with RIF show that intracavity lesions and intrauterine adhesions may be found during routine hysteroscopy in 25–50% and 8.5% of patients, respectively.[50,51] Role of noncavity distorting intramural fibroids remains controversial and myomectomy does not improve PRs. According to the ASRM Practice Committee 2017, in asymptomatic women with cavity-distorting myomas (intramural with a submucosal component or submucosal), myomectomy (open or laparoscopic or hysteroscopic) may be considered to improve PRs.[52] Implantation failure in hydrosalpinx results from a mechanical washout effect of the hydro salpingeal fluid and an alteration in ER. Removal of hydrosalpinx by salpingectomy or clipping before IVF almost doubles the PRs and reduces the miscarriage rate to half.[53]

Adenomyosis is an acquired condition that may lead to alteration in ER, embryo-endometrial crosstalk, uterine contractility, and defective decidualization thereby affecting implantation.[54-56] ER studies have identified defects in the expression of important implantation factors such as LIF, HOXA10, and integrins that may play a role in the implantation failure associated with adenomyosis.[57] The role of the immune system in implantation failure is

acknowledged though the exact mechanisms involved are yet to be defined. An increase in macrophages and NK cells has been demonstrated in women with adenomyosis.[58] producing inflammatory mediators and reactive oxygen species which may harm the embryo. Increased production of nitric oxide with abnormal expression of protein molecules has also been implicated. Long downregulation with gonadotropin releasing hormone (GnRH) agonist improves endometrial milieu and implantation.[59] Surgery could be beneficial for women with large focal adenomyosis who have experienced IVF treatment failures.

Thin endometrium: Endometrial thickness <7 mm is associated with implantation failure. The causes of thin endometrium could be either acute or chronic infections that lead to the destruction of the basal layer of the endometrium. Genital Kochs is an important cause of thin endometrium in developing nations; it may lead to extensive destruction of the basal layer. Iatrogenic causes include repeated or vigorous curettage, myomectomy and polypectomy, drugs such as clomiphene citrate, and individual uterine architecture or the intrinsic properties of endometrium that affect its growth.[60]

KEY POINTS

- The process of implantation is initiated with a dialogue between the hatched blastocyst and the endometrium. Paracrine signaling between the two, aids blastocyst adhesion and invasion.
- Since the endometrium becomes refractory in a short period, blastocyst entry must coordinate precisely with the period of ER.
- Cytokines and growth factors regulated by ovarian steroids and chorionic gonadotropin from the blastocyst play a crucial role in embryonic signaling.
- Implantation thus is a finely tuned, well-coordinated event involving a multitude of factors and a cascade of interactions.
- Precise identification of the factors involved and the spatial organization of events may bring us closer to a better understanding of the event and consequently improve assisted reproductive technology (ART) results.

CHAPTER 8

Synthesis and Metabolism of Steroid Hormones

R Suchindra

INTRODUCTION

Steroid hormones, the lipophilic molecules, are synthesized from cholesterol which in turn is formed from acetate.[1] Plasma low-density lipoproteins derived from diet contribute to the major part of cholesterol. Cholesterol produced in the liver circulates in the form of high-density lipoprotein and low-density lipoprotein. Major sites of steroid synthesis include the adrenals, testes, ovaries, and placenta. Recently, neurosteroids have been discovered in the central nervous system and they have mainly "autocrine" or "paracrine" functions.

STEROID HORMONE SYNTHESIS

The four major types of steroid hormones are progestins, androgens, estrogens, and corticoids, which contain 21, 19, 18, and 21 carbons, respectively.[2] Steroid hormones are synthesized by dehydrogenases and cytochrome P450 enzymes from cholestane, a common cholesterol precursor through hydroxylation and dehydroxylation-oxidation reactions.

Cytochromes P450 are membrane-bound oxidative enzymes present in either the endoplasmic reticulum or inner mitochondrial membranes of steroidogenic cells.[3] Six cytochrome P450 enzymes are involved in the steroidogenesis.

The rate-limiting step for the synthesis of all steroid hormones is cleavage of the side chain from cholesterol (C27) to yield pregnenolone (C21) which is catalyzed by P450 cholesterol side-chain cleavage enzyme (P450scc). The anterior pituitary trophic hormones such as follicle-stimulating hormone (FSH), luteinizing hormone (LH), and adrenocorticotropic hormone (ACTH) regulate the synthesis and secretion of steroid hormones (adrenal and gonadal) through negative feedback mechanisms.

Angiotensin II and ion concentrations in the circulation regulate the mineralocorticoids synthesis.

Synthesis of Progesterone

Pregnenolone is the principal precursor for the synthesis of all the other steroid hormones by the testes, ovary, and adrenals. The rate-limiting step for the progesterone synthesis is side-chain cleavage of cholesterol by the enzyme cytochrome P450scc to yield pregnenolone. 3β-hydroxysteroid dehydrogenase (3β-HSD) converts pregnenolone into progesterone.

Progesterone produced during folliculogenesis serves as an intermediate for synthesis of androgen and estrogen. Whereas in the periovulatory and luteal phases, progesterone serves as a primary secretory hormone from the ovary. During the early stages of folliculogenesis, the synthesis of P4 is under the control of FSH and later in the ovarian cycle LH plays a role due to acquisition of LH receptors in the growing follicle. In early pregnancy, the increasing levels of human chorionic gonadotropin (hCG) stimulates the corpus luteum to synthesize and secrete progesterone. During pregnancy, the placenta secretes high levels of progesterone by a different isoenzyme of 3β-HSD (i.e., type I).

Synthesis of Androgen

The primary sites of androgen synthesis and secretion are the Leydig cells of the testes, theca cells of the ovary, and cells in the reticularis region of the adrenals. In the testis, LH stimulates the synthesis of testosterone by upregulating the levels of 17α-hydroxylase and C17,20-lyase. It is a rate-limiting enzyme for the conversion of C21 steroids into androgens. Testosterone is the predominant circulating androgen in the body. The circulating testosterone taken up by the target issues is reduced by 5α-reductase to an active metabolite 5α-dihydrotestosterone (5α-DHT). By a process of aromatization, the aromatase enzyme converts testosterone and androstenedione into estrogens such as 17β-estradiol (E2) or estrone. It is present in the granulosa cells of the ovary, Leydig cells of the testes, and other tissues including the pituitary, brain, placenta, liver, and adipose tissue. The testosterone exerts its effects on the target tissues mainly after conversion into either 5α-DHT or E2 within the tissues.

Synthesis of Estrogen

The predominant estrogen and progestin hormones (estradiol and progesterone) are synthesized primarily by maturing follicles of the ovary, corpus luteum, and the placenta. During folliculogenesis, androstenedione and testosterone are synthesized in the theca cells under the influence of LH. These hormones are subsequently aromatized in the granulosa cells to estrone and E2, respectively.

The production of estrogens and aromatase activity in the granulosa cells is under the control of FSH during midfollicular phases. Later in the cycle, E2 production is regulated by LH through the expression of greater number of LH receptors in the follicle and corpora lutea. During pregnancy, the placenta secretes large amounts of E2 by utilizing androgen precursors from the fetal adrenal gland.

Steroidogenesis in the Adrenal Cortex

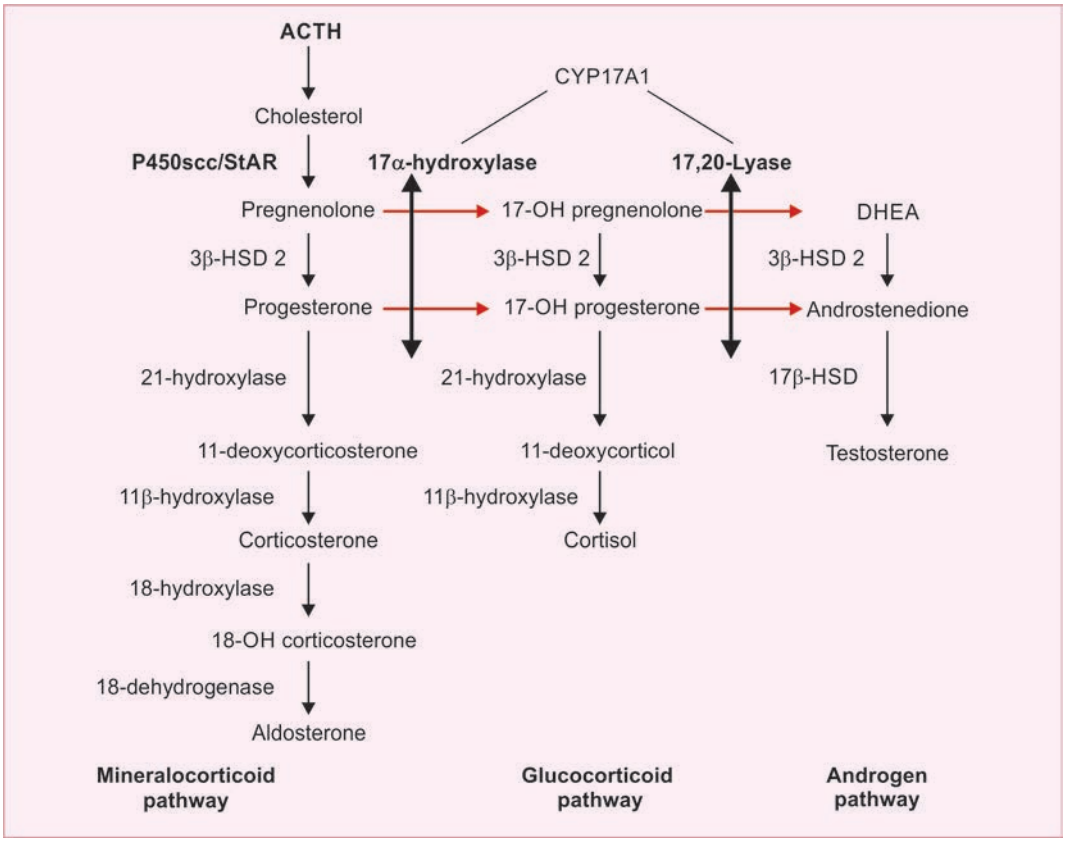
The adrenal cortex is divided into three zones: (1) zona glomerulosa (outer zone), (2) zona fasciculata (intermediate), and (3) central zona reticularis. Each zone synthesizes a specific steroid hormone, the mineralocorticoids, glucocorticoids, and androgens, respectively. ACTH regulates mainly glucocorticoid production and weak androgen production via the cyclic adenosine monophosphate (cAMP)-mediated protein kinase A pathway that activates factors such as steroidogenic acute regulatory protein (StAR) and steroidogenic factor-1. Angiotensin II and potassium increases mineralocorticoid synthesis via the inositol triphosphate or diacylglycerol-mediated protein kinase C pathway.

Glucocorticoids play an important role in glucose homeostasis, stress response, fetal lung development, immune modulation, and maintenance of normal function of the tissues. Mineralocorticoids regulate the Na^+/K^+ balance in extracellular fluids.

In the adrenal cortex, the enzyme 21-hydroxylase (CYP21) plays an important role in the biosynthesis of mineralocorticoids and glucocorticoids. It is present in the smooth endoplasmic reticulum of all three zones and converts progesterone and 17α-hydroxyprogesterone to 11-deoxycorticosterone (mineralocorticoid) and 11-deoxycortisol (glucocorticoid) **(Flowchart 1)**.

These precursor hormones are in turn converted to the biologically active hormones aldosterone and cortisol by the two unique mitochondrial enzymes in the adrenal cortex, aldosterone synthase (CYP11B2) and steroid 11β-hydroxylase

Flowchart 1: Adrenal steroidogenesis pathway.



(ACTH: adrenocorticotropic hormone; DHEA: dehydroepiandrosterone; OH: hydroxylase; P450scc: P450 cholesterol side-chain cleavage enzyme; StAR: steroidogenic acute regulatory protein; 3β-HSD: 3β-hydroxysteroid dehydrogenase; 17β-HSD: 17β-hydroxysteroid dehydrogenase)

(CYP11B1). CYP11B1 seen in the zona fasciculata and reticularis has got only 11β-hydroxylase activity. CYP17, a single enzyme with both 17α-hydroxylase and 17,20-lyase activities, helps in the formation of adrenal androgens. CYP17 is also found in other steroidogenic tissues like ovary and testis but absent in human placenta.

The enzyme CYP17 has two distinct catalytic sites and it is expressed in the smooth endoplasmic reticulum. CYP17 hydroxylates pregnenolone and progesterone to form 17α-hydroxypregnenolone and 17α-hydroxyprogesterone. This process of hydroxylation occurs in the zona reticularis and fasciculata but not in the zona glomerulosa. So in the zona glomerulosa, from the C21-deoxysteroids, the mineralocorticoid aldosterone is produced as the final product.

In the zona fasciculata, where CYP17 hydroxylase activity is present but lyase is absent, C21, 17-hydroxysteroids are produced, and the main product formed is the glucocorticoid cortisol.[4] Where both the activities are seen in the zona reticularis, the 17α-hydroxylated steroids (17α-hydroxy-pregnenolone and 17α-hydroxyprogesterone) are converted to the weak androgens dehydroepiandrosterone (DHEA) and androstenedione, respectively.

Human Ovarian Steroidogenesis

The ovaries play an important role in the oogenesis and steroid hormone production. The two pituitary gonadotropins, FSH and LH are essential for the growth and development of the follicles. In the early antral follicles, FSH stimulates growth and differentiation of granulosa cells, steroidogenesis, and induces LH receptors expression on the follicles and transforming growth factor-β (TGF-β)-related growth factors.

The dominant follicle in the natural cycle continues to grow and synthesize hormone with decline in FSH concentrations, through increased LH sensitivity.[5,6] The follicular growth and estrogen secretion is mediated by FSH and LH through cAMP.

Follicle-stimulating hormone and LH receptors stimulation on granulosa cells activate the various intracellular and extracellular signaling pathways, such as protein kinase C, adenylate cyclase, and mitogen-activated protein kinase (MAP).[7] There are no known signaling pathways in human theca cells. However, bovine studies have shown that LH action on the theca cells is mediated via the MAP kinase signaling pathway.[8]

Granulosa Cells Responsiveness to Luteinizing Hormone

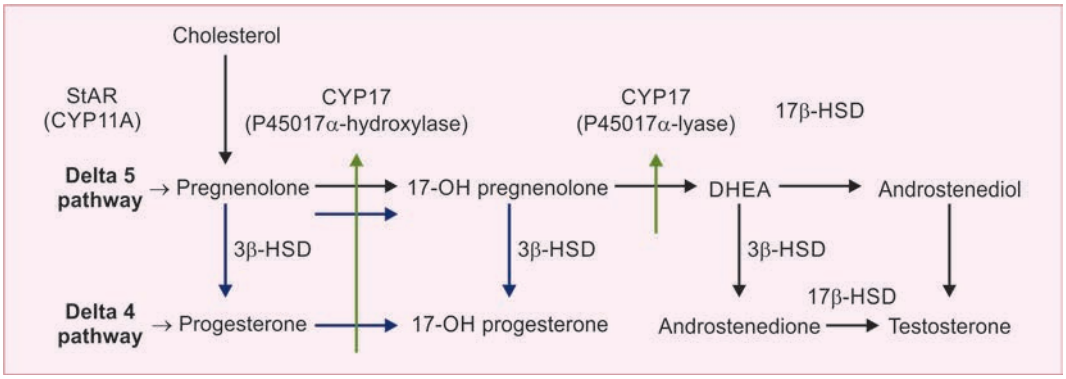
In the natural cycle, during early follicular phase the granulosa cells show low sensitivity to LH. As the follicles grow sensitivity to LH increases and they show reduced sensitivity toward FSH.[6] In the granulosa cells, LH receptor activation increases the protein production of cholesterol side-chain cleavage and aromatase (steroidogenic enzymes).

A study by Yong et al. has shown that both FSH and LH needed for maximal P450scc mRNA expression and biosynthesis of progesterone.[9] During follicular maturation, LH plays a key role in the steroid biosynthesis through supply of the androgen substrate for aromatase and the regulation of the enzyme activity.

Ovarian Steroidogenesis

The rate-limiting step in steroidogenic pathway is the conversion of cholesterol to pregnenolone which is catalyzed by **(Flowchart 2)**[4,10] cytochrome P450scc enzyme (mitochondrial enzyme) encoded by the *CYP11A* gene. There exists three metabolic pathways for the resulting pregnenolone. Two of which seen in the ovary are shown in **Flowchart 2**. One of the metabolic pathway is via the Δ5 (delta 5) pathway **(Flowchart 2)** in which the initial two steps are catalyzed by CYP17. This enzyme complex (17-hydroxylase/17,20-lyase) exhibits both hydroxylase and lyase activity.

Flowchart 2: Ovarian steroidogenesis in humans.



(CYP11A: gene encodes cytochrome P450 side-chain cleavage enzyme; CYP17: gene encodes the enzyme complex 17-hydroxylase/17-lyase; DHEA: dehydroepiandrosterone; StAR: steroidogenic acute regulatory protein; OH: hydroxylase; 3β-HSD: 3β-hydroxysteroid dehydrogenase; 17β-HSD: 17β-hydroxysteroid dehydrogenase)

Pregnenolone is hydroxylated to yield 17-hydroxypregnenolone and further removal of the acetyl group forms DHEA. The enzyme CYP17 is seen in thecal or interstitial cells exclusively,[11] whereas the aromatase enzyme (CYP19) is present only in the granulosa cells.[12] Thus, the androgens required to get converted to estrogens by the granulosa cells of the developing follicles is provided by the theca cells.[13]

Pregnenolone metabolism via the delta 5 pathway is shown by black arrows. An alternative route of metabolism of progesterone via delta 4 pathway is shown in blue arrows. In this pathway, the enzyme 3β-HSD converts pregnenolone to progesterone.

The second route of pregnenolone metabolism in the ovary **(Flowchart 2)** is mediated by the action of 3β-HSD which converts pregnenolone to progesterone. The enzyme CYP17 through the D4 pathway converts the resulting progesterone to 17-hydroxyprogesterone (17-OH progesterone). 17-OH progesterone produced in this pathway cannot be further metabolized in humans due to the species-specific differences in the lyase activity of CYP17.[14] Thus in humans CYP17 acts exclusively on 17-hydroxypregnenolone to form DHEA. But, only very little 17-OH progesterone can be converted to androstenedione.

Thus, pregnenolone metabolized through delta 4 pathway to progesterone and/or 17-OH progesterone serves as the end products in the granulosa cells. In humans, the only route for estradiol synthesis is through the delta 5 pathway. The third pathway for pregnenolone metabolism, which forms aldosterone, takes place in the adrenals.

CYP17 Activity

Factors which Regulate CYP17 Activity

Follicle-stimulating hormone is an important regulator of CYP17 activity in theca cells. Insulin and insulin-like growth factors (IGF-1 and IGF-2) stimulate human theca cells to produce androstenedione *in vitro*, and inhibin produced in the granulosa cells, also induces theca cell androgen synthesis.[15] Inhibitory factors include fibroblast growth factor, epidermal growth factor, TGF-β, growth differentiation factor-9 and activin.[14,16-18]

Implications of CYP17 Activity

The changes in enzyme activity of CYP17 will alter the relative contribution of progesterone from granulosa and theca cells. In theca cells, CYP17 activity mediates the pregnenolone metabolism to estradiol via the delta 5 pathway. This leads to the reduced pregnenolone substrate for 3β-HSD for progesterone production. When the follicle grows, the sensitivity of granulosa cells to LH increases and contributes to the increased proportion of progesterone from the granulosa cells.

Regulation of Other Steroidogenic Enzymes

CYP11A (P450scc)

The StAR protein, which facilitates cholesterol influx into mitochondria, exerts acute regulation on *CYP11A*.

Expression of StAR protein is enhanced by cAMP and by FSH and LH/hCG through granulosa cell stimulation. Chronic regulation is mediated through *CYP11A* gene transcription.

3β-hydroxysteroid Dehydrogenase

The dehydrogenase enzyme 3β-HSD expressed in both theca and granulosa cells is essential for synthesis of all other steroid hormones. The pregnenolone metabolism is determined by the relative levels of activity of the two enzymes (CYP17 and 3β-HSD). Pregnenolone metabolized via the delta 5 pathway leads to production of estrogen and the metabolism via delta 4 pathway leads to progesterone and 17-OH progesterone production. The expression of 3β-HSD is augmented by LH in the theca cells and FSH in the granulosa cells.[19]

Folliculogenesis and Steroids

During folliculogenesis, the general pattern of steroidogenic activity is that small follicles of <6 mm diameter are androgenic and larger follicles are estrogenic and become "progestogenic" in preovulatory stage. Both increased steroidogenic activity and increased LH sensitivity in the granulosa cells contribute to the change in the steroidogenic state in the follicles.[20]

Steroidogenesis in the Testes

Testosterone is the most important androgen produced by the testis. Testosterone plays a crucial role in the development of male secondary sexual characteristics at puberty, maintains adult sexual behavior and function, and necessary for the spermatogenesis in the late stages.[21] The most potent endogenous androgen DHT is formed from testosterone by the enzymatic action of 5α-reductase. This reaction is predominant in the epididymis and prostate where DHT plays an important role in maintaining sexual function. It is also expressed in other peripheral tissues such as skin and liver.

During fetal development, testosterone is essential for Wolffian duct differentiation into epididymides, vasa deferentia, and seminal vesicles and DHT for the development of external male urogenital system. Deficiency of 5α-reductase in men leads to male pseudohermaphroditism with the normal development of internal genital structures.[22]

Leydig cells of the testis secrete testosterone and E2 into seminiferous tubules, gonadal lymphatics, and venules. During intrauterine life, the peak testosterone secretion occurs at 12–14 weeks of gestation under the influence of maternal hCG on the fetal Leydig cells. This peak testosterone

secretion is essential for the development of male urogenital system. Thereafter fetal Leydig cells start degenerating leading to decline in the testosterone production.

A second peak of androgen production occurs postnatally at 2–3 months due to proliferation of Leydig cells in the neonatal period and augmented pulsatile secretion of LH. The immature Leydig cells in the testis secrete 3α- and 5α-reduced androgens, whereas the mature ones seen in puberty secrete large amounts of testosterone. Testosterone concentrations decline with increased abdominal obesity and ageing.[23,24] The decrease in testosterone levels is by 0.6–1.1% annually. The decline begins in adulthood and progresses thereafter which results in a net decline of 35–50% from the young adult.

Testosterone synthesis from cholesterol is catalyzed by cytochrome P450 enzyme complexes. Five major enzymes involved are:

1. Cholesterol side-chain cleavage enzyme
2. 3β-hydroxysteroid dehydrogenase
3. 17α-hydroxylase
4. C17,20-lyase (enzyme complex)
5. 17β-HSD type III **(Flowchart 3)**.

The rate-limiting step in steroidogenesis is catalyzed by cytochrome P450scc which converts cholesterol to pregnenolone. However, the StAR protein regulates the delivery of cholesterol to the inner mitochondrial membrane and this StAR protein[25] in turn is activated by LH during steroidogenesis. Any defect in the steroidogenic pathway will result in male pseudohermaphroditism.

Pregnenolone is converted to progesterone under the enzymatic action of 3β-HSD. Pregnenolone (or its metabolite, progesterone) through cleavage and hydroxylation reactions catalyzed by enzyme complex C17,20-lyase and 17α-hydroxylase form androstenedione. Androstenedione is then converted to the potent androgen testosterone by the enzyme 17β-HSD type III.

Testicular steroidogenesis contributes to >95% of testosterone production in men, and only 5% is produced by the adrenal gland and extraglandular conversion of DHEA and androstenedione to testosterone. The average testosterone production in young men ranges from 4 to 9 mg/day.

The aromatase enzyme expressed in Leydig, Sertoli, and germ cells further converts testosterone produced from the Leydig cells into estradiol which is necessary for the initiation of spermatogenesis and mitosis of spermatogonia.[26]

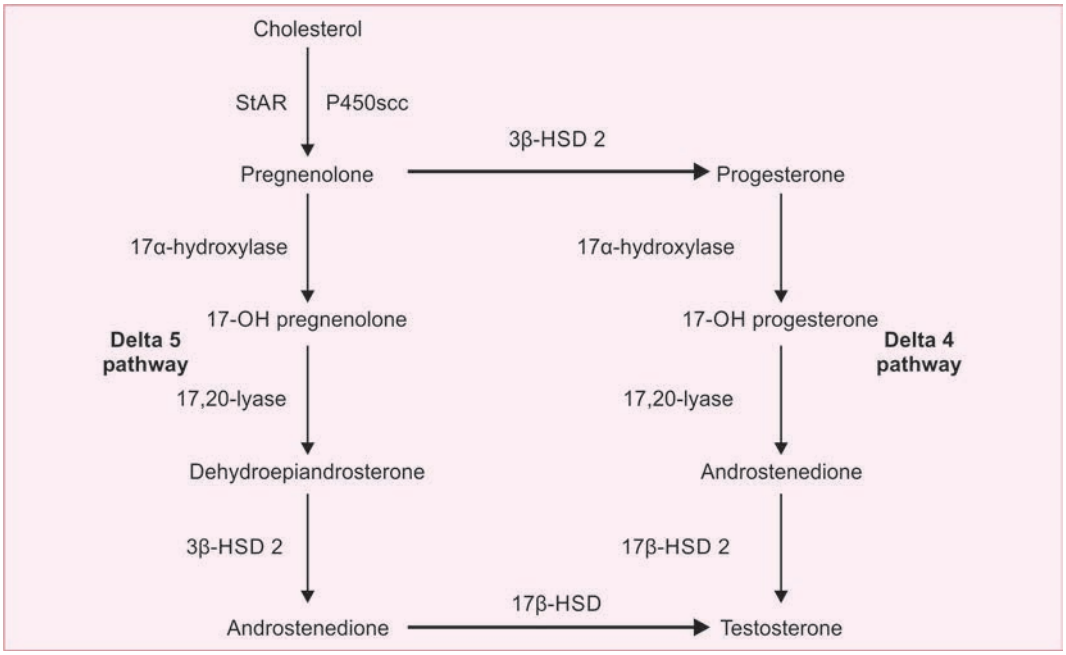
STEROIDS AND PATHOPHYSIOLOGY

Steroid-related disorders include cancers that occur in the steroid target tissues such as breast, uterus, and prostate and steroid insensitivity syndromes resulting from defective steroid synthesis or function and receptor defect.

Disorders Resulting from Defective Synthesis of Steroids

- *Congenital adrenal hyperplasia (CAH):* This syndrome occurs due to deficiency of 21-hydroxylase with inadequate adrenal steroids secretion. It is associated with increased secretion of adrenal androgens following hyperstimulation by ACTH and partial virilization in

Flowchart 3: Testicular steroidogenesis. The principal delta 5 pathway takes place in humans.



[P450scc: cytochrome P450 cholesterol side-chain-cleavage enzyme (CYP11A); P450c17: C17,20-lyase/17α-hydroxylase (CYP17A); P450arom: aromatase (CYP19); StAR: steroidogenic acute regulatory protein]

girls.[27] Occurrence of CAH due to enzyme deficiencies such as 17-hydroxylase or 18-hydroxylase is less common.

- *Male pseudohermaphroditism:* Defective androgen synthesis in the testis due to the deficiency of 17,20-lyase or 17β-HSD can lead to male pseudohermaphroditism. However, in 80% of the individuals it results from androgen action abnormalities at the target cell level due to 5α-reductase deficiency.

Disorders Resulting from Defects in Target Tissue Metabolism

Deficiency of 5α-reductase type 2 results in male pseudohermaphroditism. It is an autosomal recessive disorder with defective conversion of testosterone to 5α-DHT in the target tissues. In these individuals, Wolffian duct structures develop normally under the influence of normal levels of testosterone with varying degrees of feminization of the external genitalia.

This androgen resistance syndrome with female phenotype usually presents with masculinization due to the high levels of testosterone and/or amenorrhea during puberty. In individuals with complete feminization, inguinal, and labial testes have to be removed due to increase in the incidence of cancer in the gonads.

Estrogen Receptor Polymorphism

The gonadotropins (FSH and LH) and the steroid hormones (androgen and estrogen) play a fundamental role in folliculogenesis. Estrogens synthesized by growing follicles increase both FSH and estrogen receptors (ERs), promote granulosa cell growth and differentiation and prevents apoptosis of the cells. Estrogen affects the oocyte maturation and estrogen levels determine the quality of an oocyte and embryo.[28]

Estrogen exerts its action on various tissues through two subtypes of ERs (ERα and ERβ). The genes *ESR1* and *ESR2* located on the chromosomes 6 and 14 encode the receptors ERα and ERβ, respectively. ERα, the most abundant one plays an important role in reproduction. ER gene polymorphisms have been associated with a variety of disorders including infertility (male and female), endometriosis, breast cancer, cardiovascular disorders, and osteoporosis.

The *ESR1* gene is highly polymorphic. *PvuII* and *XbaI are the two most common single nucleotide polymorphisms (SNPs) in ESR1 gene.*[29] These two SNPs have been associated with the risk of infertility.[30]

Both the ERs are present in testicular germ cells at different stages of spermatogenesis, and play an important role in male reproduction. The receptors show variable expression in *ESR1 (PvuII* and *XbaI*) and *ESR2* (*RsaI* and *AluI*) genes in different ethnic groups. There is a significant risk of association of *ESR1 Pvu*II and *ESR2 RsaI* polymorphisms with male infertility. Asian male population shows a decreased risk for these polymorphisms, while the Caucasians show increased susceptibility to male infertility.[31]

The estrogen receptors (ERα and ERβ) mediate various effects of estrogen such as folliculogenesis, oogenesis, and endometrial preparation for successful implantation of an embryo. SNPs of various reproduction-related genes have been associated with recurrent implantation failure (RIF). These genes include *TP63*, *VEGFA*, *MMP2*, *ESR1*, and *ESR2* genes and *LIF* gene.

A study by LD Vagnini et al. in 2019 has shown that there is a stronger association between *ESR1* and *LIF* gene polymorphisms and RIF with an increase in the chance of women (7.9-fold) presenting with RIF when compared with women who became pregnant on their first cycle of *in vitro* fertilization/intracytoplasmic sperm injection (IVF/ICSI) treatment.[32]

Estrogen receptor-α gene polymorphisms affect male gamete maturation. Prevalence of p and x alleles in ER-α gene *PvuII* and *XbaI* polymorphisms was more among fertile men. Presence of P and X alleles was associated with increased incidence of male infertility (oligoasthenoteratozoospermia) for genotypes PP, XX than the genotypes pp and xx.[33]

Metabolism of Steroid Hormones

- The peripheral inactivation and catabolism of steroids mainly occur in the liver, but some metabolic activity also takes place in the kidneys and adipose tissue. Once inactivated, steroids are eliminated from the body as urinary excretion products after conversion to hydrophilic compounds (conjugated metabolites). The following reactions may be involved in the metabolism of steroid based on its structure:[34,35]
- Reduction
- Oxidation
- Hydroxylations of the steroid nucleus at different positions
- Conjugation (glucuronide and/or sulfate).

Steroid Excretion Products

Steroid excretion products have been shown in **Table 1**.

KEY POINTS

- Steroid hormones, the lipophilic molecules are derived from cholesterol.
- Dehydrogenases and cytochrome P450 enzymes are essential for the steroid hormone synthesis through hydroxylation and dehydroxylation-oxidation reactions.
- The rate-limiting step for the synthesis of all steroid hormones is cleavage of the side-chain from cholesterol to yield pregnenolone.
- Pregnenolone serves as a principal precursor for the synthesis of all the other steroid hormones by the gonads or adrenals

TABLE 1: Steroid excretion products.

Steroid class	*Starting steroid*	*Excretion product*	*Type of conjugate*
Progestins	Progesterone	Pregnanediol	Glucuronide
	17α-OH progesterone	Pregnanetriol	Glucuronide
Androgens	Testosterone	• Androsterone • Etiocholanolone	Glucuronide and/or sulfate
Glucocorticoids	Cortisol	11β-hydroxyandrosterone, allotetrahydrocortisone	Glucuronide

- Pregnenolone metabolism through the delta 5 pathway in the human ovary serves as the only route for estradiol synthesis
- The most potent endogenous androgen is DHT and is predominantly seen in epididymis and prostate.
- Defective adrenal steroid synthesis results in various disorders including CAH and male pseudohermaphroditism
- Estrogen receptor gene polymorphisms (*ESR1* and *ESR2*) have been associated with a variety of disorders including infertility (male and female), endometriosis, RIF, breast cancer, cardiovascular disorders, osteoporosis, etc.

CHAPTER 9

Puberty and Aberrations

Pratibha Saran Malik

INTRODUCTION

The term *puberty* is used to indicate the maturity of the reproductive axis, appearance of secondary sex characteristics, and the ability to reproduce. Puberty is a dynamic process which is brought about by a sequence of events resulting in the episodic secretion of gonadotropin-releasing hormone (GnRH) from hypothalamus.[1] This process is finely regulated by genetic, neuronal, environmental, and metabolic factors.

HYPOTHALAMIC–PITUITARY–GONADAL AXIS

Pulsatile secretion of GnRH into the hypophyseal portal venous system is critical for normal gonadotropin secretion and proper functioning of the reproductive system. The innate GnRH signaling from the hypothalamus to the anterior pituitary occurs episodically (every 1–4 hours). The GnRH hormone is a decapeptide secreted by GnRH neurons which attaches to its special receptors present on the gonadotrope cells of the anterior pituitary. GnRH is also known as luteinizing hormone-releasing hormone (LHRH) as it induces the release of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the anterior pituitary. This occurs in a synchronous manner which is vital for the proper functioning of gonads and normal menstrual cycle.

Onset of puberty occurs by the activation and maturation of the hypothalamic–pituitary–gonadal (HPG) axis and can be described in six phases **(Table 1)**:

1. *Fetal period:* During embryogenesis, the olfactory placode is the place of origin of the GnRH neurons from where they move to their definite destination in the medial basal hypothalamus between 6 and 9 weeks of pregnancy.[2] The development of the hypophyseal portal venous system starts at 6–10 weeks of pregnancy and is accomplished by 19–20 weeks.[3] The axons of the GnRH neurons establish contact with the blood vessels of the portal venous system in the floor of the hypothalamus. The GnRH neurons begin pulsatile secretion into the hypophyseal portal venous system.

   In response to the pulsatile GnRH secretion, the anterior pituitary starts to produce FSH and LH in the circulation of the fetus by the end of 12 weeks,[4] rising steadily to reach a peak at 20–24 weeks and then their levels gradually fall over the last 10 weeks of pregnancy.[5-7] Thus, the HPG axis is active in early intrauterine life.
2. *Function in infancy:* Soon after birth, there is temporary arousal of the newborn's HPG axis. During this phase, sometimes called as *minipuberty*, the FSH rises more in girls and LH rises more in boys. Gonadotropin and gonadal steroid levels escalate to maximum levels at 3–6 months in males and around 12–18 months in females, after which they fall continuously.[7]

   It was initially proposed that minipuberty occurred due to fall in placental steroid levels and the abrupt escape of the hypothalamic–pituitary–ovarian (HPO) axis from their negative feedback effect. But it was later found that the duration of this resurgence in gonadotropin levels is greater in preterm as compared to full-term born infants, hinting toward the fact that it is more of a function of a development of the HPG axis than its mere escape.

TABLE 1: Phases of onset of puberty.

1. In utero	*2. At birth*	*3. Neonatal period*	*4. Juvenile pause*	*5. Reactivation*	*6. Puberty*
HPG axis active in early intrauterine life	Brief activation of HPG axis	Peak at different times in boys and girls	Juvenile pause	HPG axis reactivates	HPG axis active
Axis inactive by birth	Minipuberty	Axis shuts down	FSH > LH	LH > FSH	Onset of pubertal changes

(FSH: follicle-stimulating hormone; HPG: hypothalamic-pituitary-gonadal; LH: luteinizing hormone)

3. *Gradual fall in activity of HPG axis:* The gonadotropin concentrations fall to low levels by 9–12 months in males and 24–36 months in females. The reproductive axis is again shut down and remains hypoactive until puberty.
4. *Juvenile pause:* Between the phases of infancy and puberty, known as *juvenile pause*, the HPG axis lies dormant. During childhood, the GnRH neurons generate pulses irregularly at reduced amplitude, although their activity is not completely abolished. Low amplitude LH pulses are detectable even in children aged 5 years, mostly during sleep. FSH levels rise more than LH levels, but there is no detectable increase in steroid hormone concentrations in blood.

   Gonadostat theory: It was postulated that the phase known as the juvenile pause occurs as there is very small amount of sex steroids in peripheral circulation, which block the gonadotropin secretion since there is increased sensitivity to the sex steroids and their negative feedback effect. However, even children with dysgenesis of gonads have comparable and often excessive biphasic patterns of gonadotropin secretion—first increase at infancy and secondly at puberty too. This proves that anterior pituitary and gonads are not the limiting factors for reactivation of HPG axis. Thus, this theory was discarded. Typical biphasic pattern of secretion of gonadotropins from birth to puberty is by changing levels of central suppression of pulsatile release of GnRH.
5. *Reactivation at night:* During adolescence, the HPG axis reawakens for a third and final time, and the GnRH neurons begin secretion in pulsatile form.

   Luteinizing hormone levels rise nocturnally in the early stages of puberty **(Fig. 1)**. LH increases in amplitude though not in frequency. Peak amplitude of LH rises 20–30 times while peak amplitude of FSH rises only twofold.[8]
6. *Puberty:* As puberty advances, LH rises even during day time but at a lower amplitude.

Increasing gonadotropin (LH) levels lead to an increase in basal estradiol (E2) and the activation of gonads or *gonadarche*. This is followed by the development of secondary sexual characters in girls[9] and hence breast development known as *thelarche.* Sustained raised basal E2 levels continuously for 1 year heralds the onset of *menarche*. Regular ovulatory cycles start after 1 year of onset of menarche. Regular ovulation gives rise to regular menstrual cycles.

MENSTRUAL CYCLE: A RECAP OF EVENTS

During each menstrual cycle, there is a synchronized interplay of multiple hormones. In the follicular phase, pulsatile release of GnRH stimulates the secretion of FSH and LH, which results in the maturation of the ovarian follicle. The steadily increasing estrogen levels during late follicular phase lead to a positive feedback effect where it causes pulsatile secretion of GnRH with increased frequency. The pituitary has increased sensitivity to GnRH and this triggers the midcycle LH surge that causes ovulation. In the luteal phase, the corpus luteum secretes progesterone which is pivotal to support the implantation of the embryo. If implantation fails, the corpus luteum is involuted by apoptosis, causing fall in progesterone and estrogen levels resulting in menstrual bleeding.

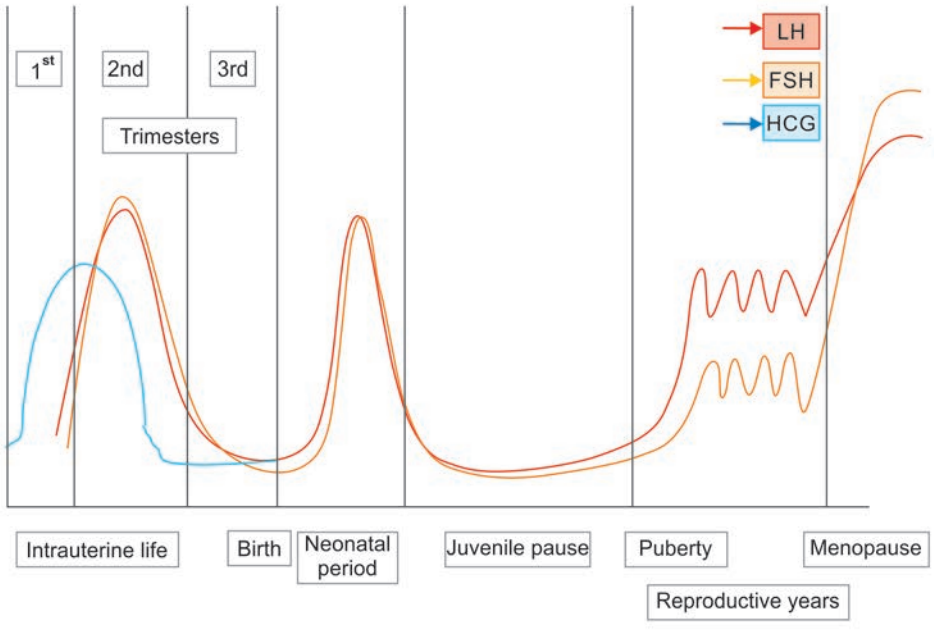

Fig. 1: Gonadotropin levels during various stages of life.

ONSET OF PUBERTY: NEUROENDOCRINE CONTROL

Two pathways are proposed:

1. *Central control mechanism:*
   a. *Gamma-aminobutyric acid (GABA):* GABA is a major neurotransmitter secreted by neurons of median eminence of hypothalamus. It has an inhibitory role on the GnRH pulse generation. Experiments in monkeys have demonstrated a fall in GABA content in the median eminence around puberty.
      i. *Clinical aspect:* Chronic administration of bicuculline, a GABA-A receptor antagonist, activates GnRH release and induces early menarche and precocious puberty in rhesus monkeys.[10]
   b. *Glutamate:* It is a neurotransmitter that stimulates GnRH release via *N*-methyl-d-aspartate (NMDA) receptors. Glutamate concentrations are found to be increased in hypothalamus at puberty.
      i. *Clinical aspect*: Prolonged intermittent NMDA stimulation of hypothalamus activates HPG axis and stimulates puberty in juvenile male monkeys.
   c. Makorin ring-finger protein 3 (*MKRN3*) gene inhibits the secretion of GnRH. Loss of function mutations in this gene leads to central precocious puberty (CPP).
   d. *Neuropeptide Y (NPY):* It is a peptide secreted by the hypothalamus which helps to regulate food intake and reproductive functions. GnRH secretion is inversely proportional to NPY gene activity.
   e. *Kisspeptins:* Exogenous kisspeptin administration switches on the dormant GnRH neurons in juvenile male monkeys.
2. *Peripheral signaling—leptin, insulin, ghrelin, peptide, and free fatty acids:*
   a. *Leptin,* a peptide produced by adipocytes, has receptors in the brain around the arcuate nucleus and ventromedial hypothalamus. Leptin acts to decrease appetite and increases energy expenditure, probably by decreasing the expression of NPY. Around puberty, leptin may play a permissive role by upregulating kisspeptin release.
   b. *Ghrelin* is a gut hormone, which operates as a signal of energy homeostasis. Its function is opposite to leptin. It is also a neuropeptide secreted in the human brain and inhibits the secretion of GnRH. It plays a physiological role in the regulation of pubertal onset and gonadal function.

GENETIC FACTORS CONTROLLING PUBERTAL ONSET

Technology of omics showed that many genes increase in expression at the age of puberty of which the *KISS1* gene is the most important. Furthermore, epigenetic mechanisms have been shown to influence pubertal onset. Imprinting disorders have been associated with CPP. Likewise, many other genetic disorders can affect the pubertal onset.

Kisspeptin System

The kisspeptin system has a paramount role in puberty. The beginning of puberty parallels the maturation of kisspeptin neurons. These neurons, also called kisspeptin/neurokinin B (NKB)/dynorphin (Dyn)/kisspeptin, neurokinin B, and dynorphin (KNDy) neurons, are present in the preoptic and infundibular region of hypothalamus. The kisspeptin axons project to GnRH neurons which express KISS1R, where they signal GnRH secretion. Thus, kisspeptin neurons regulate GnRH neurons.

The *KISS1 gene* on the long arm of chromosome 1 (1q32) encodes the neuropeptide kisspeptin and is secreted by the kisspeptin neurons of the hypothalamus.[11] The kisspeptin neurons also secrete neuropeptides NKB (TAC3 in humans) and Dyn A.

Neurokinin B acts on kisspeptin neuron to cause its stimulation, whereas Dyn A causes inhibition of kisspeptin release; thus, both are autocrine regulators of kisspeptin neurons **(Fig. 2)**.[12] Kisspeptin released from KNDy neurons acts directly on GnRH neurons. An increase in *KISS1* messenger ribonucleic acid (mRNA) expression occurs during pubertal maturation. Arousal of kisspeptin system activates the secretion of GnRH in a regular and pulsatile manner, bringing about the release of predominantly LH hormone from anterior pituitary. This leads to the reawakening of the reproductive axis and lifting the breaks leading to the pubertal switch.

It was shown in some patients with isolated hypogonadotropic hypogonadism (HH) that absent pubertal development was due to "loss of function" mutations of kisspeptin receptor *KISS1R* and *KISS1* gene.[13] Simultaneously, it was shown that an activating mutation in *KISS1R* and *KISS1* gene lead to CPP in girls.[14] Thus, kisspeptin system is an important regulator of HPG axis.[15,16]

Menstrual Cycle and Kisspeptin Neurons

Estrogen and testosterone are unable to act directly on GnRH neurons as the latter lacks receptors for the same.

Kisspeptin neurons express estrogen receptor alpha (ERα), progesterone receptors (PRs), and androgen receptors (ARs). Kisspeptin neurons act as intermediaries as they receive signals from sex steroids and relay it to the GnRH neuron. Therefore, the kisspeptin system has a vital role in the modulation of HPG axis and particularly in the timing of onset of puberty.

Kisspeptin neurons mediate both excitatory and inhibitory feedback of sex steroids on the hypothalamus.

- In the follicular phase of the menstrual cycle, estrogen secreted from the growing follicle acts on the receptors on kisspeptin neurons to decrease kisspeptin and NKB

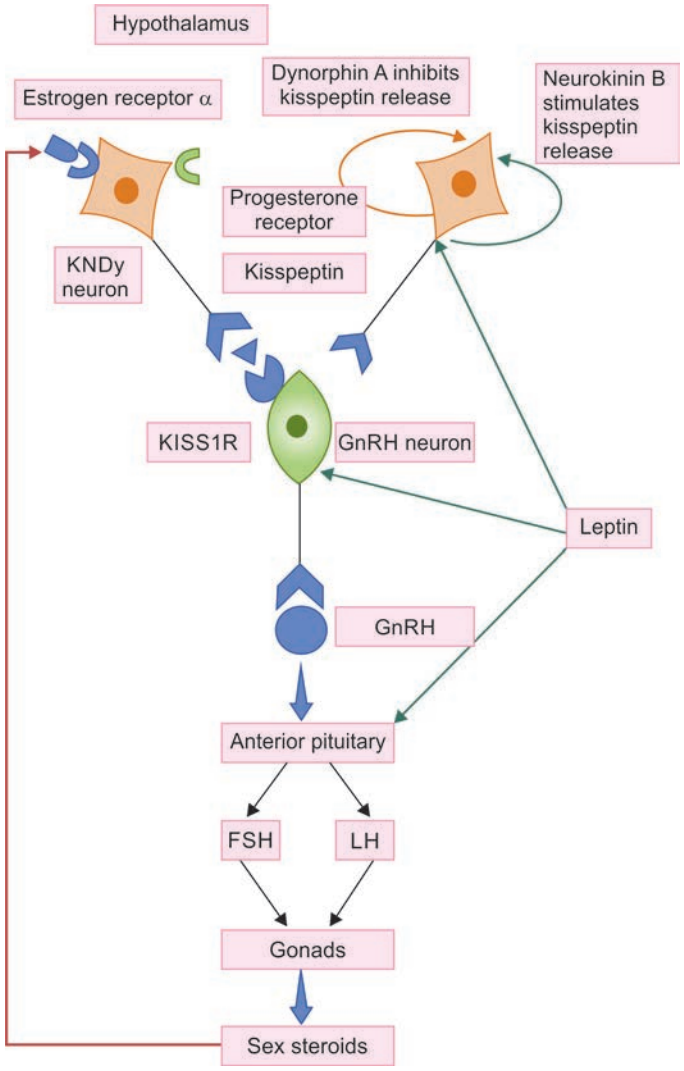

Fig. 2: The kisspeptin pathway.
(FSH: follicle stimulating hormone; GnRH: gonadotropin-releasing hormone; KNDy: kisspeptin, neurokinin B, and dynorphin; LH: luteinizing hormone)

release and increase the Dyn release.[17] Dyn inhibits the pulse frequency of GnRH release from hypothalamus to cause decrease in level of gonadotropin, which causes a dominant follicle to emerge and suppresses other growing follicles. This is the *negative feedback* effect.

- In the late follicular phase, sustained high estrogen levels mediate the release of kisspeptin, which increase the pulsatility of GnRH neurons and lead to an increased LH output from the anterior pituitary. This switch from negative to *positive feedback* of sex steroids induces the midcycle LH surge, which results in ovulation.[18]

Various experiments have successfully demonstrated that administration of kisspeptin induces LH secretion much more than FSH secretion in men and women, although the response is different.[19] The use of kisspeptin as a trigger for inducing final oocyte maturation during controlled ovarian stimulation (COS) is being explored as an innovative way to avoid ovarian hyperstimulation syndrome (OHSS) in high-risk in vitro fertilization (IVF) patients.

NUTRITIONAL FACTORS DETERMINING ONSET OF PUBERTY

Excessive eating of processed high-fat food, physical inactivity, and childhood obesity is consistently associated with early onset of puberty in girls with resultant slightly decreased adult height. Various epidemiological studies across all ethnic groups indicate a trend in relation to earlier onset of puberty, especially in girls, than in the previous century, probably as a result of better nutritional status.

One hypothesis stated that only after attaining a total body fat concentration of about 17% could puberty be triggered in girls.[20] The brain tracks the somatic cues and thus is thought of as the somatometer. In girls, higher body fat is correlated with early puberty.[21] One postulated mechanism of triggering puberty in overweight girls may be due to increased levels of leptin. Increased leptin levels are postulated to induce the release of kisspeptin. Other proposed mechanisms linking obesity to early onset of puberty are elevated insulin-like growth factor 1 (IGF-1), adiponectin, and C-reactive protein levels, insulin resistance as well as decreased levels of sex hormone-binding globulin (SHBG), thus increasing the bioavailable sex steroid levels. Recent studies also point toward vitamin D deficiency to early puberty in girls.

The relation between obesity and pubertal onset in boys is controversial and not yet proven. Few studies indicate that higher animal protein intake such as meat and milk consumption during childhood may be associated with the early puberty. It is thought that animal foods and dairy products cause stimulation of IGF-1 secretion, increased levels of which have been correlated with an earlier onset of puberty.[22,23] Animal foods are rich sources of many other nutrients, such as essential micronutrients and fatty acids, which may lead to an earlier sexual maturation.

Humans are abundantly exposed to environmental endocrine-disruptive chemicals (EDCs), which may lead to premature puberty.[24] EDCs hamper the endocrine system as they may have multiple modes of action, which may be cumulative. Examples include phthalate esters in plasticizers, polychlorinated biphenyls (PCBs) in fish from adulterated water, lead, bisphenol A, and plant-derived phytoestrogens used in packaging of food and beverage. Exposure to EDCs is proposed to increase the kisspeptin secretion. Their estrogenic content may be responsible for the early breast development in girls.

STAGES OF PUBERTAL DEVELOPMENT

The sequence and tempo of the events of puberty greatly varies in different children due to genetic factors accounting for 50–80%. Maternal and paternal pubertal timing is directly correlated with the age of onset of puberty in their children. The variables that may influence pubertal development are genetics, gender, nutrition, endocrine factors, physical inactivity, race, and many comorbid conditions.

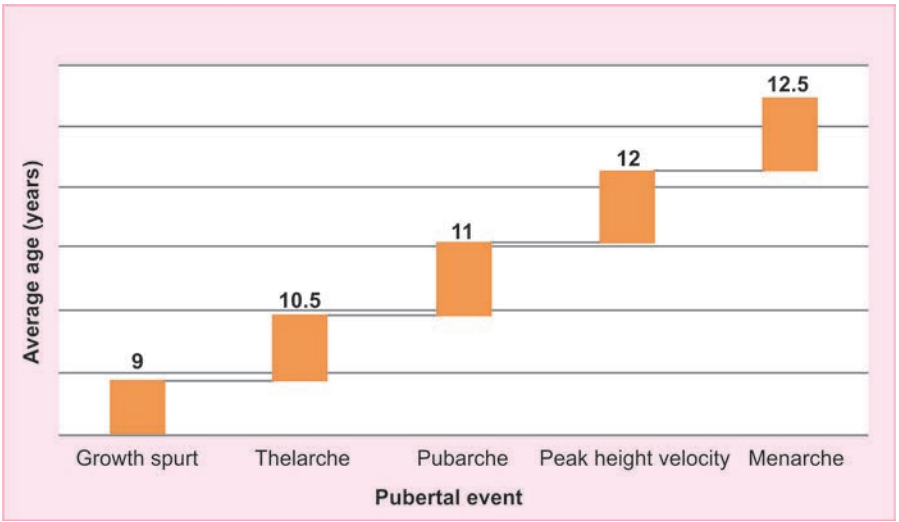

Fig. 3: Pubertal milestones in girls.

Adrenarche denotes adrenal cortex activation and secretion of adrenal androgens, namely dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione. Androgens stimulate the development of axillary and pubic hair, which is termed *pubarche*. Adrenarche occurs independently of onset of puberty.

Gonadarche denotes the activation of the gonads, gonadal sex steroid production, and initiation of gametogenesis. Gonadarche is recognized clinically by breast development or *thelarche* and finally *menarche* in girls and by testicular enlargement and virilization in boys.

In Girls (Fig. 3)

- *Adrenarche:* It starts around 6 years of age. Androgens secreted from the zona reticularis of adrenal cortex increase. Serum level of DHEAS reaches >40 µg/dL, which serves as the biochemical indicator of adrenarche.[25] The HPO axis generally activates 2–3 years after the attainment of adrenarche.
- *Pubertal growth spurt:* Approximately 15–20% of adult height is contributed by pubertal growth, which occurs before epiphyseal closure.

There is an increase primarily in height as well as weight which begins at early or mid-puberty at around 9–10 years in girls and 11–12 years in boys. Acceleration in height is the first sign of pubertal onset in girls. Both the peak growth rate and duration are higher for boys accounting for a difference of 11–13 cm in their final adult heights. Peak growth velocity is a part of pubertal growth spurt and occurs at 11–12 years in girls.

Increase in height is due to elongation of bones due to chondrogenesis at the epiphyseal plate, which is known as the growth plate. Estrogen enhances growth hormone (GH) levels early in puberty. GH stimulates the secretion of IGF-1 from liver and locally at the epiphyseal plate, which enhances longitudinal bone growth.[26] Prolonged high levels of estrogen ultimately result in epiphyseal plate closure, which halts further growth of bones.

Clinically, bone age or skeletal age is found by comparing X-ray of the wrist bones of the left hand to a standard. The Bayley–Pinneau tables in combination with the Greulich–Pyle atlas are used as a standard of reference. Bone age changes as age advances until the epiphysis fuses.

Typically bone age equals chronological age. In those with delayed puberty, bone age is delayed, while bone age is accelerated in precocious puberty.

Insulin is also essential for proper pubertal growth. Besides this, normal levels of thyroid hormones are essential for proper skeletal growth.

- *Thelarche* (breast budding): The first stage of breast development. Average age is 10–11 years.
- *Pubarche:* The appearance of pubic hair. Average age is 11 years.
- *Menarche:* The initiation of menses. Average age is 12.5 years.

In Boys (Fig. 4)

The first sign of puberty in males is *growth and enlargement of the testes* (Tanner stage 2 testicular length >2.5 cm or volume >4 mL), occurring around 11.5 years. In boys, testicular enlargement is followed by growth of pubic hair 2 years later. Axillary hair appears 2 years after pubic hair growth.

Rising testosterone levels lead to voice cracking or deepening and increased muscle mass. Testosterone is converted to the more potent dihydrotestosterone (DHT) by 5α-reductase, which leads to growth of the penis and scrotum, enlargement of prostate, and pubic hair. DHT leads to facial hair growth and is responsible for recession of the scalp temporal hairline.

The *growth spurt* is initiated when testicular volume reaches about 10–12 mL. Boys attain peak height velocity usually at 13–14 years.

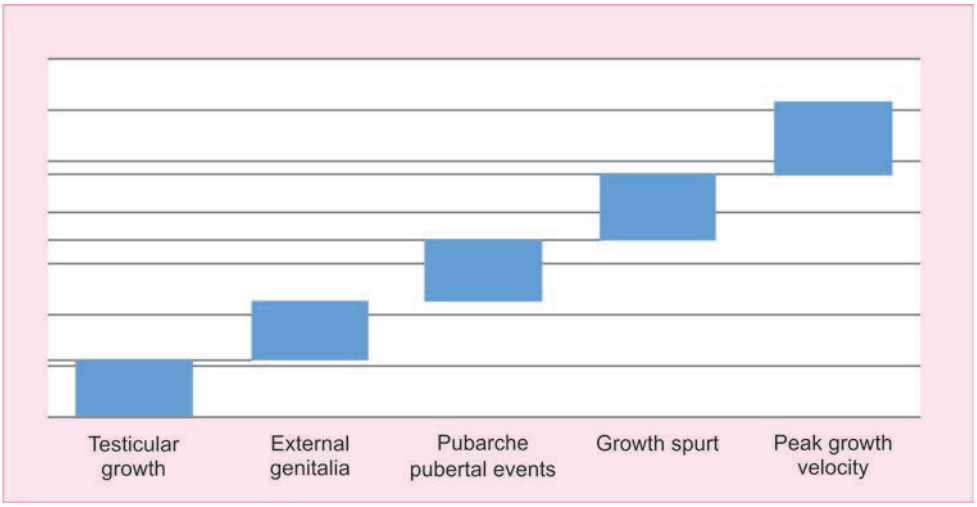

Fig. 4: Pubertal milestones in boys.

TABLE 2: Tanner stages of puberty.

Stage	*Breast*	*Pubic hair in boys and girls*	*Male genitalia*
1	Prepubertal	Prepubertal	Prepubertal. Testicular size <4 cc in volume and <2.5 cm in longest dimension
2	Breast buds (thelarche), growth of both breast and nipple as a small mound, slight increase in diameter of areola. Average age 11 years	Lightly pigmented hairs grow at the base of penis in boys and the mons/labia majora in girls	Growth of scrotum and testes—scrotal skin is thin and red, growth of testis to >4 cc or >2.5 cm, penis remains prepubertal
3	Further enlargement of both breast and areola with same contours. Average age 12.5 years	Darkening, curling, and coarsening of hair, extending over the pubic symphysis	Increase in length of penis. Further growth of testes and scrotum
4	Areola and nipple form a secondary mound which projects above the contour of the breast. Average age 13–14 years	Adult in appearance and extend to the suprapubic area	Further enlargement of the penis in width and length with enlargement of the glans. Further pigmentation of the scrotal skin
5	Adult shape. Areola and nipple merge with the contour of the breast. Average age 15 years	Spread to the medial thighs. May spread to the lower abdomen in boys	Testes, scrotum, and penis are adult in size and shape

Tanner stages refer to developmental milestones that occur during puberty. Changes in the development of breasts, growth as well as pattern of pubic hair, growth of male and female external genitalia are described conventionally in five stages as shown in **Table 2**.[27]

NORMAL VARIANTS OF PUBERTY

In *constitutional delay* puberty (pubertas tarda), puberty starts >2 standard deviations (SDs) later than the normal mean age of onset.

In *constitutional acceleration* puberty, puberty occurs >2 SDs earlier than the normal mean age of onset but not before age 8 in girls or before age 9 in boys.

Premature thelarche is an isolated form of breast development without any other signs of pubertal changes. Follow-up is needed at 6 monthly intervals to differentiate it from CPP. Premature thelarche is benign and may occur due to exposure to EDCs as elaborated above.

DISORDERS OF PUBERTY

Classification of Pubertal Disorders

Pubertal disorders can be due to either precocious (early) or delayed onset. Abnormal pubertal development can cause a huge distress to the child and family members. Failure in early recognition and treatment can lead to adverse outcomes such as decrease in adult height. In some cases, it could be a sign of underlying organic pathology (e.g., tumors).

Precocious Puberty

Precocious puberty results from increased sex hormone production and has been defined as development of secondary sexual characters before 8 years in girls and before 9 years in boys.[28] Precocious puberty may occur due to abnormal gonadotropin stimulation (central cause) or intrinsic disease of the ovary or adrenals (peripheral cause)

BOX 1: Causes of precocious puberty.

- *Gonadotropin-dependent or central or true precocious puberty*:
  - Idiopathic (familial/nonfamilial)
  - Central nervous system (CNS) tumors or lesions:
    - Hypothalamic hamartoma
    - Pituitary microadenoma
    - Craniopharyngioma
    - Ependymoma
    - Pinealomas
    - Optic astrocytoma
    - Optic glioma
    - Abscess, encephalitis, trauma
    - Hydrocephalus
    - Arachnoid cyst
    - Hydrocephalus
    - Encephalocele
    - Neurofibromatosis
    - CNS vascular malformation
    - CNS infections
  - Other miscellaneous cause:
    - Genetic causes
    - Cranial radiation
    - Chemotherapy
    - Primary hypothyroidism
    - Endocrine-disrupting chemical
    - Obesity
- *Gonadotropin-independent or pseudo or peripheral precocious puberty*:
  - Gonadal:
    - Ovarian cysts
    - Ovarian tumors (granulosa cell tumor, theca cell tumor, germ cell tumors)
    - McCune–Albright syndrome
    - Familial testotoxicosis [activating mutation of luteinizing hormone (LH) receptor]
    - Leydig cell tumor
  - Adrenal:
    - Congenital adrenal hyperplasia
    - Adrenal functional tumor
    - Familial glucocorticoid resistance
  - Human chorionic gonadotropin-producing tumors:
    - Choriocarcinoma
  - Others:
    - Familial male-limited precocious puberty (FMPP)
    - Exogenous hormone exposure

(Box 1 and Flowchart 1). The incidence of precocious puberty is almost 10 times more common in girls than in boys.[29] Central causes of precocious puberty are more common than peripheral causes.

Precocious puberty can be further categorized as either isosexual (where there are secondary sexual characteristics that are appropriate for the child's sex) or heterosexual/contrasexual (where secondary sexual characteristics are contrary to the phenotypic sex, i.e., there is virilization in girls). CPP is always isosexual, whereas peripheral precocious puberty (PPP) can be isosexual or heterosexual.

Clinically, the progression from Tanner stage 1 to another in 6 months along with increase in height velocity makes it a progressive condition. It is recognized as early breast development in females and increased testicular volume (>4 mL) in boys. Follow-up of the early signs of sexual development is important. If these signs are stationary at follow-up, then it could be assigned as a normal variant.

Due to early sex steroid secretion, there is accelerated bone development with advanced bone age on X-ray. Thus, there is early tall stature, but due to early epiphyseal closure, there is reduced final adult height. Although there is early physical sexual maturation, psychosexual maturation is lagging, which places these children at risk of sexual abuse, alcohol abuse, smoking, illicit drug intake, teenage pregnancy, sexually transmitted infections, and behavioral abnormalities such as aggressive behavior and poor academic performance. Thus, counseling is important. Early puberty is also associated with a higher risk of diabetes, obesity, and breast cancer in later life.

Central precocious puberty: Gonadotropin-releasing hormone-dependent or CPP is caused by premature activation of the HPG axis, pulsatile secretion of GnRH, gonadotropin secretion, and subsequent activation of the gonads. In most cases of CPP, no cause can be found on magnetic resonance imaging (MRI) of central nervous system (CNS), thus termed idiopathic. The prevalence of CPP is around 1 in 5,000–10,000 children, with a higher prevalence of idiopathic CPP in girls. Several cerebral disorders can cause CPP such as congenital malformations, tumors, or trauma, and such organic causes of CPP are common in boys **(Box 1)**. Among CNS lesions, hypothalamic hamartomas are most commonly associated with CPP.

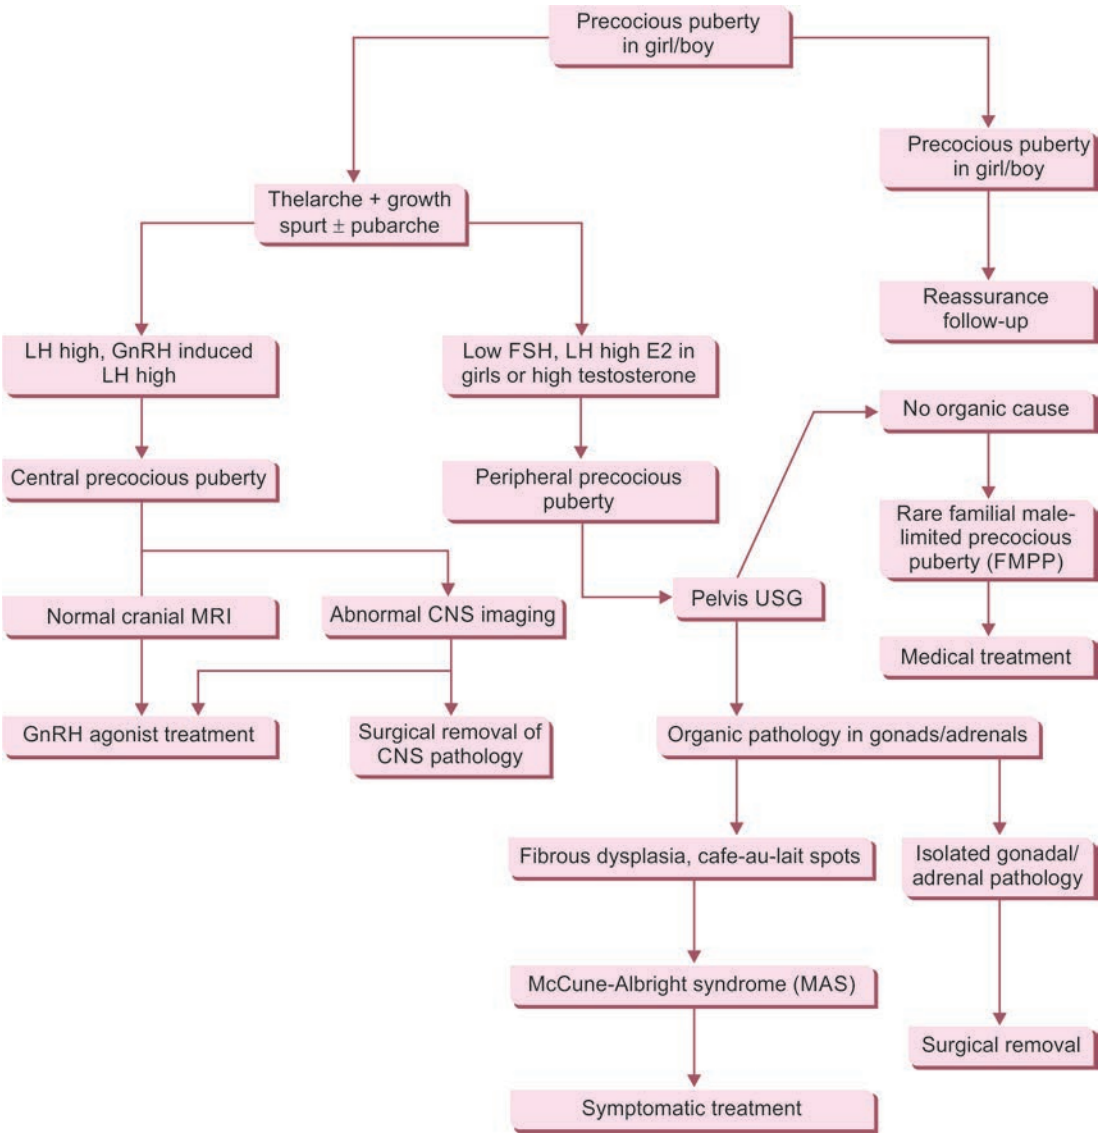
Among familial causes of CPP is an imprinting disorder due to loss of functional mutations in the *MKRN3* gene. The gene for MKRN3 is present on chromosome 15 near the gene for Prader–Willi syndrome. Only the paternal allele is expressed, the maternal MKRN3 allele is imprinted or silenced, and thus inheritance is from fathers.[30] The average age of presentation of CPP in children with this genetic defect is usually around 6–8 years.

A recent systematic review suggests that small fetuses at birth which includes intrauterine growth restriction (IUGR), small for gestational age (SGA), and low birth weight (LBW) babies are associated with early onset of menarche and puberty in girls.[31]

In primary hypothyroidism, thyroid-stimulating hormone (TSH) is elevated in addition to elevated gonadotropins. Prolactin may also be increased, and galactorrhea may also occur.

Approach to the patient: The evaluation of CPP should include imaging of the CNS (high-resolution MRI of cranium and pituitary) to search for organic causes

Flowchart 1: Precocious puberty.



(CNS: central nervous system: E2: estradiol; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone; MRI: magnetic resonance imaging; USG: ultrasonography)

(Box 2), particularly in girls <6 years of age, all boys, and in those with neurological symptoms. A funduscopic examination should be performed to check visual fields and to detect papilledema.

Initial workup should include baseline FSH, LH, and sex steroids (testosterone and E2). LH level <0.1 mIU/L by a sensitive assay indicates prepubertal stage. Elevated E2 with low LH may suggest an estrogen-secreting tumor.

Biochemical diagnostic criteria for CPP include **(Box 3)**:

- Baseline LH >0.3 mIU/mL—most reliable laboratory finding for CPP.
- A serum LH concentration >5 mIU/L after GnRH agonist administration (GnRH stimulation test) once a child is 3 years old (specificity of 77%, and sensitivity of 95%).[32]

Bone age estimation by X-ray of the left wrist as advanced bone age (>2 SD) than the chronological age points in favor of progressive CPP and requires further testing.

Pelvic ultrasound for dimensions of uterus and ovaries should be done. Progressive precocious puberty is likely with increase in uterine length >35 mm, thickening of endometrium, and change in shape of uterus from prepubertal to pearl-like shape **(Box 3)**.

Treatment: While some CNS lesions will need surgical treatment, the majority of remaining causes of true precocious puberty (i.e., idiopathic) respond to GnRH analogs including GnRH hamartomas.[33] GnRH analogs should be used only in progressive cases of idiopathic CPP when it presents before 6 years of age. In cases of nonprogressive CPP, only follow-up every 3–6 months is needed. Counseling is important to deal with associated psychosocial problems. Decrease in adult height is a major concern with CPP, and early treatment is successful in preserving final adult height. A recent meta-analysis suggests that GnRH agonist treatment

BOX 2: Evaluation of precocious puberty.

History:
- Age of starting, order, and development of pubertal stages
- Family history in parents and siblings: Timing of puberty in them
- Personal history of any neurological symptoms (headache, seizures, cognitive, and visual changes)
- Steroid exposure in food, drugs, or cosmetics
- Social history

Clinical examination:
- Growth velocity (cm/year)
- Body mass index
- Pubertal Tanner staging
- Neurological examination including visual fields and fundoscopy
- Skin lesions
- Abdominal examination
- Examination of external genitalia
- Signs of virilization

Biochemical investigations:
- Serum LH and FSH level
- GnRH stimulation test
- Estradiol/testosterone levels
- Adrenal steroids
- Adrenocorticotropic hormone stimulation test
- Free thyroxine and thyroid-stimulating hormone
- Serum prolactin levels

Imaging:
- Bone age—X-ray of left wrist joint, bone scans for skeletal survey
- Head magnetic resonance imaging (MRI)/computed tomography (CT)
- CT adrenals
- Pelvic ultrasound

(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)

BOX 3: Criteria to identify girls with progressive precocious puberty.

- Progression of pubertal staging in <3–6 months
- Growth velocity >6 cm/year
- Bone age advancement of >2 SD
- Uterine volume >2.0 mL, long diameter >35 mm, presence of thickened endometrium
- Ovarian volume >2–3 mL
- Peak LH >5.0 mIU/L at GnRH test, peak LH/FSH ratio >0.66
- Basal LH >0.3 mIU/mL, detectable basal estradiol

(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone; SD: standard deviation)

has significant improvement in final adult height in girls presenting early before 6 years with CPP, while it points toward the need for additional studies to prove the role of adding GH to this therapy.[34]

Long-acting GnRH analogs are the gold standard of treatment for patients with idiopathic CPP. GnRH analogs are utilized to suppress the HPG axis, pause pubertal development, retard bone maturation, and stop early fusion of growth plates, thus preserving height potential. Leuprolide acetate acts as an agonist at GnRH receptors. It causes prolonged desensitization and inhibits the release of FSH and LH from anterior pituitary, thus causing drastic reduction in output of sex steroids from gonads.

Leuprolide acetate depot is given at a starting dose of 3.75 mg intramuscularly or subcutaneously every 28 days in a child above 20 kg to continually suppress the gonadotropin output. Monitoring of pubertal stages, velocity of growth, and skeletal maturation is done during follow-up. Dose may be increased to 7.5 mg when there are progressive pubertal signs at subsequent visits.

Treatment with GnRH has been associated with a significant increase in final adult height of up to 5 cm, especially when it is initiated in cases presenting before the age of 6 years. The HPG axis restarts again within 3 months after discontinuation of the GnRH analog. Gonadal function is restored promptly after completion of treatment. GnRH analog treatment for CPP does not have negative impact on bone mineral density (BMD) when evaluation is done at least 2 years after stopping treatment.

Newer advances in the treatment of CPP include subdermal histrelin 50 mg implant for long-term treatment over 1 year.[35] Recently, extended-release leuprolide acetate injections of 11.25 mg used once in 3 months have been given in CPP, which has shown to clinically suppress signs of puberty, although it may not provide full biochemical suppression in CPP.[36]

Peripheral precocious puberty: In PPP, sex hormones are usually derived from the gonads or adrenals (autonomous production) or from exogenous sources (pharmacological or environmental). It occurs in girls with a frequency of about 1:400–1,000. Pelvic ultrasonography (USG) aids in confirming the source of the endogenous hormones. The hormone estrogen is secreted most commonly from ovarian follicular cysts. Other causes are gonadal and adrenal tumors **(Box 1)**. Overall, PPP is rarer than CPP.

Congenital or genetic causes include McCune–Albright syndrome (MAS), familial male-limited precocious puberty (FMPP), and congenital adrenal hyperplasia (CAH).

McCune–Albright syndrome is a rare genetic disorder that has a triad of café au lait spots, polyostotic fibrous dysplasia, and precocious puberty. MAS results from activating mutations in *GNAS1* gene, which is involved in intracellular cyclic adenosine monophosphate (cAMP) production, which is present in many tissues.[37] The café au lait spots in MAS have jagged borders known as "coast of marine" and do not cross the body's midline. Precocious puberty in girls with MAC is due to functioning ovarian cysts autonomously producing E2. Long bone X-rays usually depict fibrous dysplasia, although bone age may be normal at presentation. Fibrous dysplasia along with precocious puberty contributes to decreased adult stature.

Other endocrinopathies like hyperthyroidism, GH excess may also be associated. Diagnosis of MAC is primarily clinical. Laboratory tests show elevated E2 with low gonadotropins. Other rare causes are human chorionic gonadotropin (hCG)-secreting tumors and Leydig cell tumors in boys.

Familial male-limited precocious puberty or testotoxicosis in boys is due to activating mutations of LH receptor gene.[38] It is autosomal dominant sex-limited in inheritance. Presentation is with early pubertal development before the age of 4 years, along with rapid growth, minimal testicular enlargement, and pubic hair. This condition is heterogeneous and may present with varying degrees of severity. Laboratories reveal increased testosterone with suppressed gonadotropins. All the above-mentioned causes lead to isosexual or same sex precocious puberty.

In patients with PPP, the sexual characteristics can be appropriate for the child's sex (isosexual) or inappropriate, with virilization of girls or feminization of boys (contrasexual). CAH can result in heterosexual precocious puberty in girls.

Recently, it has been shown that girls with polycystic ovarian syndrome (PCOS) may show precocious puberty. The underlying pathology is ovarian hyperandrogenism and hyperinsulinemia. There may be LBW and IUGR in these girls, and so they are also at risk of metabolic syndrome in later life and need long-term follow-up.

Treatment: Treatment is directed toward the underlying causes. Surgical removal is advised for gonadal and adrenal tumors. Glucocorticoids are used for treatment of children with CAH. In primary hypothyroidism, thyroxine supplementation causes fast recovery.

McCune–Albright syndrome treatment is a challenge due to its heterogeneous nature of presentation. Cyproterone acetate (CPA) and medroxyprogesterone acetate (MPA) are two agents most commonly used in medical management of vaginal bleeding. A combination of anastrozole with leuprorelin has shown to improve predicted adult height (PAH) in girls with MAS.[39]

Various other agents like third-generation aromatase inhibitors like letrozole and selective estrogen receptor modulators (SERMs) like tamoxifen have been tried in MAS to block the estrogen synthesis with limited long-term benefits. Spironolactone (a weak androgen antagonist), testolactone (aromatase inhibitor), and ketoconazole have been shown to normalize growth rate and bone maturation and to improve PAH in boys with FMPP when used over a long period of time. Orthopedic treatment is required for bon deformities.

Delayed Puberty

Delayed puberty is the absence of secondary sexual characteristics by age 13 years in girls (absent breast development) or by age 14 years in boys (no testicular enlargement to at least 4 mL or 2.5 cm in length). In girls with some pubertal changes, the absence of menarche by 15 years demands evaluation. The prevalence of delayed puberty is estimated to be around 3% and is more common in boys. Constitutional delay of puberty (CDP) is the most common cause of delayed puberty (60%) when healthy teenagers spontaneously develop puberty after the upper age limit.

BOX 4: Delayed puberty.

Constitutional delay:
With positive family history, short stature and normal fertility:
- Chronic disease
- Malnutrition
- Anorexia nervosa
- Type 1 diabetes mellitus
- Hypothyroidism

Hypergonadotropic hypogonadism:
- Premature ovarian failure—oophoritis
- Idiopathic testicular failure—orchitis
- Anorchia
- Chemotherapy for malignancy
- Turner syndrome
- Klinefelter syndrome

Hypogonadotropic hypogonadism:
Hypothalamic and pituitary causes of primary amenorrhea:
Inherited:
- Kallmann syndrome (with anosmia)
- Laurence–Moon–Biedl syndrome

Acquired:
- Anorexia nervosa
- Severe underweight
- Intense exercise
- Intracranial tumors, e.g., craniopharyngioma, prolactinoma
- Head injury
- Central nervous system (CNS) infections, e.g., encephalitis, meningitis
- Radiotherapy

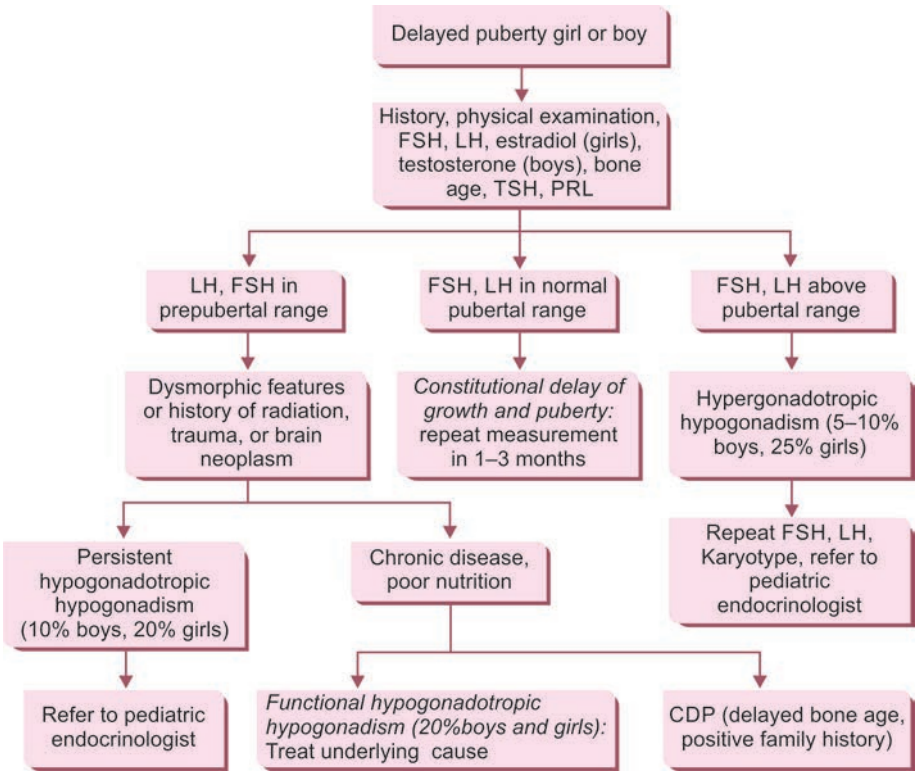
Normogonadotropic eugonadism:
Uterine causes:
- Müllerian agenesis
- Testicular feminization syndrome
- Imperforate hymen
- Polycystic ovarian syndrome

The absence or incomplete development of secondary sexual characteristics by age 18 years in both sexes is classified as hypogonadism **(Box 4)**.

Delay in puberty can have major psychological impact both on the individual and their parents. Concerns that need to be addressed are any associated pathology, short final adult height, decision for treatment and its duration, and long-term impact on fertility.

Approach to the patient: Family history of delay in pubertal milestones in older siblings and parents, anosmia points toward familial causes. Personal history of chronic medical illness (fatigue, pain, abnormal stools) suggests underlying metabolic disorder (inflammatory bowel disease), endocrine, or autoimmune disorders.

Flowchart 2: Delayed puberty.



(CDP: constitutional delay of puberty; FSH: follicle-stimulating hormone; LH: luteinizing hormone; PRL: prolactin; TSH: thyroid-stimulating hormone)

Physical examination may show the presence of small penis and/or undescended testis, which go more in favor of congenital hypogonadotropic hypogonadism (CHH). Other features found in syndromic forms of CHH, such as Kallmann syndrome, are anosmia, cleft lip, cleft palate, sensorineural deafness, eunuchoid body proportions (arm span exceeds height by ≥5 cm), and coloboma of eyes. In girls, features of Turner syndrome may be seen, such as short height, webbed neck, shield chest, and cubitus valgus.

Tests such as X-ray of wrist joints may show delayed bone age which goes in favor of CDP.

Basal levels of FSH, LH, and sex steroids are low in CDP and HH, while FSH and LH levels are high in gonadal failure **(Flowchart 2)**. TSH and prolactin levels also need to be done.

Gonadotropin-releasing hormone-induced maximal LH levels (cutoff 4.3 mIU/L) are more in CDP than CHH.[40] Testicular size >2.5 cm indicates the child onset of puberty. Lower testicular volumes (<1.1 mL) are more associated with CHH.[40]

Apart from this, growth velocity should be charted. A slow growth velocity of <3 cm/year goes more in favor of CHH than a functional delay in boys but not so much in girls.[40] Differentiating between CDP and CHH is challenging. Newer investigations include 36-hour LHRH tests, anti-Müllerian hormone, and inhibin B, but they still require further evaluation.

Pelvic USG may reveal the absence of uterus. MRI is helpful for diagnosing dysgenetic or absent gonads and intracranial pathologies.

Karyotype will reveal chromosomal disorders such as Turner syndrome and Klinefelter syndrome. Genetic analysis may be done when karyotype is normal to diagnose rare genetic causes of HH.

Hypergonadotropic hypogonadism is more common in girls of which Turner syndrome is the prototype. Turner syndrome (45X0) is a chromosomal disorder with an incidence of 1:2,500 in live-born girls caused by the loss of an entire X chromosome, loss of a portion of the X chromosome, or complex rearrangements of the X chromosome.[41] Prenatal diagnosis can be done by the combined test in first trimester. A positive screening test can be confirmed by diagnostic tests such as chorionic villus sampling (CVS) in the first trimester and amniocentesis in the second trimester. A karyotype confirms the diagnosis. Postnatally, the girls show classical stigmata of short stature, ovarian failure secondary to gonadal dysgenesis, cardiac anomalies, renal anomalies, skeletal malformations, and autoimmune disorders. Treatment includes GH, estrogen, and progesterone for increase in height and induction of puberty, respectively.[42] Oocyte donation and IVF are indicated for the management of infertility, with caution as coarctation of aorta and other structural cardiac defects, along with many systemic disorders, place the patient in a high-risk obstetric category.

Thus, surrogacy is a better option.[43] Klinefelter syndrome (47XXY) is the most common cause of hypergonadotropic hypogonadism in males.

Premature ovarian insufficiency (POI) is the loss of ovarian activity before the age of 40 years. Although POI in adolescents traditionally is associated with primary amenorrhea and delayed puberty, a proportion of girls will present with irregular bleeding that may be mistaken for expected menstrual disturbances of puberty, thus delaying the diagnosis.[44]

Congenital hypogonadotropic hypogonadism occurs due to congenital deficiency of production of GnRH hormone. When it occurs due to abnormal embryonic migration of GnRH neurons from olfactory placode to forebrain and associated with deficient smell perception, hyposmia or anosmia, it is known as Kallmann syndrome. Kallmann syndrome is four times more common in boys. Anosmia suggests strongly a genetic cause, such as a *KAL1, KAL2, KAL3, NELF,* and *CHD7* gene mutation (all associated with different forms of Kallmann syndrome).[45] HH is considered idiopathic (IHH) when there is an isolated GnRH secretion deficiency in individuals over 18 years of age. Other genetic causes of HH could be due to mutations in *KISS1R*.

Treatment: Correctable causes must be addressed first, such as thyroid hormone therapy for hypothyroidism, dopamine agonist therapy for hyperprolactinemia, and excision of a craniopharyngioma or other operable central lesion. During infancy, cryptorchidism must be surgically corrected at 6–12 months.

A healthy lifestyle should be adopted to maintain normal body weight, recommended daily intake of calcium, vitamin D, and vitamin A.

In girls with Turner syndrome, GH therapy should be initiated early around 4 years of age.[46] Recombinant GH (rGH) is administered at a dose of 0.35–0.375 mg/kg/week given by daily subcutaneous injections at night.[47] Side effects of rGH are glucose intolerance, pancreatitis, slipped capital femoral epiphysis, and intracranial hypertension. Monitoring is done by measuring serum IGF-1 levels yearly with an aim to keep its level below 2 SD above the mean for age. Those girls who are older than 10 years with a decreased PAH with rGH therapy may be treated with additional oxandrolone, an anabolic steroid, at a dose of 0.03–0.05 mg/kg/day.[48] Virilization, enlargement of clitoris, and acne are its side effects. Puberty should be induced with low-dose transdermal 17β-E2 (TDE) at a dose of 3–7 μg/day at 11–12 years of age. Cyclic progestins should be started after at least 2 years of estrogen or when breakthrough bleeding occurs. Hormone replacement therapy (HRT) should be given throughout the reproductive life.

In gonadal failure, long-term sex hormone replacement is the only option, and gamete donation is for addressing the issue of fertility.

In girls with gonadal failure, estrogen is used to stimulate epiphyseal growth. Low-dose conjugated estrogens (0.3 mg) or E2 (0.5 mg) administered daily are effective in hypogonadal individuals.

In practice for delayed puberty, treatment with sex hormone replacement is often initiated in girls older than 13 years and boys older than 14 years as it causes significant psychological stress and low self-esteem. Goal of treatment is induction of virilization or estrogenization, promotion of growth, bone health, libido, psychological, and emotional well-being. In some cases (10–20%), pubertal onset is reported spontaneously, commonly by increase in testicular volume after the initiation of sex steroid treatment which indicates reversal and thus CDP. When therapy is discontinued, pubertal development continues in CDP. Monthly follow-up is needed. As soon as bone age and chronological age match, hormone intake should be stopped.

In CHH, sex steroids may be used for induction and maintenance of puberty as it is cheaper compared to gonadotropins. Gonadotropins result in testicular growth and spermatogenesis and their use is thus more physiological. hCG may be given at 1,500–2,000 IU intramuscularly at twice weekly intervals. hCG is costly and requires more frequent doses as compared to steroids. Serum testosterone levels are done to monitor response and preferably kept in the low normal range. Choice of treatment may be guided by physician and patient preference as well as cost.

Sex hormone replacement is the main available treatment for delayed puberty. Oral testosterone (undecanoate) has a short half-life and thus is not used for pubertal induction. In boys, long-acting injectable testosterone is started at low doses (e.g., 50–100 mg testosterone enanthate or cypionate intramuscularly every month) for 3–6 months. This is done to mimic the natural progression of puberty by gradually increasing the circulating testosterone levels. Monitoring is done by measuring serum testosterone levels 1 week after the injection to maintain testosterone levels in the mid-normal range.[49] In girls, overnight transdermal E2 (6.25 μg) for 3–6 months is initiated. Dose escalation should be individualized. Absence of pubertal progression within 3–6 months is an indication for referral to pediatric endocrinologist.

In CHH, genetic counseling is also indicated. When patients with CHH reach adulthood and fertility is desired, then treatment with gonadotropins is indicated.

GROWTH PROBLEMS IN NORMAL ADOLESCENTS

Growth in the height of humans can be divided into four phases:

1. Intrauterine—governed by maternal factors, placental factors, metabolic factors, genetic, and nutritional factors

2. Infancy—first 2–3 years are governed by nutritional factors and contribute to 30–35 cm in length
3. Childhood phase—governed by GH and thyroid hormone with a rate of 5–7 cm/year
4. Pubertal phase—governed by GH, sex steroids, and thyroid hormone. Peak height velocity is a penultimate part of pubertal growth spurt, which is around 8–14 cm/year.

   Predicted adult height in a prepubertal child can be assessed by taking an X-ray of the left wrist to know the bone age. Bayley–Pinneau tables, along with Greulich–Pyle atlas, can aid to predict the adult height.

Short Stature

Idiopathic short stature is defined as height falling <2 SDs below mean height for children of the same age and gender with no identifiable cause including heredity.

Treatment

- Support and reassurance
- A systematic review analyzing the use of rGH showed an increase in final height up to 3–7 cm with no serious adverse effects.

A recent meta-analysis showed that the use of rGH in children and adolescents showed an increase in the height of up to 4 cm.[50] Drawbacks are the response to therapy with rGH is highly variable, rGH treatment is very costly, has to be injected daily subcutaneously, and the increment in final height is small and modest.

Aromatase inhibitors prevent the conversion of testosterone to E2 and thus may aid in halting the epiphyseal closure brought about by E2.

Use of aromatase inhibitors in prepubertal boys with idiopathic short stature was studied in a systematic review which stated that it may be of some benefit, although 45% of boys reported with mild abnormalities of vertebrae as a side effect of letrozole.[51]

Tall Stature

Idiopathic tall stature is defined as height falling >2 SDs above the mean height for children of the same age and gender with no identifiable cause.

For boys, parents rarely seek treatment. Parents of girls may seek treatment when the PAH is >6 feet or >2.5 SDs above the mean.

Treatment

The most accepted way of treatment is inducing puberty early by utilizing testosterone in boys and estrogen in girls.

Treatment may start as early as 8 or 9 years of age and continue till epiphyses are fused.

Ethinyl E2, 50–100 μg, is started in girls. High doses of synthetic estrogens—ethinyl E2 has adverse effects such as weight gain, headache, nausea, vomiting, hypertension, deep vein thrombosis (DVT), risk of melanoma, migraine, and coagulation defects. Long-term risks on future fertility and risks of carcinoma breast are still not known. If such high doses are producing unpleasant symptoms, then the dose can be reduced or switched to 0.625–1.25 mg conjugated estrogens or 1–2 mg E2 (17β-E2).

In boys, testosterone enanthate 500 mg by intramuscular route is given at 2 weekly intervals.

Surgical method of height reduction by pediatric orthopedic surgery of the growth plates of femur, tibia, or fibula is used rarely.[52]

CONCLUSION

Puberty is a essential stage of life in humans. There can be aberrations and deviations from normal in some individuals. Timely identification and appropriate treatment can pave the way toward a normal transition to adulthood.

KEY POINTS

- Activation of the HPG axis is essential for puberty to develop normally.
- Kisspeptin system plays an important role in pubertal development.
- Central precocious puberty is treatable by GnRH analogs in idiopathic cases.
- In delayed puberty sex hormone replacement may be tried in idiopathic cases.

CHAPTER 10

Amenorrhea

Abha Majumdar, Neeti Tiwari

INTRODUCTION

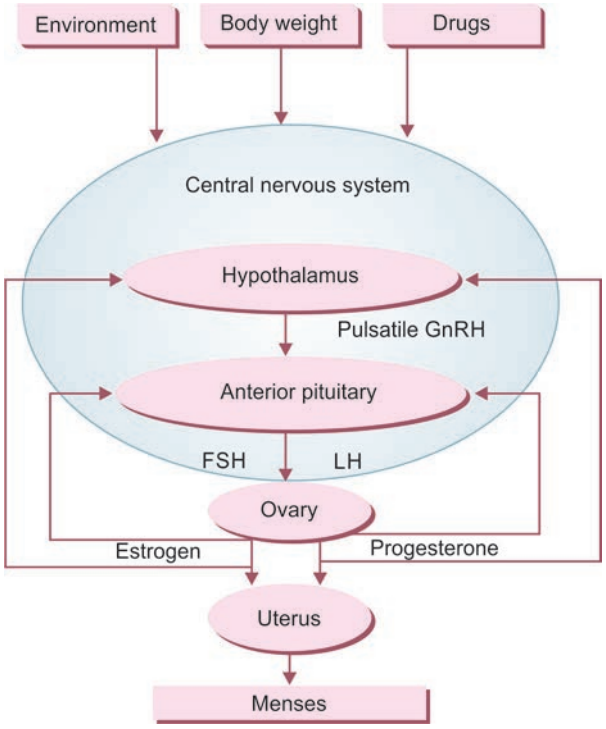
Amenorrhea is the absence of menses in a young girl till a particular age or in a woman of reproductive age for a defined period. This is categorized into two types: Primary and secondary amenorrhea. Primary amenorrhea is diagnosed if a girl fails to menstruate by the age of 15 years in the presence of secondary sexual characteristics or by the age of 13 years in absence of secondary sexual characteristics.[1] Secondary amenorrhea, on the other hand, is defined as cessation of menses in otherwise regularly menstruating women for a length of time equivalent to her three menstrual cycles or for 6 months.[2]

PHYSIOLOGY OF MENSTRUATION (FLOWCHART 1)

The normal menstrual flow requires a patent outflow tract between internal genital organs and perineum, i.e., patency and continuity of the uterine cavity with the cervical canal and vaginal canal to the perineal area. To achieve menstruation, the uterine cavity has to be lined with endometrium which must develop under the influence of steroidal hormones secreted by the ovary. These steroidal hormones are estrogen and progesterone; estrogen causes the proliferation of the endometrium and primes it to the effect of progesterone which in turn leads to secretory changes within this estrogen-primed endometrium. Withdrawal of progesterone secretion stops to support endometrial growth and brings about shedding of this carefully designed endometrium, thus resulting in menstruation.

The ovarian steroid production is orchestrated by the higher centers of the brain comprising the pituitary gland and the hypothalamus. The principal pituitary hormones are follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secreted from its anterior lobe, which influence cyclical ovarian steroid production. Hypothalamus regulates the pituitary by secreting pulsatile gonadotropin-releasing hormone (GnRH), which reaches the pituitary via the portal vessels of the pituitary stalk, and thus a hypothalamic–pituitary–ovarian (HPO) axis is established. Environmental factors such as stress, excessive weight loss or gain, and certain drugs can influence the menstrual pattern through the hypothalamus and central nervous system. The ovarian hormones estrogen and progesterone also provide feedback signals to the anterior pituitary and hypothalamus to control their secretions.

Flowchart 1: Hypothalamo–pituitary–ovarian axis.



(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)

CLASSIFICATION OF AMENORRHEA (ACCORDING TO THE ETIOLOGY LIST OF CONDITIONS) (BOX 1)

Menstruation is regulated by a complex interaction of the hormonal signals and disturbance at any level can result in

BOX 1: Classification of amenorrhea.

Anatomic or end-organ defects
- Müllerian agenesis
- Complete AIS
- Endometrial hypoplasia or aplasia
- Cervical agenesis
- Transverse vaginal septum
- Imperforate hymen
- Intrauterine synechiae (Asherman's syndrome)

Primary ovarian failure
- *Abnormal karyotype:*
  - 45, XO Turner's or mosaic Turner's syndrome (gonadal agenesis)
  - 46XY AIS and Swyer syndrome (gonadal dysgenesis)
- *Normal karyotype:*
  - 46XX pure gonadal agenesis
- Metabolic disorder: Galactosemia
- Enzymatic deficiency (17α-hydroxylase, 17,20-lyase, aromatase)
- Premature ovarian failure—injury or idiopathic or resistant ovary
- Fragile X syndrome

Pituitary causes
- Tumors—prolactinoma and pituitary adenoma
- Hyperprolactinemia—idiopathic and drug induced
- Necrosis—Sheehan's syndrome or panhypopituitarism
- Space-occupying lesions—empty sella and arterial aneurysm
- Mutation of FSH or LH receptor
- Autoimmune disease

Hypothalamic causes
- Dysfunctional—stress, exercise, and nutrition related
- Isolated gonadotropin deficiency—Kallmann's syndrome and hypogonadotropic hypogonadism
- Infections (tuberculosis, syphilis, and encephalitis)
- Inflammatory or infiltrative—sarcoidosis and hemochromatosis
- Chronic debilitating diseases
- Tumors—craniopharyngioma and hamartoma

Other endocrine gland disorders
- Adrenal—adult-onset adrenal hyperplasia and Cushing's syndrome
- Thyroid—hypothyroidism and hyperthyroidism
- Ovarian tumors—granulosa—theca cell tumor, Brenner tumor, cystic teratomas
- Multifactorial—polycystic ovary syndrome

(AIS: androgen insensitivity syndrome; FSH: follicle-stimulating hormone; LH: luteinizing hormone)

amenorrhea. There are three important areas involved in the causation of amenorrhea. Firstly, it could be the passage to reveal menstruation, i.e., the uterovaginal canal may be absent or obstructed; secondly, the failure of ovarian steroid production which is the endocrine organ responsible for making the endometrial layer to be shed during menstruation, and lastly, there could be reduced or absent stimulus from the anterior pituitary or the hypothalamus to the ovary owing to dysfunction of the HPO axis resulting in amenorrhea. In women presenting with secondary amenorrhea, 66% are either due to hypothalamic–pituitary causes or due to polycystic ovarian syndrome (PCOS), which is multifactorial in origin with dysfunction at all three levels of the HPO axis. Hyperprolactinemia and ovarian failure are further responsible for 13 and 12% of cases of secondary amenorrhea, respectively. In the remaining cases who present as secondary amenorrhea, end-organ failure is responsible for 7% of cases whereas 2% are due to hyperandrogenic states such as ovarian tumor or nonclassic congenital adrenal hyperplasia (CAH).[3]

In cases presenting with primary amenorrhea, gonadal agenesis and dysgenesis leading to primary ovarian failure alone account for 40% of cases. Out of the remaining cases of primary amenorrhea, 22% of the girls have normal secondary sex characteristics such as adequate breast development but have end-organ pathologies. In this group, Müllerian agenesis is seen in 10% of cases, androgen insensitivity syndrome (AIS) in 9%, and other obstructive pathologies in 3%. Hypothalamo-pituitary causes are responsible for approximately 20% of cases with primary amenorrhea. The remaining 18% of the girls have constitutional delay in attaining menarche.[3]

EVALUATION OF AMENORRHEA

In many instances, diagnosis can be clinched based on detailed history and physical examination only. Hence, it is important to keep in mind the common causes while evaluating the patient for the first time.

HISTORY AND EXAMINATION

Primary Amenorrhea

The history of pubertal development is important in terms of breasts, axillary, and pubic hair growth, the absence of which suggests primary ovarian or pituitary failure. If the patient is remarkably short as compared to other family members, Turner's syndrome should be considered. It is pertinent to seek the history of significant stress or change in diet, exercise, and weight to rule out hypothalamo-pituitary causes. The history of severe headaches, fatigue, and visual field defects also points toward hypothalamo-pituitary tumors. If secondary sex characteristics are well developed along with symptoms and signs of hirsutism or virilization, one needs to consider PCOS, CAH, and androgen-secreting ovarian or adrenal tumors as one of the underlying causes. The presence of the Y chromosome, absent uterus, or obstruction of menstrual flow generally presents with adequate development of secondary sexual characteristics. It is worthwhile to take detailed drug history as many drugs such as antidepressants and antipsychotics lead to hyperprolactinemia which can also result in primary amenorrhea. Constitutional delay is a diagnosis of exclusion and is generally accompanied by a family history of delayed puberty.

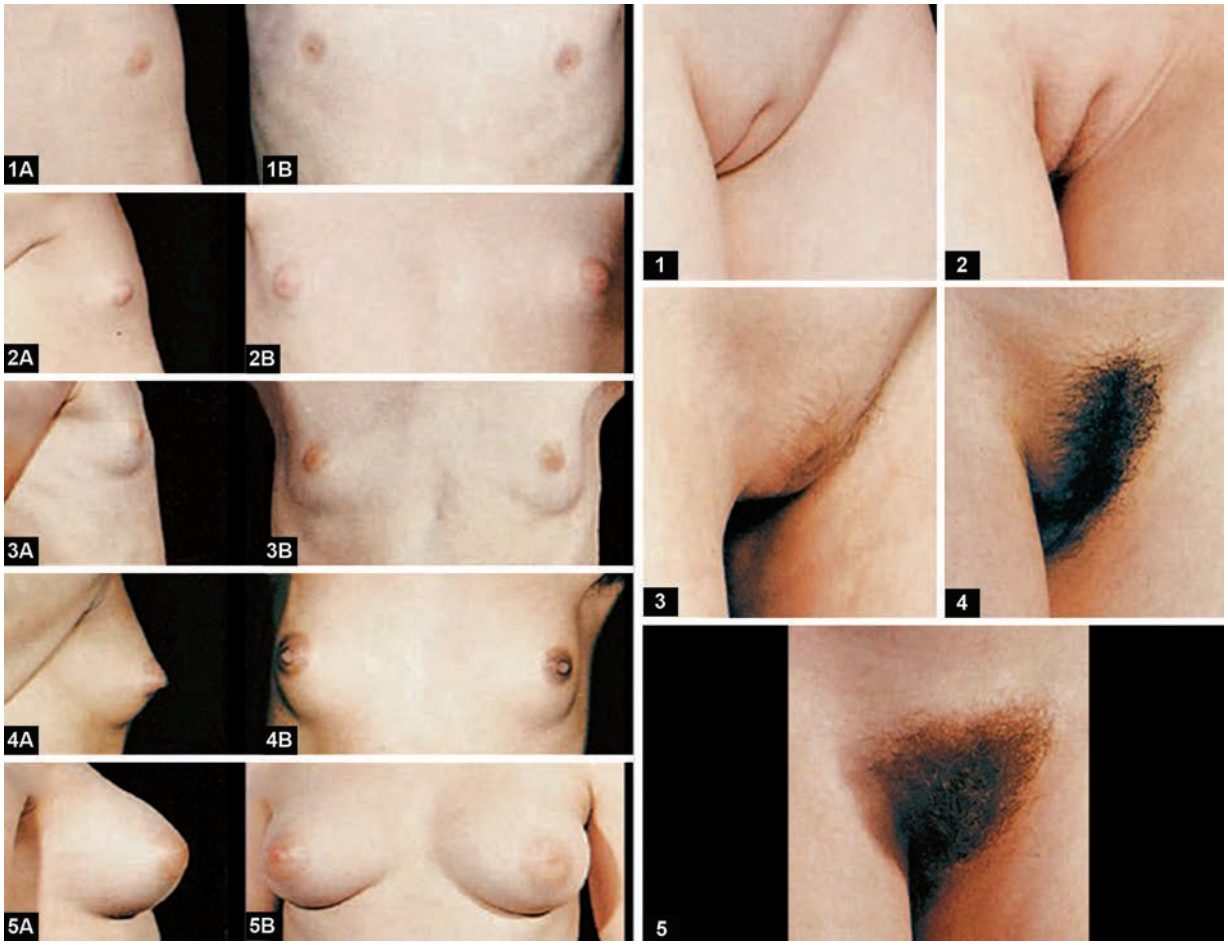


Fig. 1: Tanner stages of pubertal development in female.
Source: Reprinted with permission from Roede MJ, van Wieringen JC. Growth diagrams 1980: Netherlands third nationwide survey. Tijdschr Soc Gezondheidsz. 1985;63:1-34.

Examination of a patient with primary amenorrhea should always be done in the presence of mother or guardian, especially if she is a minor. Evaluation of pubertal changes, i.e., height, weight, and growth charting and Tanner staging of breasts and pubic hair is important in a girl with primary amenorrhea **(Fig. 1)**. We need to carefully look for signs of hirsutism, acne, striae, and acanthosis nigricans. A patient with Turner's syndrome can present with typical stigmata on examination, i.e., short height, webbed neck, low hairline, shield chest, and widely spaced nipples or may have a normal physical appearance. A gentle pelvic examination is required to establish patency of the outflow tract, i.e., hymenal opening, depth of vagina, and the presence and size of cervix and uterus. Fifteen percent of the patients with primary amenorrhea have blind or absent vagina. Clitoromegaly may be found in patients with virilizing disorders such as CAH.

Secondary Amenorrhea

History of significant change in diet and exercise, loss of weight, acute stress, or chronic illness suggests functional hypothalamic amenorrhea. On the other hand, severe headaches, visual disturbances, polyuria, and polydipsia can be due to hypothalamic or pituitary tumors. History of severe obstetric hemorrhage followed by failure of lactation and secondary amenorrhea implies the possibility of Sheehan's syndrome. History of repeated curettage after delivery or abortion or a surgical procedure such as myomectomy or even uterine artery embolization for conservative management of fibroids may be followed by amenorrhea with the development of Asherman's syndrome.[4] This syndrome leads to the destruction of endometrial lining, which can also occur after genital Koch's or long-standing endometritis. Significant weight gain with acne and hirsutism is a feature of PCOS, whereas the sudden onset of virilization with deepening of voice indicates adrenal or androgen-secreting ovarian tumor. Symptoms of estrogen deficiency, e.g., hot flashes, vaginal dryness, and decreased libido along with secondary amenorrhea, could be present due to premature ovarian failure (POF). History of milk discharge from breast makes it pertinent to obtain a drug intake history as mentioned before.

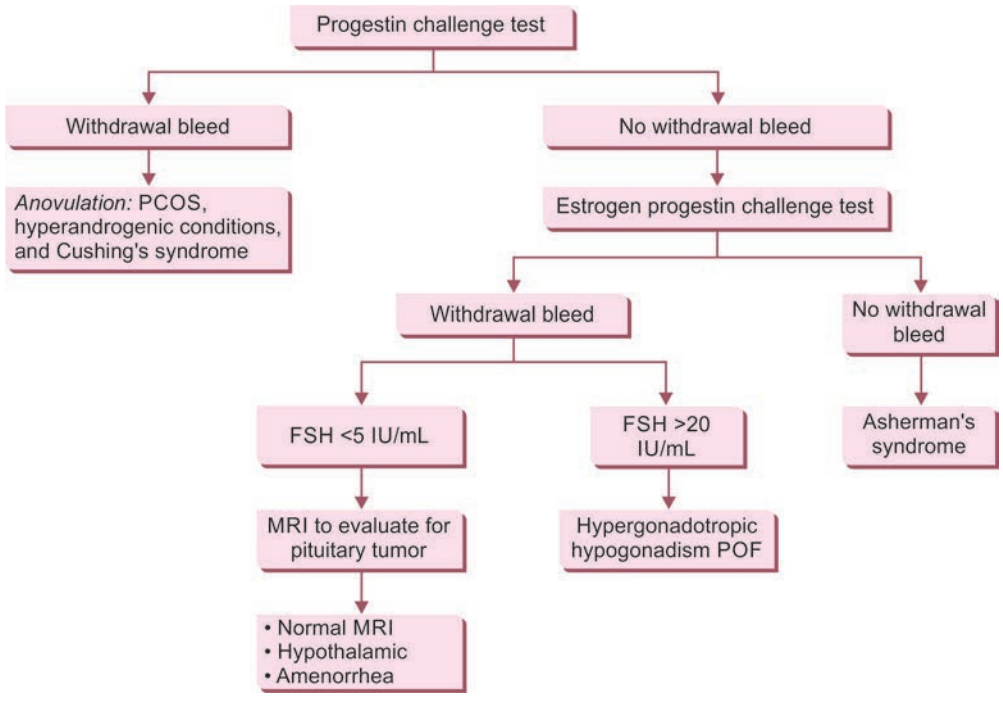
While examining a patient with amenorrhea apart from making a note of weight and body mass index, one must also

look for signs of hirsutism, acne, acanthosis nigricans, and striae. Any thyroid enlargement or discharge from breasts should be noted. Pelvic examination is done to look for the presence of vaginal dryness, size of the uterus, and adnexal masses.

INVESTIGATIONS FOR PRIMARY AND SECONDARY AMENORRHEA

- Rule out pregnancy
- Pelvic ultrasound: 2D pelvic ultrasound is done to look for the presence and size of the uterus, endometrial thickness, ovarian volume, and antral follicle count and to rule out adnexal masses or tumors
- Serum prolactin and thyroid profile
- *Hormonal tests:* Serum FSH, LH, estradiol (E_2), and anti-Müllerian hormone (AMH).
  - Low serum FSH, LH, and E_2 levels with normal or low AMH indicate hypogonadotropic hypogonadism and one must look for hypothalamic and pituitary causes in these women.
  - Normal FSH and E_2 with normal or high LH and AMH are generally associated with PCOS and all three hormones in the normal range are mostly associated with obstructive amenorrhea.
  - High serum levels of FSH and LH with low serum E_2 imply ovarian failure.
- Serum prolactin two and a half times higher than the normal limit on two occasions without any history of drug intake may be considered as a cause for oligomenorrhea or amenorrhea.
- Thyroid profile which includes the estimation of T3, T4, and thyroid-stimulating hormone (TSH) should be done for women with amenorrhea as 40% of patients with hypothyroidism can have simultaneous hyperprolactinemia. Low serum level of T4 in primary hypothyroidism leads to increased secretion of thyrotropin-releasing hormone (TRH). This results in increased stimulation of both thyrotropes and lactotrophs, thereby increasing both TSH and prolactin.[5] This can manifest as galactorrhea and/or as amenorrhea.
- *Progestin challenge test* **(Flowchart 2)**: This test is a simple way to assess ovarian function. If a patient gets withdrawal bleeding after progestin treatment, it implies normal circulating estrogen levels and a patent outflow tract. For conducting this test, tablet medroxyprogesterone acetate (MPA) is given in doses of 10 mg once a day, or sustained release micronized progesterone 300 mg orally once a day for 5 days, or a single dose of 200 mg injectable progesterone in oil is given to initiate a withdrawal bleed which occurs usually within 7 days (range of 5–10 days) after the conclusion of progestin treatment.[5] If very little bleeding or spotting occurs, it generally indicates marginal levels of circulating estrogen. Endometrial thickness on ultrasound correlates well with estrogen levels as well as with the progestin challenge test; endometrial thickness of 6 mm or more predicts withdrawal bleeding with 95% accuracy. It is important to note that there is a subset of patients who may not have withdrawal bleeding after progestin treatment despite adequate circulating estrogen levels and endometrial thickness; this is due

Flowchart 2: Progestin challenge test.



(FSH: follicle-stimulating hormone; MRI: magnetic resonance imaging; PCOS: polycystic ovary syndrome; POF: premature ovarian failure)

to decidualization of endometrium in response to high androgen levels as sometimes seen in women with PCOS with hyperandrogenemia.[6]

- *Magnetic resonance imaging (MRI) of head:* In patients with hypogonadotropic hypogonadism where there is suspicion of hypothalamic or pituitary masses, an MRI of the head is mandatory.
- *Chromosomal analysis:* Karyotype helps to clinch the diagnosis in patients with primary amenorrhea with chromosomal abnormalities; deletion of one X chromosome is associated with Turner's syndrome, (46, XO) or the presence of Y chromosome in a female phenotype is either due to AIS, also called testicular feminization syndrome, or due to Swyer syndrome. Chromosomal analysis is also desirable in patients of secondary amenorrhea with POF to rule out mosaic variants of Turner's syndrome.

EVALUATION OF SPECIFIC CONDITIONS IN AMENORRHEA

- *Primary amenorrhea with blind vagina* **(Flowchart 3)**: The presence of cyclical pain may suggest the possibility of imperforate hymen or transverse vaginal septum which can be diagnosed by local vaginal examination as well as confirmed by ultrasound examination by seeing collected blood in the vagina. If a girl with blind vagina is asymptomatic and has scant pubic hair consider the possibility of AIS, whereas if she has normal secondary sex characteristics the diagnosis of Müllerian agenesis is to be considered [also known as Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome]. Both AIS and MRKH syndromes are characterized by congenital absence of uterus and vagina. A karyotype will help to finally differentiate between the two as it will be normal 46XX in Müllerian agenesis while in AIS it will be 46XY.
- *Secondary amenorrhea with hyperandrogenism:* Women presenting with the absence of menses with clinical symptoms and signs of raised circulating androgen levels, e.g., acne, hirsutism, male pattern baldness, and in severe cases signs of virilization which include features of clitoromegaly, can be attributed to one of the following probable causes:
  - *Ovarian:* PCOS and ovarian neoplasm
  - *Adrenal:* Late-onset CAH, Cushing's syndrome, and adrenal neoplasm.

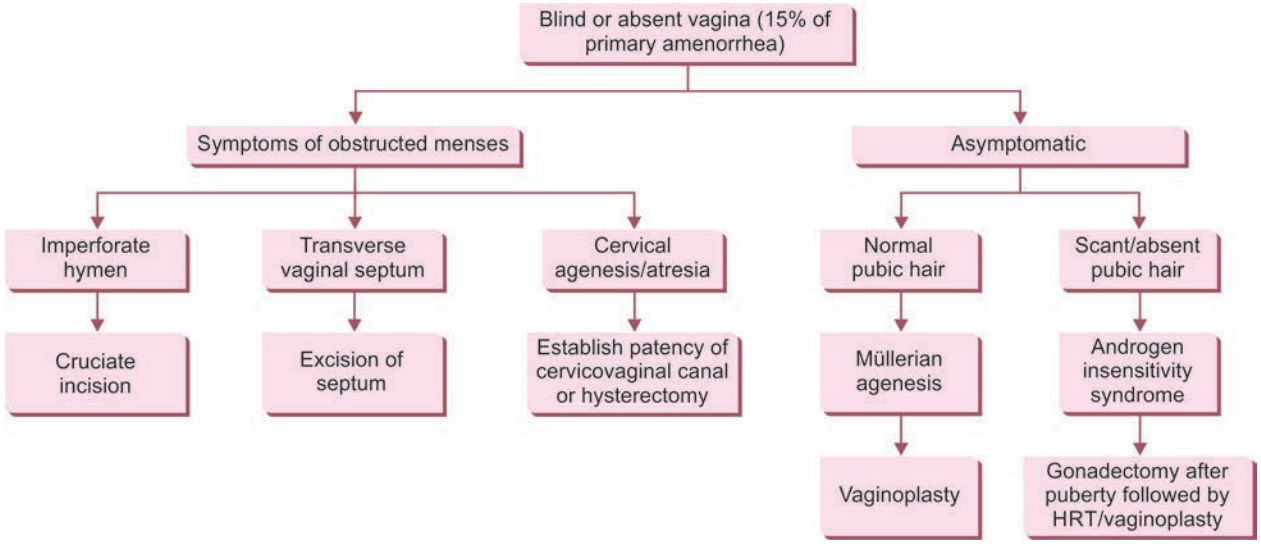
To identify the underlying cause, one needs to assess serum testosterone, serum dehydroepiandrosterone sulfate (DHEA-S), and serum 17α-hydroxyprogesterone and then interpret the results to arrive at a diagnosis according to **Table 1**.

TABLE 1: Evaluation of secondary amenorrhea and hyperandrogenism.

Hormone	*Level*	*Indication*
Testosterone	≤200 ng/dL	PCOS
	>200 ng/dL	Evaluate for adrenal or ovarian tumor
DHEA-S	≤700 µg/dL	PCOS
	≤700 µg/dL	Evaluate for adrenal or ovarian tumor
17α-Hydroxypro-gesterone	>200 ng/dL	Consider ACTH stimulation test to diagnose CAH

(ACTH: adrenocorticotropic hormone; CAH: congenital adrenal hyperplasia; DHEA-S: dehydroepiandrosterone sulfate; PCOS: polycystic ovarian syndrome)

Flowchart 3: Evaluation of blind or absent vagina.



(HRT: hormone replacement therapy)

- *Secondary amenorrhea with POF:* The diagnosis of POF is made if a persistently high serum FSH with low E_2 is seen in women with secondary amenorrhea. The history of surgical intervention on ovaries, e.g., cystectomy or ovarian irradiation or chemotherapy, should be looked for in such cases. POF can also be encountered in chronic smokers; women with obesity; carriers of hepatitis B, C, or HIV; or those who have had chronic pelvic inflammatory diseases and genial tuberculosis. A family history of premature menopause should be sought for. In absence of these, it is important to identify the underlying pathology for which the following tests are recommended:
  - *Karyotype:* Turner mosaics can have normal cycles for a few years before they get amenorrheic.
  - *FMR 1 gene mutation:* 10–20% of carriers of Fragile X syndrome have POF.[7] Screening for Fragile X syndrome should always be considered in women with POF with a family history of premature menopause.
  - *Screening for autoimmune disorders:* POF may be associated with autoimmune disorders such as Addison's disease, autoimmune thyroid disease, and type 1 diabetes. All patients with POF should have an oral glucose tolerance test, thyroid profile, and anti-thyroid peroxidase antibodies. If symptoms warrant, Addison's disease should be ruled out with adrenal antibody titer (titer <1:10 is normal) or adrenocorticotropic hormone stimulation test.[8]

Galactosemia is a rare, inherited autosomal recessive disorder associated with POF. The deficiency of galactose-1-uridyl transferase leads to the accumulation of toxic metabolites, which can lead to reduced initial oocyte pool, increased follicular atresia during maturation, and perhaps reduced maturation of primordial follicles. These girls usually have impaired growth and development and can present as primary amenorrhea, secondary amenorrhea, or oligomenorrhea.[9]

- *Hypogonadotropic hypogonadism:* Both primary and secondary amenorrhea can be a manifestation of hypogonadotropic hypogonadism which is diagnosed by low serum FSH, LH, and estradiol levels. It is pertinent to look for an underlying cause to correct and treat or reverse the disorder effectively. The following conditions should be looked for:
  - *Severe weight loss:* Significant weight loss due to severe exercise, extreme nutritional deficiency or restriction, anorexia nervosa, bulimia, or wasting due to chronic illnesses can lead to an abnormal pattern of GnRH secretion causing disruption of the HPO axis and hence amenorrhea. This response of higher centers in the brain is considered vital, which aims to suppress reproductive function as a protective reaction to stressful situations in the body.[10]
  - *Hyperprolactinemia:* High serum prolactin levels may lead to hypogonadotropic hypogonadism which is one of the common causes of secondary amenorrhea. If it affects a girl before menarche, it can also present as delayed puberty with primary amenorrhea. A woman with increasing levels of prolactin usually progresses from luteal phase defect to anovulation, amenorrhea, and finally frank features of hypoestrogenism.[11] Only one third of the patients with hyperprolactinemia will present with galactorrhea. If serum prolactin levels are >100 ng/mL, an MRI of the brain is recommended to rule out prolactinoma or other adenomas of the pituitary gland.
  - *Sheehan's syndrome:* History of severe hemorrhage associated with cardiovascular collapse following delivery, with failure of lactation to occur and secondary amenorrhea, suggests postpartum pituitary gland necrosis. Immense hypertrophy and hyperplasia of lactotrophs during pregnancy lead to enlargement of the anterior pituitary without a corresponding increase in blood supply; hence, hypovolemic shock due to acute blood loss quite often may cause ischemic necrosis of the gland and deficient secretion of gonadotropins eventually.[12]
  - *Kallmann's syndrome:* This condition is characterized by a congenital deficiency in the pulsatile release of GnRH which is typically associated with a loss of sense of smell, also known as anosmia. Inheritance can be sex linked or autosomal dominant or recessive; therefore, obtaining a family history is important.[13]
  - *Idiopathic hypogonadotropic hypogonadism (IHH):* This condition is characterized by decreased secretion of gonadotropins and thus of sex steroids with intact uterus resulting in amenorrhea with poorly developed secondary sex characteristics. The pathogenesis is the failure of GnRH neurons to develop or differentiate from the hypothalamus for which many genetic mutations have been studied. It is different from Kallmann's syndrome by the fact that patients with IHH have an intact sense of smell.[14]

MANAGEMENT OF AMENORRHEA

Amenorrhea if left untreated may lead to many complications. On one side, it could be associated with poorly developed secondary sex characteristics along with other hypoestrogenic symptoms such as hot flashes, vaginal dryness, and high risk for osteoporosis owing to deficient mineralization of bones, stroke, and heart disease and on the other side, it may also be associated with unopposed estrogen exposure leading to endometrial hyperplasia and sometimes also to endometrial cancers. Thus, the objectives of management of amenorrhea are as follows:

- To treat the underlying disease

- To achieve resumption of menstruation and fertility, when desired
- To prevent complications of amenorrhea.

MANAGEMENT OF END-ORGAN DISORDERS

- *Imperforate hymen:* This condition requires a simple surgical procedure of cruciate incision and drainage.
- *Transverse vaginal septum:* A pelvic ultrasound or pelvic MRI should be done to rule out hematometra and hematosalpinges. Excision of the septum and primary anastomosis of the upper and lower vagina over the defect are done. If the defect is large, the application of graft may be required.
- *Cervical atresia:* This is a rare condition which is difficult to treat as it is difficult to make a sustainable passage between the vagina and uterus. Cervicovaginoplasty can be attempted, but hysterectomy is often required in these girls. Young girls with cervical atresia and severe dysmenorrhea can be treated with hormones to stop menstruation till surgery is undertaken.
- *Müllerian agenesis:* Development of normal secondary sexual characters along with history and local examination showing an absent or small but blind vagina clinches the diagnosis of MRKH. However, final confirmation can be done by a pelvic ultrasound and the presence of a normal 46XX karyotype. An ultrasound should be done to rule out associated renal anomalies. The primary goal of the treatment is to create a functional vagina which can be done by either of the following procedures:
  - *Frank's vaginal dilators* are used to gradually deepen the vaginal dimple.
  - *McIndoe procedure:* In this procedure, neovagina is created by dissection in the rectovesical space. This is followed by skin graft from the inner side of the thigh, buccal mucosa, oxidized cellulose, or amniotic membrane to cover the raw area created.
  - *Vecchietti operation:* This procedure is originated in Italy, and it involves surgical traction to dilate the rudimentary vaginal canal. It was earlier described as an open procedure, but then laparoscopic Vecchietti became more popular due to a surgeon's ease and patient's comfort. An ellipsoid bead or olive is placed on the vaginal dimple outside with inward traction applied through two sutures, one at each end. These sutures are taken inside through the peritoneal cavity and then taken out extraperitoneally to be attached to a traction device placed on the abdominal wall. Postoperatively, the traction is increased every day in such a way that the vaginal cavity is created at the rate of 1 cm/day; hence, by the end of 7 days, a 7 cm vagina is created.[15] In these patients, fertility is possible only with the help of surrogacy.
  - *Laparoscopic Davydov's vaginoplasty:* In this procedure, abdomen and vagina are approached simultaneously. Dissection of rectovesical space is done at the blind vaginal summit from below and then from above laparoscopically a transverse incision is made at the summit of blind vagina, the peritoneum is mobilized and it is pulled down to cover the neovagina and is stitched to the edges of the incised vaginal mucosa. The apex of the neovagina is then closed by a purse-string suture laparoscopically.
  - However, advocates feel that one must delay this reconstructive surgery until children are old enough to decide for themselves, and only if they choose to have it, one of the techniques described above can be used.
- *AIS:* Women with AIS are phenotypically tall and usually pretty, but their chromosomal analysis reveals a 46XY or male karyotype. These women have the presence of testis within their abdomen which produces both testosterone and AMH which on the one hand leads to either increased or normal serum testosterone or dihydrotestosterone (DHT) levels and on the other hand secretion of AMH prevents the development of the uterus and upper vagina. Imaging studies, such as pelvic ultrasound, confirm the absence of fallopian tubes and uterus due to the AMH secreted by these testes. The testes usually remain in the abdomen or occasionally move into the inguinal canals. The testes make enough testosterone, but no androgenic sexual differentiation occurs, and internal male genital ducts fail to form because of the lack of testosterone receptors. Puberty tends to begin slightly later as some of the testosterone is converted to estradiol, inducing normal breast development. Little or no pubic hair or other androgenic hair appears, and acne is rare but the most conspicuous feature of AIS is the absence of vagina. The length of the vagina may vary from a dimple at the perineum to almost normal length but is always blind ending.
  - Genetically in these cases of AIS the androgen receptor is rendered insensitive to the action of androgens secreted from the testes because of the presence of mutation of androgen receptor gene, which is situated on the X arm of the male sex chromosome. There could be complete or partial gene deletions, point mutations, or small insertions or deletions of the affected area on the X chromosome. DNA tests can be done for mutation analysis for androgen receptor gene on X chromosome.[16]
  - Developmental arrest of fetal germ cells in AIS can lead to the development of carcinoma in situ in the gonocytes which can further progress into malignant germ cell tumors, i.e., gonadoblastoma, seminoma,

teratoma, and embryonal tumors. Benign tumors such as hamartomas, Sertoli cell adenomas, and rarely Leydig cell tumors have also been reported in association with AIS. Gonadectomy is thus essential after these girls achieve puberty due to >30% risk of tumors in these dysgenetic gonads in adulthood.[17] This allows spontaneous pubertal development under the effect of estrogen produced from the aromatization of the high levels of testosterone in blood. However, there is a tendency to do gonadectomy as soon as the diagnosis is confirmed in childhood and these girls then need to take estrogen replacement for pubertal development. In addition, many women with AIS require vaginal lengthening procedures. These patients require both donor oocyte and surrogacy when fertility is desired.

- *Asherman's syndrome:* Intrauterine adhesions can occur due to endometrial infections such as genital tuberculosis or due to iatrogenic causes such as repeated curettage, especially of a pregnant uterus or following operative hysteroscopic procedure such as intrauterine polypectomy and myomectomy. This condition was first described in 1894 by Heinrich Fritsch[18] and further characterized by Israeli gynecologist Joseph Asherman in 1948.[19] It is also known as Fritsch syndrome, or Fritsch–Asherman syndrome. This syndrome is diagnosed when the cause of amenorrhea or hypomenorrhea is adhesions or synechiae within the endometrial cavity. These synechiae can be picked up quite often at 3D ultrasound and further confirmed by hysterosalpingography or saline sonohysterography. Hysteroscopic division of intrauterine synechiae is considered the standard procedure for this disorder. Generally, synechiolysis is followed by a high dose of exogenous estrogen given to the woman for 2–3 weeks followed by progesterone withdrawal. A study done on menstrual outcomes after surgical intervention in Asherman's syndrome over a period of 10 years in the Netherlands showed resumption of normal menses in 95% of the patients, though recurrence was reported in 27% of them.[20] Follow-up assessment of uterine cavity is recommended preferably with hysteroscopy after treatment of intrauterine adhesions.[21]

MANAGEMENT OF POLYCYSTIC OVARIAN SYNDROME WITH AMENORRHEA

The role of lifestyle modification should be emphasized in detail to women with PCOS, especially those who are overweight and obese. Women with PCOS with weight loss of even 5% of initial weight have reported spontaneous resumption of menses. The lifestyle changes include aerobic exercise for 150 minutes per week and a hypocaloric diet which could be started as a 500-calorie daily deficit in diet.[22] Periodic treatment with progestin is given to these women to induce regular menses and protect them from endometrial hyperplasia. The most commonly used regime is tablet MPA 10 mg twice daily for 5–7 days every month or alternate months. In women desiring contraception or those suffering from acne and hirsutism, combined oral contraceptive pills are recommended. Pills containing cyproterone acetate as progestogen are preferred as they not only ensure regular cycles but also reduce circulating androgen levels too. When fertility is desired ovulation induction is the way to it, which can be done by ovulation-inducing agents such as clomiphene citrate, letrozole, or tamoxifen and if they fail to induce ovulation then second-line drugs in the form of injectable gonadotropins are recommended to induce ovulation and attain fertility.

MANAGEMENT OF GONADAL AGENESIS AND DYSGENESIS

Turner's syndrome (46, XO): It is one of the common causes of primary amenorrhea and mosaics can present with POF. It is imperative to look for associated medical conditions which are additional features of Turner's syndrome; hence, echocardiography, audiometry, thyroid profile, blood sugar profile, liver and renal function tests, and ultrasonography should be done. These girls need estrogen replacement therapy which must be started as soon as the diagnosis of primary amenorrhea is confirmed, preferably before 15 years of age, so that they can attain adult height. Estrogen is started at a low dose (0.25–0.5 mg micronized estradiol) and increased every 6 months till sexual maturation is achieved. After 1–2 years of continuous estrogen, progestin is added to induce withdrawal bleeding. Fertility is possible with donor oocytes only Turner's syndrome: In classic Turner's syndrome, fertility is possible with donor oocytes only. Most of the mosaic variants also present with POF and require donor oocytes though spontaneous pregnancy has also been reported.

Swyer syndrome and AIS (46XY): AIS has been discussed in end-organ disorders. In Swyer syndrome, SRY region on Y chromosome is missing so testes fail to develop and there are only streak gonads present. In the absence of testicular development there is neither testosterone nor AMH secreted which leads to failure of the development of male secondary sexual characteristics, hence the female phenotype. In addition, in the absence of AMH, the Müllerian system develops in these girls resulting in functional uterus and vagina, which responds to hormones. Menstruation follows sequential hormone replacement therapy (HRT) with estrogen and progesterone in these girls as well as the development of endometrium, to support a pregnancy through a donated oocyte or embryo by in vitro fertilization (IVF). In Swyer syndrome, unlike AIS, gonadectomy is

recommended as soon as the diagnosis is made to avoid the high risk of malignant transformation in these nonfunctional gonads as hormonal replacement for the development of secondary sex characters is mandatory.

MANAGEMENT OF PREMATURE OVARIAN FAILURE

These women require HRT, both estrogen and progestin, either in a continuous or cyclic manner. They should also take calcium and vitamin D_3 supplementation and exercise regularly to protect their bones. In case fertility is desired, IVF with donor oocytes is the only option to have children.

MANAGEMENT OF HYPOGONADOTROPIC HYPOGONADISM

In case of anorexia nervosa or severe malnutrition, behavioral and nutritional therapy alone can bring back the menstrual pattern once an optimal weight gain is achieved. If the condition is due to stressful situations, they must be treated by a psychiatrist to reverse the condition. Women with hyperprolactinemia are treated with dopamine agonists (cabergoline or bromocriptine) and ovulation and menses are resumed after 2–3 months of therapy. Women with hyperprolactinemia who are experiencing hypoestrogenic symptoms can be prescribed HRT also. Women with hypogonadotropic hypogonadism need to undergo ovulation induction with gonadotropins which contain both FSH and LH or human menopausal gonadotropin (HMG) when desirous of conception. Otherwise, HRT should be offered to prevent adverse sequel of the absence of ovarian steroid hormones in the body.

KEY POINTS

- Amenorrhea can occur as a natural part of life, such as during pregnancy or breastfeeding, or it can be a sign of a health problem; hence, it is pertinent to know the underlying reasons to decide on the appropriate treatment. However, in some cases leading to amenorrhea, it may not be possible to induce menstruation, as for those who do not have a uterus, as in MRKH syndrome, or AIS, or for girls with cervical atresia where hysterectomy needs to be undertaken to relieve her from cyclical pain.
- We also need to identify the subset of women who may not desire treatment for the resumption of menses as far as they have no health consequences such as those with end-organ failure or Asherman's syndrome.
- For all causes of amenorrhea which root from hypothalamus or pituitary, lifelong HRT is advisable till conception is desired.
- Amenorrhea stemming from the ovary has the most diverse management strategies; dysgenic gonads as those with XY karyotype need to be removed and HRT instituted, and ovarian agenesis or failure requires HRT lifelong during the reproductive years with oocyte donation and IVF for reproduction.
- Amenorrhea associated with androgen excess conditions, such as PCOS, needs to be managed as per the presenting features and health issues.
- Ovulation induction in this group of women is the best method to attain fertility. The key to the management of women with amenorrhea is to make a correct diagnosis, especially in young girls.
- Irregular menses can be managed with oral contraceptive pills, especially if hirsutism is a prominent feature, but a progesterone withdrawal may be sufficient to regularize menstruation. However, fertility issues are best addressed by induction of ovulation.
- Primary amenorrhea is a very emotionally draining concern, not only for the girl but also for the family, and counseling is an integral part of the management of all such cases.

CHAPTER 11

Endocrine Disorders Affecting Reproduction

Chaitra Narayan Nayak

INTRODUCTION

Reproduction is affected by various factors, including, among others, nutrition, exposure to infections, and the hormonal milieu of the individual. Endocrine disorders have a profound impact on reproduction, and in women, polycystic ovarian syndrome (PCOS) is the most common endocrine syndromic disorder affecting reproduction.[1] The regulation of the hypothalamic–pituitary–gonadal axis is covered in Chapter 1, and the physiology of steroids and their regulations are covered in Chapter 2.

In this chapter, we will be discussing abnormalities of the hypothalamus, pituitary, adrenals, and thyroid and their effect on reproduction.

HYPOTHALAMUS–PITUITARY UNIT

For long known as the "master gland", the pituitary was thought to regulate almost all essential functions of the body, including growth, response to stress, functioning of thyroid, and reproduction to name a few.[2] In recent years, it has been found that the pituitary largely acts as a relay, transporting the regulatory hormones released by the hypothalamus. The pituitary is anatomically and embryologically divided into the anterior and posterior pituitary. Details of the same are covered elsewhere.

Unique Features of the Hypothalamus–Pituitary System[3]

- The neurosecretory cells of the hypothalamus secrete regulating factors in a pulsatile manner and control the functioning of the pituitary.
- The inhibitory and releasing factors are transported by a portal system through the pituitary stalk to the anterior pituitary.
- The posterior pituitary hormones, oxytocin, and vasopressin are secreted and regulated by the hypothalamus.
- Diurnal variation has an important impact on the functioning of the hypothalamus and, in turn, the pituitary.
- Most of the peptides secreted act as releasing hormones, except for prolactin, which is under inhibitory control.
- A strict feedback system from the end organs regulates the secretions of both the hypothalamus and the pituitary.

Only the most important endocrine abnormalities known to affect reproduction are discussed here.

Prolactin

Prolactin is a polypeptide of 198 amino acids, 23 kDa coded on a single gene on chromosome 6. Initially found to be secreted in a pulsatile manner from the lactotrophs of the anterior pituitary, prolactin has been isolated in other areas of the hypothalamus, placenta, and mammary glands. Dopamine through the pituitary portal system tonically suppresses prolactin. Estrogen, antidopaminergics, epidermal growth factor, and thyrotropin-releasing hormone are known to increase prolactin.[4]

While the majority (85%) of prolactin exists as the 23 kDa molecule, variants occur due to proteolytic cleavage, alternative splicing, or modifications post-translation. Covalently bound dimer (big prolactin) and polymeric dimer (big big prolactin) cause macroprolactinemia, where asymptomatic patients have incidental hyperprolactinemia. Delayed renal clearance of macroprolactin causes a false elevation in prolactin levels. It is detected by *polyethylene glycol precipitation* of the serum. If the only cause of hyperprolactinemia is confirmed to be macroprolactinemia, no further treatment is required.[5]

A single measurement of serum prolactin is recommended, and dynamic testing for prolactin is to be avoided. The serum sample can be taken at any time of the day, provided minimal venepuncture is done. Normal prolactin levels are <25 μg/L in women and lower in men. Prolactin levels of >500 μg/L are indicative of macroprolactinoma.

Most people with prolactin >250 µg/L should be evaluated for pituitary tumors.[5]

If a large pituitary tumor is found with mildly elevated prolactin levels, serial dilution of serum must be done to test for the "hook effect". High serum prolactin causes saturation of antibodies in the two-site immunometric assay. This results in direct binding of prolactin to signaling (second) antibody and less availability of the latter to bind to prolactin-bound coupling (first) antibody. It is recommended to either repeat the assay with 1:100 dilution or wash out the sample before adding the signaling antibody to prevent the hook effect.[5]

EPIDEMIOLOGY

Biochemical hyperprolactinemia is seen in about 0.4% of the general population, 9–17% in infertile patients, and is one of the most common disorders of the pituitary. Females have a higher incidence as compared to males, with peak prevalence at 25–34 years.

Women with galactorrhea, amenorrhea, oligomenorrhea, or infertility and men with hypogonadism, infertility, or impotence need the evaluation of prolactin levels.

About 10% of women with amenorrhea, 25% of women with galactorrhea, and 70% of women with both amenorrhea and galactorrhea are found to have high prolactin.

About 5% of men with either impotence or infertility have high prolactin. Impotence is not responsive to testosterone supplementation and is associated with reduced body hair, low muscle mass, and osteoporosis.

Hyperprolactinemia has also been called World Health Organization (WHO) type 4 anovulation due to the hypogonadism caused by high prolactin levels.

Causes of Hyperprolactinemia

Causes of symptomatic nonphysiological hyperprolactinemia would include medications, renal failure, parasellar tumors, and hypothyroidism **(Table 1)**.[6]

Drugs Causing Hyperprolactinemia[6]

- Medications are the most common cause of nontumoral hyperprolactinemia, with most patients having prolactin between 25 and 100 µg/L.
- Neuroleptics, antipsychotics, anticonvulsants, antihistamines, opiates, and antidepressants can all cause hyperprolactinemia.
- About 40–90% of patients on antipsychotics and 50–100% of patients on risperidone have hyperprolactinemia.
- Women present with amenorrhea and galactorrhea; men exhibit low libido or erectile dysfunction.
- In suspected symptomatic patients with hyperprolactinemia, it is recommended to discontinue or substitute the medicines for 3 days and reassess prolactin levels.
- Antipsychotics should be either modified or discontinued only after consulting the psychiatrist if found to cause hyperprolactinemia.
- Antipsychotics, such as aripiprazole, which has both dopamine agonistic and antagonistic properties or similar alternatives, are advisable where applicable.
- Dopaminergic drugs may worsen the psychosis in patients with hyperprolactinemia due to antipsychotics.

Delayed breakdown or clearance of prolactin causes hyperprolactinemia in one-third of patients with chronic *renal failure*. Dialysis is ineffective and only renal transplant normalizes the levels of prolactin.

Tumors of Pituitary

- Both functional and nonfunctional tumors of the pituitary can cause hyperprolactinemia.
- Most patients with prolactin >250 µg/L will have prolactinomas.
- Prolactinomas can be microadenomas (<10 mm) or macroadenomas (>10 mm).
- Stalk compression by intracranial tumors, parasellar tumors, and inflammation may also cause hyperprolactinemia by preventing the transport of inhibitory signals to the pituitary.

Common Presentations of Hyperprolactinemia

Common presentations are shown in **Table 2**.[4]

Management (Evidence-Based Guidelines)

Goals of treatment in hyperprolactinemia are mentioned in **Box 1**.

TABLE 1: Causes of hyperprolactinemia.

Physiological	*Pituitary*	*Central nervous system disorders*	*Systemic disease*
• Pregnancy • Lactation • Stress • Nipple stimulation • Sleep • Coitus • Exercise	• Prolactinoma • Hypothyroidism • Nonsecretory adenomas • Acromegaly • Cushing's disease • Empty sella turcica	• Tumors • Vascular malformations • Granulomatous autoimmune disease • Metastasis	• Chronic renal failure • Severe hypothyroidism • Cirrhosis • Cranial radiation • Chest wall trauma • Herpes zoster

Note: Pharmacological causes of hyperprolactinemia are discussed in the text.

TABLE 2: Common presentations of hyperprolactinemia.

Female (prolactin levels)	*Male*
• >100 ng/mL: Hypogonadism, galactorrhea, amenorrhea • 51–75 ng/mL: Oligomenorrhea • 31–50 ng/mL: Luteal phase defect, decreased libido, infertility • Osteopenia	Decreased libido, impotence, infertility, oligospermia, retrograde ejaculation gynecomastia

BOX 1: Goals of treatment in hyperprolactinemia.

- Restoration of normal gonadal function
- Restoring fertility
- Avoiding osteoporosis

Medical Management of Hyperprolactinemia

- Dopaminergic drugs are the first line of treatment in all cases of hyperprolactinemia and reduce tumor size, lower prolactin levels, and reestablish normal gonadal functions.
- Both bromocriptine (2.5–40 mg/day) and cabergoline (0.125–1 mg twice weekly) may be used.
- Cabergoline is highly efficacious and causes better shrinkage of tumors when compared to bromocriptine.
- Bromocriptine has been used for a longer duration. Nausea, giddiness, and nasal stuffiness are common side effects of the drug. The dosage is gradually increased until the serum levels of prolactin are normalized, which may take about 10 days.
- Cabergoline is used in bromocriptine resistance or intolerance.
- Men on 0.5–1 mg twice weekly cabergoline had normalization of semen parameters and prolactin levels after 6 months of treatment. 80% of men on dopamine agonists for micro- or macroadenoma respond to treatment.
- Patients on antidopaminergics need to have prolactin levels checked about 1 month after starting therapy to adjust the dosage. Repeat magnetic resonance imaging (MRI) after 1 year for microadenoma and 3 months for macroadenoma is done to look for tumor shrinkage.
- Dopamine agonists can be stopped after 2 years of achieving normal prolactin or no tumor residue on MRI.

Despite therapy, about 10% of patients with microprolactinomas and 18% with macroprolactinomas will continue to have high blood levels of the hormone. Newer drugs such as kisspeptin for hyperprolactinemia are under trial and results are awaited.

Drug-induced asymptomatic hyperprolactinemia needs no treatment other than discontinuation of the drug or substitution. Hypogonadism from prolonged drug-induced hyperprolactinemia is treated with estrogen or testosterone supplements.

Surgery

Surgery is reserved for nonfunctional tumors causing visual defects or stalk effect, and in those patients where *medical therapy has failed* or is not tolerated. Transsphenoidal resection is to be done with extreme caution in a center well versed in handling such cases. Recurrence of 20–50% has been reported with higher cure rates for microprolactinomas compared to macroprolactinomas. Such patients may ultimately require radiation if symptoms persist.

Hyperprolactinemia and Pregnancy[5]

- Women with prolactinoma on dopaminergic agonists should stop after discovering pregnancy.
- Patients with macroadenoma and visual symptoms with no prior radiotherapy or surgery may continue bromocriptine.
- Testing of prolactin in pregnancy is not recommended.
- Routine MRI of the pituitary in pregnancy in patients with macro- or microadenomas is to be avoided and must be done only if new symptoms, such as changes in the visual field, occur.
- Women with macroprolactinomas resistant to or intolerant to dopamine agonists must be strongly counseled for surgery before attempting pregnancy.
- Pregnant women with prolactinoma presenting with visual changes or severe headaches should have a formal assessment of the visual field and a noncontrast MRI.
- Bromocriptine is the drug of choice in pregnant women with symptomatic prolactinomas.

OTHER DISORDERS OF PITUITARY

Acromegaly

Acromegaly is a rare disorder occurring due to the hypersecretion of growth hormone (GH) or insulin-like growth factor 1 (IGF1) due to somatotropinomas or GH-releasing hormone tumors.[7] Changes in the bone and soft tissues along with easy fatigability, headache, excessive sweating, carpal tunnel syndrome, and sleep apnea may also occur. Gigantism occurs in children and has similar etiopathology to acromegaly but is identified earlier due to its florid manifestations.

Overexpression of the *GPR101* gene on the X chromosome has been found in patients with acromegaly or gigantism. Affected individuals have an insidious onset with most patients being diagnosed late. Acromegaly causes impaired fertility due to numerous factors, including stalk compression, hyperprolactinemia, mass effect, and direct excess GH.

Preconceptional counseling is essential before pregnancy is attempted. Acromegalic women have anovulation (69%) or may ovulate (31%), with the latter having better fertility outcomes. Common causes of anovulation include

hyperprolactinemia, mass effect, and increased GH/idiopathic guttate hypomelanosis (IGH) levels. Most women ovulate after correcting underlying pathology. 174 pregnant patients with acromegaly have been documented in the literature, with 33 patients being included in the literature review. Most women have had no complications in their pregnancy.[8]

The best screening test is a serum IGF1 with age, gender, and Tanner stage corrections. Suppression tests are done to prognosticate therapy response. Diagnosis is confirmed by high GH levels (>10 ng/mL) after an oral glucose test or elevated IGF1 levels in patients suspected to have acromegaly.

Additionally, MRI with gadolinium contrast will be able to detect adenomas of the pituitary, and computed tomography (CT) scan of the abdomen will detect tumors of the ovary, pancreas, or adrenal glands, which may secrete GH.

Somatostatin analogs such as depot octreotide or lanreotide, dopamine agonists, or GH receptor antagonists may be used in newly identified pregnant patients and is the first line of management. Transsphenoidal surgery is recommended in patients with pituitary tumors prior to pregnancy and is preferred in older women.

THYROID AND REPRODUCTION

The thyroid gland consists of numerous follicles made of a simple secretory epithelium around a gelatinous lumen containing thyroglobulin and thyroxine (T4). Functions of the thyroid are enumerated in **Box 2**.

Iodide is taken up from the blood, converted to iodine, and the resulting monoiodo or diiodotyrosine is incorporated into the thyroglobulin. Organification occurs with the coupling of two diiodotyrosine to form T4 or one mono and one diiodotyrosine to form triiodothyronine (T3). Both iodination and organification are done by the enzyme thyroid peroxidase (TPO) **(Fig. 1)**. Autoantibodies to this enzyme are common and result in various pathologies of the thyroid gland.

The majority of the T4 in the circulation is bound to plasma proteins [70% to thyroxine-binding globulin (TBG), 20% to transthyretin, and 10% to albumin], and changes in the protein concentration have a profound impact on the free T4 concentration.

Prevalence

Thyroid disorders are more prevalent in women than men and most of them unsurprisingly have an autoimmune etiology.[9] Most common causes of hypothyroidism (Hashimoto's thyroiditis) and hyperthyroidism (Graves' disease) have associated antithyroid antibodies.

About 2.3% of subfertile women and 1.5% of women in the general population are found to have hyperthyroidism. About 3.1% of reproductive-age women are hypothyroid, with most of them having menstrual symptoms and anovulation. *Subclinical hypothyroidism*, which presents

BOX 2: Functions of the thyroid.[3]

- The thyroid controls the basal metabolic rate through triiodothyronine and thyroxine
- The thyroid is essential for the growth and development of the central nervous system, especially the brain
- Both hypothyroidism and hyperthyroidism are known to affect reproduction
- Patients with antithyroid antibodies are known to have adverse pregnancy outcomes despite being euthyroid

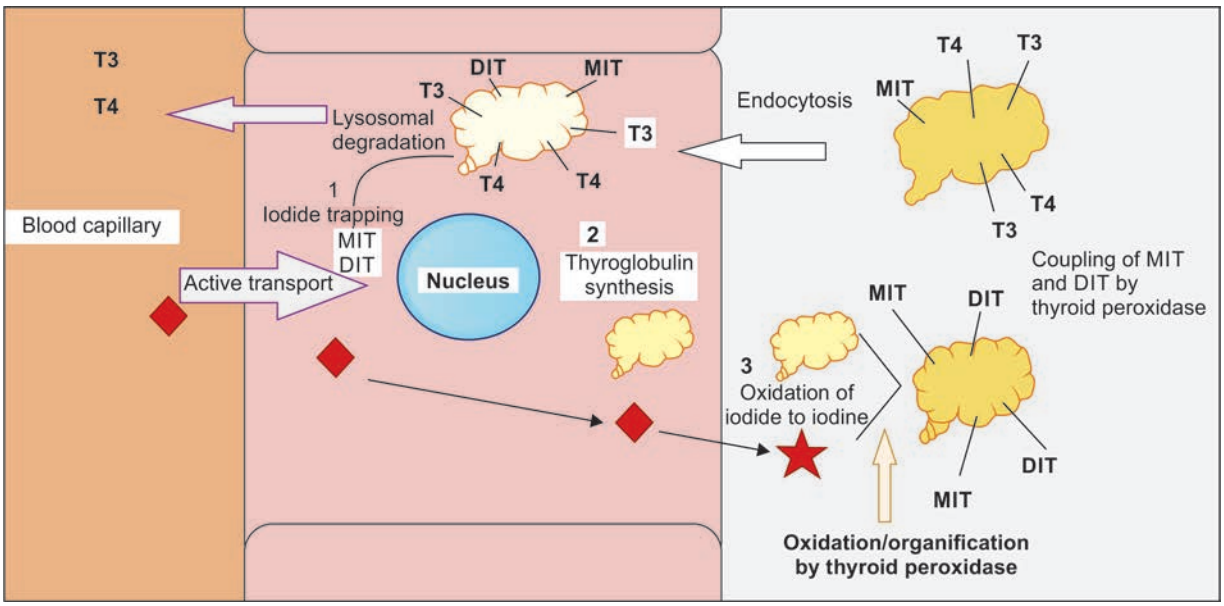

Fig. 1: Synthesis of triiodothyronine (T3) and thyroxine (T4) hormones.
(DIT: diiodotyrosine; MIT: monoiodotyrosine; ◊: iodide; *: iodine; : thyroglobulin)

with normal T4 levels (9–25 pmol/L) but raised thyroid-stimulating hormone (TSH) (>4.5 μM/mL), affects 2–4% of reproductive-age women.

All women who are infertile or in the initial stages of their pregnancy are evaluated to find the risk of thyroid disease according to **Box 3**. India is a high prevalence country where universal screening of all infertile and pregnant women may be recommended **(Flowchart 1)**.

Hypothyroidism[10]

- Hypothyroidism inhibits the pulsatile release of gonadotropin-releasing hormone (GnRH), preventing cyclical follicle-stimulating hormone (FSH) and luteinizing hormone (LH) release, causing anovulation.
- Children or adolescents with hypothyroidism present with delayed sexual development.
- Adults may manifest with menstrual irregularities such as oligomenorrhea, menorrhagia or amenorrhea, and hyperprolactinemia. Weight gain, intolerance to cold, sleepiness, dry skin, and hair loss may be other manifestations.
- Hypothyroidism is common in infertile women and controlled ovarian stimulation causes high estradiol levels, resulting in higher binding of T4 to TBG, temporarily making euthyroid women hypothyroid.

BOX 3: Screening for thyroid disorders.[3]

- History of hyper/hypothyroidism or recent thyroid disorders
- Goiter present or presence of thyroid antibodies
- History of thyroid surgery or neck irradiation
- More than 30 years of age
- Autoimmune diseases including type I diabetes
- Morbid obesity >40 kg/m^2
- Resides in area of high iodine deficiency
- History of previous pregnancy loss, infertility, or preterm birth
- Multipara >2 pregnancies
- Intake of lithium, amiodarone, or radioiodine contrast
- Family history of thyroiditis or autoimmune thyroid disorder

- Correcting both subclinical and overt hypothyroidism has been shown to improve implantation, pregnancy, and live birth rates in assisted reproductive technology (ART) pregnancies. It has been therefore recommended to maintain TSH levels of <4 mU/L in the preconceptional period as well as in the first trimester of pregnancy.[11]

Investigations[12]

The American Thyroid Association recommends screening from 35 years, once every 5 years. High-risk patients such as pregnant women, women >60 years, those with autoimmune disease, or with a history of irradiation to the neck require more monitoring.

Serum TSH and T4 are checked to detect overt hypothyroidism or subclinical hypothyroidism. If TSH is >2.5 mU/L, TPO antibody levels should be measured.

Treatment[12]

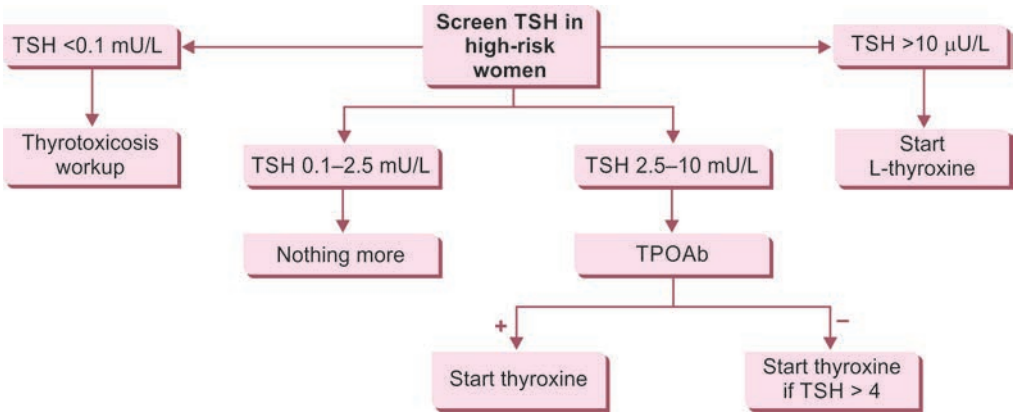
- Levothyroxine (LT4) replacement is the sole therapy with titration required for the dose.
- Young adults will usually require 50–75 μg and can be started with the full replacement dose.
- Older patients and those with cardiac disease may need to be started with a smaller dose and increased gradually to a higher dosage.
- Improvement of symptoms is seen within about 3–5 days, and dose adjustments are done every 6–8 weeks.[11]

Hyperthyroidism

Patients having hyperthyroidism typically present with palpitations, anxiety, involuntary weight loss, increased sweating, intolerance to heat, and excessive bowel movements.

Women with hyperthyroidism have a higher sensitivity to GnRH causing high LH, sex hormone-binding globulin (SHBG), and total estradiol levels resulting in either *oligomenorrhea* or *hypomenorrhea*.

Flowchart 1: Screening of thyroid-stimulating hormone (TSH).



(TPOAb: thyroid peroxidase antibody)

Source: Vanderpump MP. The epidemiology of thyroid disease. Br Med Bull. 2011;99(1):39-51.

Most women with hyperthyroidism are *ovulatory* despite having these menstrual irregularities, and therefore treating hyperthyroidism generally does not increase the ovulation rate but does improve the quality of life in affected women. Pregnant women with thyrotoxicosis must be differentiated from those with hyperemesis gravidarum, molar pregnancies, and women having physiological changes in pregnancies.

Graves' disease, the most common cause of hyperthyroidism, occurs due to anti-TSH receptor antibodies (TRAb), causing unregulated stimulation of thyroid hormone production. On examination, affected patients have a classical protuberant gaze with exophthalmos due to the paralysis of extraocular muscles with periorbital infiltration and ophthalmopathy, resting tachycardia, tremors, and proximal muscle weakness. Pregnant women affected by Graves' disease have an increased risk of fetal or neonatal thyrotoxicosis due to the transplacental transport of the antibodies.

Men with Graves' disease present with hypogonadism, with low free testosterone levels despite high SHBG and high total testosterone. Low sperm counts unresponsive to human chorionic gonadotropin (hCG) and gynecomastia may also be present.

Inflammation of the thyroid gland causes thyroiditis, with subsequent release of the stored thyroid hormone into the circulation causing thyrotoxicosis. There is immediate hyperthyroidism, which may last up to 8 weeks followed by transient hypothyroidism and subsequent euthyroid state in most patients. Typically, both serum thyroglobulin and erythrocyte sedimentation rate are elevated in subacute thyroiditis.

Subacute thyroiditis (de Quervain's disease) may present with the classical symptoms of neck pain, fever, and tender thyroid gland following a viral infection in the recent past.

Other causes of hyperthyroidism include toxic adenoma, where a germline mutation results in a solitary tumor autonomously producing T3 and T4 or toxic multinodular goiter producing.

Diagnosis of Hyperthyroidism

Triiodothyronine, T4, and TSH are essential to make a diagnosis of hyperthyroidism in symptomatic patients.

Low TSH levels (<0.5 μIU/mL) with high free T4 and total T3 levels are seen in thyrotoxicosis. Subclinical hyperthyroidism presents with normal FT4/T3 and low TSH levels.

Antibodies[13]

Autoantibodies are an important cause of hyperthyroidism. Anti-TPO antibodies are specific for autoimmune thyroiditis and are significantly elevated in Graves' disease. Other causes of hyperthyroidism such as toxic multinodular goiter and toxic adenoma have a normal or slight increase in anti-TPO antibodies. About 8–10% of the population has a slight increase in anti-TPO antibodies, and hence a universal screening is not recommended.

Radioactive iodine (RAI) uptake by the thyroid gland can also be used to differentiate the etiology of hyperthyroidism, with a diffuse uptake seen in Graves' disease and focal areas of uptake seen in toxic adenoma and multinodular goiter. Both iodine-123 (^{123}I) and technetium-99m (^{99m}Tc) have been used for scintigraphy of the thyroid.

Treatment[12]

Management of Graves' disease involves a multidisciplinary approach with interventions for the ophthalmopathy, dermopathy, and β-blockers for the cardiac and neurological signs.

Antithyroid medications such as methimazole and propylthiouracil are the mainstay of treatment in children, pregnant women, and adults awaiting radioiodine therapy. They inhibit the synthesis of thyroid hormones and act over 2–8 weeks. Titration of drug dosage is done by measuring hormones every 4–6 weeks until the euthyroid state is obtained.

Methimazole is a more potent antithyroid drug with ease of once-a-day dosage due to its longer action as compared to propylthiouracil which is given in two to three doses. Propylthiouracil is safer in the first trimester of pregnancy, in patients intolerant to methimazole. In patients with thyroid storm, propylthiouracil inhibits the peripheral conversion of T4 to T3. Hepatotoxicity is a known adverse effect of the medication, and it is recommended to do liver function tests within 6 months of therapy, with discontinuation if results are abnormal.

About 1–5% of patients may have an intolerance to antithyroid medications and manifest as fever, arthralgia, and rash. This must be differentiated from the more serious aplastic anemia, agranulocytosis, hepatitis, or vasculitis, which are also known to occur.

Radioactive iodine is preferred in all other patients as it is given as a single oral capsule, is more effective, with lesser adverse effects. The gland undergoes fibrosis over a while, with patients becoming hypothyroid. It is avoided in pregnant, lactating women and young children.

Surgery is preferred in pregnant women with noncompliance or intolerance to antithyroid drugs, patients with large goiters, and those who reject radiotherapy or need a rapid correction to the euthyroid state.

THYROID AND SUBFERTILITY[12]

- Evidence suggests routine screening for thyroid disorders by a TSH and thyroid peroxidase antibody (TPOAb) is beneficial in infertile women. If TSH is <2.5, no further tests are needed. However, a TSH of >2.5 needs to be

repeated along with antithyroid antibodies [TPOAb and thyroglobulin antibody (TgAb)]. LT4 supplementation with repeat TSH measurements done 6 weeks thereafter, until TSH is <2.5, is recommended. Women with overt thyroid disorders should be promptly treated.

- Routine screening of thyroid disorders in male partners is not recommended. Men with abnormal semen parameters, erectile, or ejaculatory disorders may benefit from the evaluation of thyroid function. Unless semen parameters are grossly affected, ART treatment may proceed despite thyroid abnormalities in males. If RAI is done, it is recommended to wait for 120 days before attempting conception/ART procedures. Sperm banking, family planning, and fertility should be discussed before offering RAI. RAI for thyroid cancers must not be delayed for fertility reasons.[14]
- Thyroid function tests are to be done either before or about 2 weeks after controlled ovarian stimulation. If TSH >4 mIU/L, with or without thyroid autoimmunity (TAI), LT4 needs to be started to keep TSH <2.5 mIU/L.
- Autoimmune disorders such as antiphospholipid antibodies (APLA), type I diabetes, systemic lupus erythematosus (SLE), and premature ovarian failure (POF) are common in infertile patients, and the significance of antithyroid antibodies has long been debated. Common thyroid disorders such as Hashimoto's thyroid disease, postpartum thyroiditis, and Graves' disease have autoantibodies as the etiology. Elevated levels of antithyroid antibodies are also seen in PCOS and endometriosis.[15]
- Infertile euthyroid women with antithyroid antibodies have a poorer pregnancy outcome with lower fertilization, bad embryos, and reduced pregnancy rates when compared to infertile women without autoantibodies. Intracytoplasmic sperm injection (ICSI) is to be offered for fertilization in cases of thyroid antibodies in females.[11] Higher levels of antibodies are also seen in ovarian follicular fluid with higher natural killer (NK) cell activity in the uterus. Limited evidence suggests an improvement in pregnancy outcomes with the treatment of thyroid antibodies.

THYROID AND PREGNANCY[11]

- The WHO recommends all pregnant women ingest 250 µg of iodine per day.
- Universal salt iodination is the most cost-effective method for increasing iodine intake, and it is to be supplemented 3 months before planning a pregnancy.
- Low iodine causes high TSH leading to compensatory goiter in both mother and fetus. This also causes long-term effects such as cognitive dysfunction and cretinism in the infant.
- All pregnant women should be asked about their history of thyroid disorders and intake of medications for the same. About 50–80% of hypothyroid women will need a change in dosage of LT4 in pregnancy and TSH must be kept <2.5 mU/L.
- All thyroid nodules can undergo fine-needle aspiration cytology (FNAC) during pregnancy. Radioiodine uptake studies are avoided in pregnancy.
- Surveillance of fetuses is done in all women with severe hyperthyroidism or with high TRAb (more than three times normal).
- Postpartum thyroiditis affects about 5% of women and is usually asymptomatic. If women are identified in the thyrotoxicosis phase, β-blockers are the first line of management. TSH should be measured about 4–8 weeks later to look for hypothyroidism.
- Antithyroid medications methimazole (up to 20 mg/day) and propylthiouracil (up to 450 mg/day) are found to be safe during pregnancy and lactation, although the lowest possible dose is to be recommended. Propylthiouracil is preferred in the first 16 weeks of pregnancy.
- ^{131}I is contraindicated during lactation, and if at all used, breast milk should be discarded for the next 3–4 days.
- Women with newly detected hypothyroidism in pregnancy on <50 µg of LT4 per day may discontinue it in the postpartum period and reassess thyroid function 6 weeks postpartum.

ADRENAL DISORDERS

The adrenal gland, embryologically and anatomically, is divided into the cortex and medulla, with the latter being a part of the sympathetic nervous system, producing epinephrine. The more important adrenal cortex has the aldosterone-secreting zona glomerulosa controlled by the renin–angiotensin–aldosterone system (RAAS), the cortisol-secreting zona fasciculata and the dehydroepiandrosterone (DHEAS)-secreting zona reticularis, both of which are regulated by the adrenocorticotropic hormone (ACTH). Adrenal glands are the major source of testosterone in women and their disorders are known to have reproductive implications, the most important of which is subfertility due to hyperandrogenemia.[16]

Cushing Syndrome

Cushing syndrome occurs due to prolonged exposure to glucocorticoids and may be classified into iatrogenic or endogenous, depending on the source of the steroids. Cushing syndrome of endogenous origin is further categorized as being ACTH-dependent or -independent.

Adrenocorticotropic hormone-producing pituitary tumors are the most common cause of Cushing syndrome and indeed are labeled as Cushing disease. Other sources of ACTH causing the syndrome are carcinomas, bronchial

carcinoids, and neuroendocrine tumors. Cushing disease commonly affects women of reproductive age who present with infertility due to high DHEAS.[16]

The disease in its initial stages is most amenable to treatment but is difficult to diagnose. Cortisol causes a redistribution of fat and change in the body habitus causing central obesity with the classical dorsocervical deposition of fat (buffalo hump), supraclavicular fat pads, and hirsutism, along with facial and upper chest plethora.

Pathognomonic features of Cushing syndrome include proximal muscle weakness and extreme thinning of skin along with easy bruisability or striae. Affected individuals typically have difficulty in getting up from a chair, combing hair, climbing stairs, or changing light bulbs.

Young women with PCOS (oligomenorrhea, polycystic ovarian morphology, and hirsutism) should be evaluated for Cushing syndrome if they have dermatological manifestations of Cushing disease.

Diagnosis[17]

In affected individuals, an excessive amount of cortisol production occurs with a loss of the normal diurnal variation. A 24-hour free cortisol measurement in the urine and serum or salivary cortisol level both will reflect the excess steroid production. The dexamethasone suppression test also fails to reduce cortisol levels in the blood.

Adrenocorticotropic hormone measurements are done to detect ACTH-dependent or independent causes of the Cushing syndrome, and a CT scan of the adrenal gland is done if ACTH levels are low to seek out local causes. Conversely, an MRI with gadolinium contrast of the pituitary is done to look for adenomas in cases of high ACTH.

Adrenocorticotropic hormone levels in the blood of both petrosal sinuses after a bovine corticotropin-releasing hormone (CRH) challenge (100 μg bolus) are measured and compared to that in peripheral blood to help in reliably detecting the pituitary origin of ACTH.

Treatment

Surgery is the modality of choice in patients with Cushing syndrome. Transsphenoidal pituitary adenectomy is done in those with Cushing disease and, if unsuccessful, may require radiotherapy or bilateral adrenalectomy.

Medical management including ketoconazole, mifepristone, and cabergoline has been tried. Mifepristone has been shown to improve metabolic features, although largely ineffective for the associated hypertension. Cabergoline may be effective if pituitary adenoma contains dopamine type 2 receptors. Pasireotide has also been found to be effective in a few patients.

Bilateral or unilateral adrenalectomy is done in cases of non-ACTH-dependent Cushing syndrome and treatment-resistant Cushing disease.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a group of autosomal recessive metabolic disorders characterized by abnormalities in the cholesterol pathway, leading to low levels of cortisol. It affects 1 in 10,000–20,000 people with a higher incidence seen in inbreeding populations such as the Ashkenazi Jews. More than 90% of affected individuals are known to have 21-hydroxylase deficiency, with mutations occurring in the *CYP21A2* gene on chromosome 6.

Depending on the severity of enzyme deficiency and age at presentation, the disease is categorized into classical virilizing CAH, simple virilizing CAH, and nonclassical CAH.

Classical CAH presents with typical ambiguous genitalia in newborn girls and is associated with salt-wasting, failure to thrive, and death due to electrolyte imbalance in affected male and female neonates. It is highly advisable to ask for newborn screening for CAH as a routine by Guthrie cards, as early diagnosis and treatment have been seen to reduce morbidity and mortality.

Simple virilizing CAH patients present with precocious puberty or clitoromegaly, virilization, and early skeletal maturity.

Late-onset CAH or nonclassical CAH presents in peripubertal girls who come with complaints of primary amenorrhea or oligomenorrhea, hirsutism, clitoromegaly, or acne. Ultrasound of the pelvis will show a polycystic ovarian morphology picture, and such patients are often labeled as having PCOS.

Serum cortisol level of <50 ng/mL with 17-hydroxyprogesterone (17-OHP) of >10,000 with high 24-hour urinary 17-ketosteroid is definitive of a diagnosis. In cases of nonclassical CAH, a Synacthen test will have to be done.

Synacthen Test

Synacthen (synthetic ACTH) testing is done to detect cases of CAH. A fasting early morning 17-OHP, cortisol, and ACTH are done, followed by an injection of Synacthen 250 mg intravenously. Repeat measurement of 17-OHP and cortisol is done after 30 minutes. Heterozygotes and homozygotes for 21-hydroxylase deficiency will have 17-OHP of 35 and >60 nmol/L.

Management[18]

All newborns with ambiguous genitalia must undergo a karyotype, abdominal scan to look for the uterus and ovaries, and a screen for CAH.

Extensive psychological support is required for all individuals suffering from CAH in all its spectrums, as issues of gender identity and infertility are common.

Glucocorticoids supplementation is the mainstay of treatment in late-onset CAH in symptomatic individuals. Counseling is also needed about the possibilities of the conception of a child with classical CAH.

ENDOCRINE-DISRUPTING COMPOUNDS

Manmade synthetic chemicals in pesticides, heavy metals, additives, and contaminants in food and personal products have been known to alter reproductive functions in both males and females. They have been thought to be responsible for the increased incidence of breast cancers, alteration in growth patterns, preterm labor, decreasing age at puberty, abnormal semen parameters, immune abnormalities, and neurodevelopmental delay in children.

Endocrine-disrupting compounds (EDC) are defined as exogenous synthetic chemicals or a mixture of chemicals that interfere with any aspect of hormone action.[19]

They can be inhaled in the air, ingested by food, water, absorbed through the skin, transferred across the placenta, or secreted in the breast milk. These chemicals have been identified by the WHO as an important cause of morbidity and mortality, with pregnant women and children being most vulnerable to their exposure.

The United Nations Environment Programme and WHO have released a joint statement on EDC and its effect on various aspects of fertility and the endocrine system. Policies must be made to reduce exposure and thereby reduce morbidity due to EDC.

CONCLUSION

Endocrine disorders affecting reproduction can have multiple etiology. This is especially pertinent when evaluating the infertile patient. Attention must be given to the common organs affecting reproduction—hypothalamus, pituitary, thyroid, adrenal gland, and ovaries. Each of these may individually or in synchrony affect reproduction. It is essential to individualize treatment based on a careful evaluation of the same.

CHAPTER 12

Hirsutism

Anjali Sharma

INTRODUCTION

Hirsutism is defined as the presence of terminal coarse hairs in a female in the androgen-dependent areas in a male-like pattern.[1] The prevalence of hirsutism is around 5–10%, and many women present in the dermatology department for cosmetic reasons.[2] Hirsutism is usually seen in patients with hormonal imbalance although very rarely may be associated with androgen-producing tumors. It is very important to identify the exact cause and offer appropriate treatment accordingly. Due to a generous contribution from adrenals and ovaries, these women are characterized by increased levels of androgens in their blood.[3] Sometimes, hirsutism can be idiopathic, where androgen levels are normal.

NORMAL DEVELOPMENT AND REGULATION OF GROWTH

Out of 50 million hair follicles distributed over the entire body, 100,000–150,000 are present on the scalp. Lips, palms of hands, and soles of the feet are the hairless areas of the body.

Hairs are classified into three categories based on their structure **(Fig. 1)**:

1. Lanugo is a soft hair that covers the skin of a neonate and gets shed off between the first and the fourth month of the postnatal phase of life.
2. Vellus hairs are longer than lanugo hairs but are similar in their texture. Vellus hairs cover the allegedly hairless areas of the body and are generally nonpigmented with a length of <2 mm.
3. Terminal hairs are longer, pigmented, and coarse in texture. The body and facial hair of men along with the eyelashes, eyebrows, scalp, axillary, and pubic hair in both sexes are terminal in nature.[4] Terminal hairs are often illustrated as being "medullated." The "medulla" is the innermost area of a terminal hair follicle and is made-up of a "collapsed protein", although the exact composition of this portion is still unknown. The lanugo and vellus hairs are nonmedullated.

There are three phases of hair growth shown in **Figure 2**.

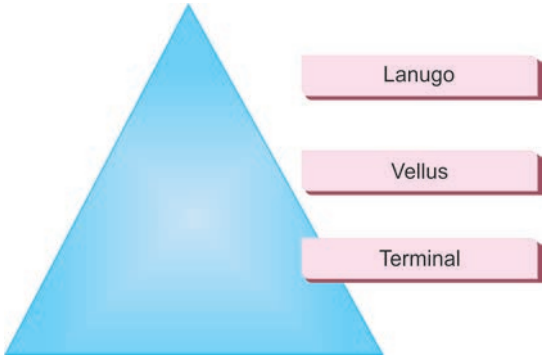

Fig. 1: Classification of hairs based on their structure.

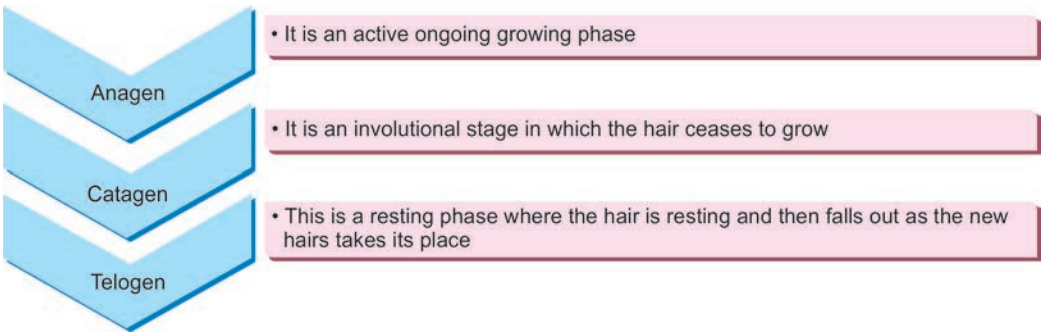

Fig. 2: Three phases of hair growth.

The hairs seem to be growing continuously due to the asynchrony in the growth phase of different hair follicles; some hairs are in the active phase while others are in the resting phase and vice versa, giving the illusion of continuous growth.

Regulatory Factors in Hair Growth

- *Local and systemic factors:* Various growth factors and cytokines have been observed to affect the hair growth.[5] These factors act by increasing the synthesis of stromelysin, which is a matrix metalloproteinase that acts on the dermal papilla to boost the growth of the hair follicle.

  Other hormones such as thyroid and growth hormone can also affect the hair growth. The anagen–telogen ratio in the scalp gets changed due to the deficiency of these hormones.[6,7] So, when patients with hypothyroidism and growth hormone deficiency are treated, regrowth of scalp hairs is seen within approximately 8 weeks, which is not associated with an increase in circulating androgens in the dermal papilla.[8]
- *Sex steroids:* The type and distribution of hairs are determined by the androgen levels in the body. The main androgens in the serum of a woman with a normal menstrual cycle in decreasing order of serum levels are dehydroepiandrosterone sulfate (DHEA-S), DHEA, androstenedione, testosterone, and dihydrotestosterone (DHT) **(Fig. 3)**.

  Testosterone and DHT activate androgen receptors, which result in gene transcription. DHEA, DHEA-S, and androstenedione are considered to be prohormones as they do not bind to the androgen receptors. Androgens can transform the hair follicles that produce vellus-type hairs into terminal hairs.

Androgens act in the following ways:

- They result in the shortening of the anagen phase of scalp hairs while prolonging the anagen phase of body hairs.[9]
- Sebaceous glands are also activated by androgens, which result in sebum production.

Hirsutism is a result of the interaction between the local androgen concentration, circulating androgen levels, and the sensitivity of the hair follicles to androgens. Yet, it has been seen that the severity of hirsutism is not associated with high androgen levels. There is an interindividual variation in the response of hair follicles to the circulating androgen levels explaining the varied response. However, some women with raised androgen levels are asymptomatic, and others may have seborrhea, acne, or alopecia even with normal androgen levels.

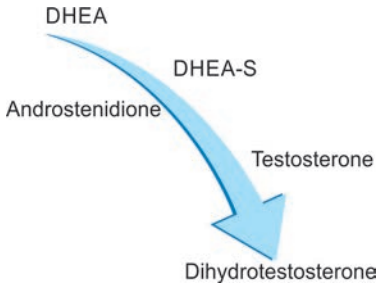

Fig. 3: Main androgens in the serum of a woman with a normal menstrual cycle in decreasing order of serum levels. (DHEA-S: dehydroepiandrosterone sulfate)

Hypertrichosis is a clinical entity that needs to be differentiated from hirsutism, where excessive growth of vellus hair is seen, which can be due to the intake of certain medications, such as glucocorticoids, phenytoin, minoxidil, and cyclosporine, or can be hereditary in nature. The hairs are distributed in a generalized nonsexual pattern.

DIAGNOSIS OF HIRSUTISM

Several hirsutism scoring systems are available, of which the modified Ferriman–Gallwey score **(Fig. 4)** has now become the gold standard for the evaluation of hirsutism.[10]

This method scores 9 out of the 11 body areas (upper lip, chin, chest, upper and lower back, upper and lower abdomen, arm, forearm, thigh, and lower leg).

- *Score 0:* If terminal hair growth is not seen in the above areas
- *Score 1:* Minimally visible terminal hair growth is present
- *Score 2:* If hair growth is more than minimal, but not equivalent to that of an adult male.
- *Score 3:* If hair growth is that of a not very hairy male
- *Score 4:* Observed in well-virilized healthy adult males

Total scores range from 0 to 36.

Hirsutism has been graded as:

- *Mild:* Up to a score of 15
- *Moderate:* For a score of 16–25
- *Severe:* Above the score of 25.

ETIOLOGY OF HIRSUTISM

Figure 5 shows the etiology of hirsutism.

- *Idiopathic hirsutism:* This term is used when a hirsute patient has normal ovulatory cycles and normal androgen levels. The pathophysiology is presumed to be the increased activity of 5α-reductase enzyme or an alteration in the androgen receptor function. It is seen in 4–7% of the patients.
- *Ovarian causes:*
  - *Polycystic ovarian syndrome (PCOS):* It is an endocrine disorder, which is seen in around 70%[11] of women with hirsutism. PCOS is characterized by oligoovulation or anovulation, hyperandrogenism (HA) (either clinical or biochemical), and the presence of polycystic ovaries on ultrasound. Classical anovulatory form is most common, while ovulatory form which is less common is seen in around 20% of the patients.
  - *Ovarian neoplasm:* Very rarely, women with ovarian malignancies, which include arrhenoblastoma,

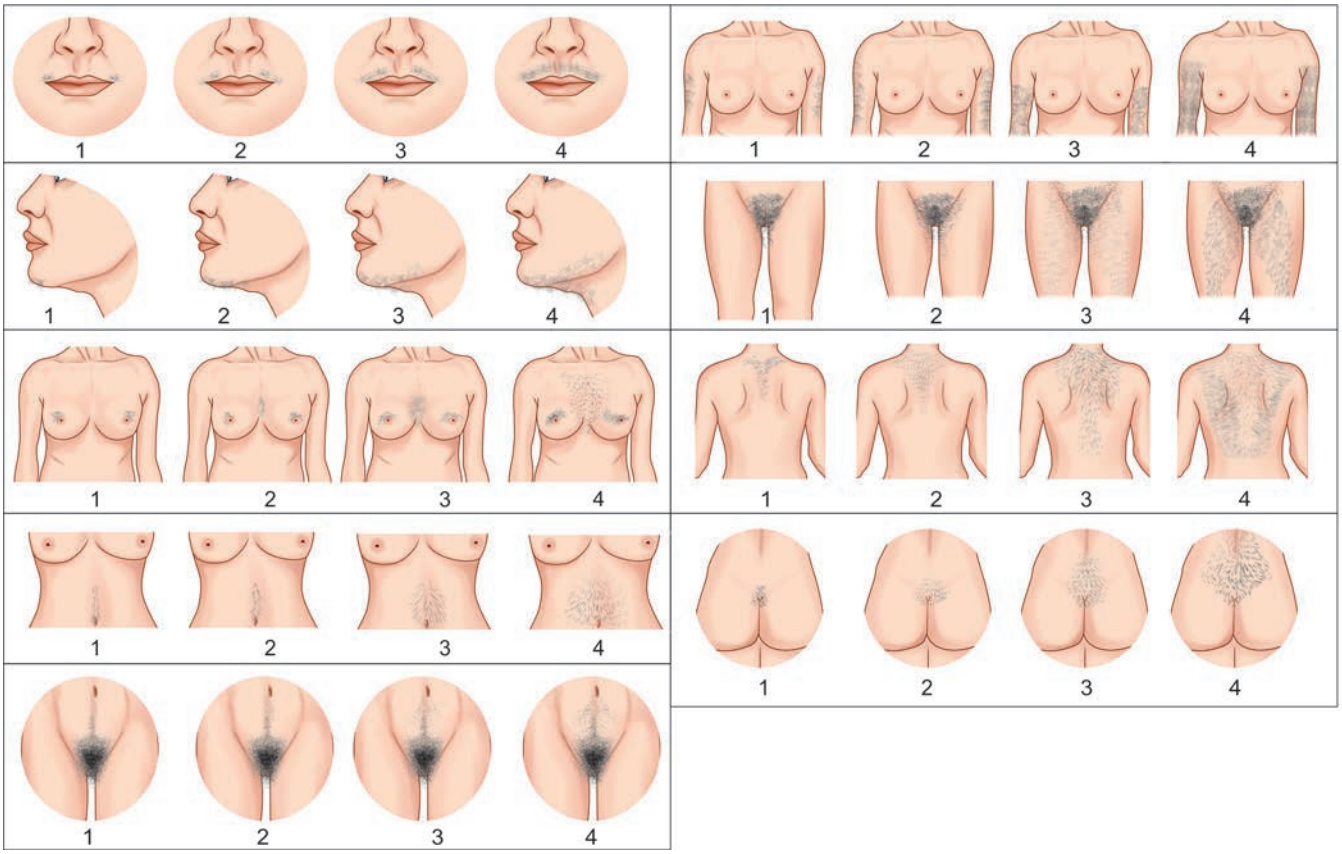

Fig. 4: Modified Ferriman–Gallwey (F–G) hirsutism scoring system. Each of the nine body areas is rated from 0 (absence of terminal hairs) to 4 (extensive terminal hair growth), and the numbers in each area are added for a total score. A modified F–G score ≥6 generally defines hirsutism.

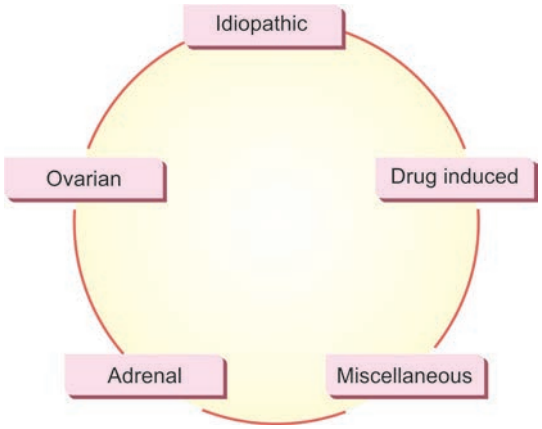

Fig. 5: Etiology of hirsutism.

Leydig cell tumor, and hilus cell tumor, can also present with hirsutism.

- *Adrenal causes:*
  - *Enzymatic deficiencies:*
    - 21-Hydroxylase deficiency (P-450c21)
    - 11β-Hydroxylase deficiency (P-450c11)
    - 3β-Hydroxysteroid dehydrogenase deficiency.

Adrenal hyperplasia is seen in around 5% of the patients with hirsutism, where due to a defect in adrenal cortisol synthesis, the precursors are redirected into the androgen synthesis pathway. Cases of classic adrenal hyperplasia are diagnosed at birth by ambiguous genitalia, while nonclassical congenital adrenal hyperplasia (NCCAH) can remain undiagnosed till puberty, when women develop menstrual irregularity along with anovulatory cycles and hirsutism.

  - *Neoplasms:*
    - Virilizing adrenal adenoma
    - Virilizing adrenal carcinoma.

These are very rare causes that are present in <0.2% of cases of hirsutism.

- *Drug induced:* Various medications that have been implicated as a cause of hirsutism are listed here:
  - Carbamazepine
  - Clonazepam
  - Corticosteroids
  - Cyclosporine
  - Diazoxide
  - Donepezil
  - Estrogens
  - Fluoxetine
  - Interferon alfa
  - Isotretinoin
  - Lamotrigine
  - Olanzapine

TABLE 1: History and the physical examination of hirsutism.

History	*Physical examination*
• Onset of symptoms whether slow or sudden with the extent of hair growth • Menstrual and reproductive history (PCOS patients may present with menstrual irregularities with infertility) • Weight gain • Breast discharge • Medication history • Skin changes (acne, striae) • Symptoms of virilization (changes in voice, atrophy of breast and muscle mass, amenorrhea, etc.) • Use of hair removal methods • Family history (idiopathic hirsutism may be familial)	• Height, weight, and blood pressure (hypertension may be seen in patients with nonclassical CAH) • Documentation of hair amount distribution • Skin changes (i.e., acne, seborrhea, thick dark velvety skin at the back (seen in acanthosis nigricans) • Galactorrhea • Signs of Cushing's syndrome (central obesity, abdominal stria, muscle weakness, and moon-like faces) • Signs of virilization • Abdominal and pelvic examination

(CAH: congenital adrenal hyperplasia; PCOS: polycystic ovarian syndrome)

- *Miscellaneous:* Many patients with hypothyroidism, acromegaly, Cushing's syndrome, and hyperprolactinemia can present with signs and symptoms of hirsutism. HAIR-AN syndrome[2] is another cause of hirsutism, which is defined as a constellation of HA, insulin resistance (IR), and acanthosis nigricans (AN).

INVESTIGATIONS AND MANAGEMENT

History and Examination

A complete and precise clinical history along with the physical examination, including the Ferriman–Gallwey scoring system, remains instrumental for the diagnosis of hirsutism. Idiopathic hirsutism shows an onset at the time of puberty with a slow progression over the years **(Table 1)**.[12]

Hormonal Evaluation (Table 2)

Free testosterone level measurement is of utmost importance as compared to the total testosterone level for the diagnosis of hyperandrogenic disorders. The significance of measuring serum androstenedione and DHEA-S levels in patients with hirsutism is questionable.[13]

Other hormonal evaluation may include:

- *Tests to rule out NCCAH:*
  - Cosyntropin stimulation test
  - 17α-Hydroxyprogesterone level >1,000 ng/dL is taken as cut-off for the diagnosis.
- Serum prolactin levels—if the patient presents with irregular menstruation and galactorrhea

Metabolic Profile

For a patient presenting with obesity and PCOS, the recommended tests, including metabolic screening should be:

- Measurement of blood pressure, waist circumference, and body mass index (BMI)
- Complete lipid profile, including total cholesterol, low-density lipoprotein cholesterol, nonhigh-density lipoprotein (HDL) cholesterol, HDL cholesterol, and triglycerides
- *A 2-hour post 75 -g oral glucose tolerance test:* In patients with a family history of type 2 diabetes, personal history of gestational diabetes, or advanced age (>40 years), this test is recommended.

TABLE 2: Hormonal evaluation.

Androgen	*Normal value in females*
Total testosterone	20–80 ng/dL
Free testosterone	0.3–1.9 ng/dL
Bioavailable testosterone	0.8–10 ng/dL
Free androgen index (T/SHBG × 100)	0.7–1
Androgen-producing tumors	>200 ng/dL

(SHBG: sex hormone-binding globulin; T: testosterone)

Ultrasound Evaluation

In addition to clinical findings and hormonal assays, ultrasound evaluation is also helpful in the evaluation of any patient with hirsutism. Ultrasound is helpful in the detection of polycystic ovarian morphology; it is also helpful in the detection of other rare disorders, such as NCCAH or androgen-secreting tumors.

TREATMENT AND MANAGEMENT

Treatment of hirsutism depends on various factors such as the severity of the condition and the amount of distress it is causing to the patient. A decision regarding the mode of treatment depends on the reproductive status of the patient; also, we need to take into consideration the potential side effects. The women should be well educated about the principles of management that the treatment will never be curative and it may take several months before the effects of treatment to become evident and the need for monitoring by an expert **(Fig. 6)**.

Lifestyle Modifications

Obesity is associated with increased serum androgen levels, and it has been seen that weight reduction improves the efficacy of other medical treatments. It has been noted that weight reduction results in a decrease in total and free testosterone and an increase in sex hormone-binding globulin (SHBG) levels; however, there is no convincing evidence to support the reduction in hirsutism following such measures.[14]

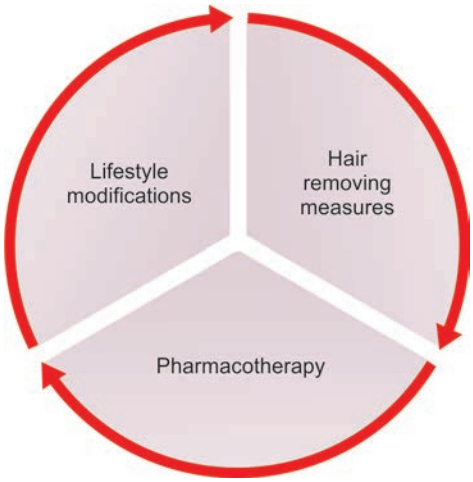

Fig. 6: Treatment and management of hirsutism.

Hair-Removing Measures

Various methods of hair removal are available, which may be used as a temporary measures or permanent measures **(Table 3)**.

Pharmacological Measures

Drug therapy is advocated for those patients who do not have any fertility issues. However, the efficacy of these drugs varies from person to person. Various pharmacological agents that can be used have been listed here.

Oral Contraceptive Pills

Combined oral contraceptives (OC) act by reducing the free androgen levels by increasing SHBG and inhibiting ovarian androgen production. The Endocrine Society recommends OC as the first-line medication for those women where infertility is not an issue.[1] Third-generation oral contraceptive pills (OCPs) are better in terms of efficacy; however, second-generation OCPs are better in terms of safety profile.

Antiandrogens

Table 4 shows list of drugs, their dose, and side effects.

While prescribing an antiandrogen, the following things should be taken into consideration:

TABLE 3: Temporary and permanent measures of hair removal.

Temporary methods	***Permanent methods***
Shaving: It is a simple, easy, and effective method, but has to be done at regular intervals. Also, the regrowth of hairs is coarser in nature because of the tip, which is blunt rather than tapered	*Electrolysis:* It is not a very popular method due to the pain. Also, it is a time-taking procedure because every follicle needs to be removed individually. It is of two types: Galvanic and thermal
Chemical depilation: It acts by dissolving the hairs, but may result in inflammation and dermatitis	*Laser therapy:* It is a more accepted form of treatment as it is less agonizing and faster than electrolysis, but it is relatively an expensive form of therapy. A recent Cochrane review of hair removal methods has found it to be less effective.[15] Diode and Alexandrite lasers are commonly used, and they reduced hair by almost 50%. Laser therapy works best in light-skinned women. Hyperpigmentation is a common adverse effect
Epilation methods: These include waxing or plucking, which removes the hairs from the roots, but comes with the side effects of folliculitis, hyperpigmentation, and sometimes scarring	

TABLE 4: List of drugs, their dose, and side effects.

Type of drug	***Drug***	***Dose***	***Side effects***	***Comments***
Androgen receptor blocker	Spironolactone	100–200 mg/day	Hyperkalemia, mild diuretic effect, postural hypotension, and irregular menses	Because of the dangers of antiandrogenic effects on fetal genital development, it is recommended that spironolactone should be given along with an oral contraceptive agent
	Cyproterone acetate	2 mg along with 35 µg of ethinylestradiol as a contraceptive pill	Nausea, fatigue, mastalgia, loss of libido, and weight gain	Should be given with ethinyl estradiol to prevent menstrual irregularities and ovulation
	Flutamide	250–750 mg/day	Liver toxicity	It is not approved for the treatment of hirsutism by the Endocrine Society because of the risk of liver failure
5α-Reductase inhibitor	Finasteride	5–7.5 mg/day	Gastrointestinal disturbances, headache, dry skin, and decreased libido	

- It can be combined with OCPs in women who do not reach a satisfactory result using OCPs alone after 1 year of treatment.
- It can be used as a single agent where OCPs are contraindicated, provided that the patient is using a reliable contraceptive method.

Topical Eflornithine

Eflornithine (13.9%) is a topical agent that reduces hair growth by inhibiting the enzyme ornithine decarboxylase, which catalyzes the conversion of ornithine to putrescine, a polyamine that is required to regulate the cell growth and differentiation within the hair follicle.[16] The effect is seen after 8 weeks of the therapy. It can be used alone or in conjunction with other therapies. However, it has been observed that the hair growth restarts after the discontinuation of the therapy. Eflornithine is currently approved for the treatment of unwanted facial hairs only.

Insulin Sensitizers

Insulin sensitizers improve IR and menstrual dysfunction and may decrease serum androgen concentrations.[17] According to a recent Cochrane review, in adult women with PCOS and hirsutism, either metformin alone or the OCP alone may be less effective in improving hirsutism as compared to metformin combined with the OCP.[18]

Miscellaneous Agents (Fig. 7)

- *Glucocorticoids:* The role of glucocorticoids in the treatment of hirsutism is controversial. They may be used in patients with NCCAH along with antiandrogens for better remission.[19] The drug used is prednisolone with a dosage of 5–10 mg daily. Currently, available studies suggest that they are less effective as compared with OCPs and antiandrogens.[20]
- *Ketoconazole:* It is an adrenal enzyme inhibitor that is used at a dosage of 400 mg/day. However, due to its side effects such as hepatotoxicity, its use is limited to the subjects of Cushing's syndrome, while waiting for definite treatment.

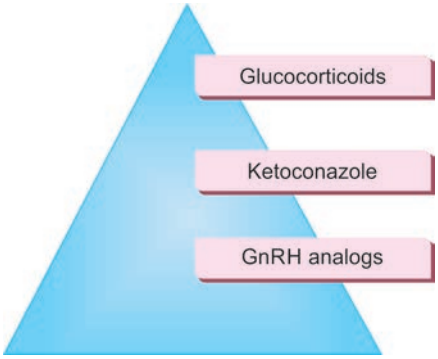

Fig. 7: Miscellaneous agents.
(GnRH: gonadotropin-releasing hormone agonist)

- *Gonadotropin-releasing hormone agonist (GnRH) analogs:* Long-acting GnRH agonists (e.g., leuprolide depot, 3.75 mg/month) have been found to be useful and may be required to suppress the hypothalamic–pituitary–ovarian axis in severely androgenized or hyperinsulinemic patients. Two to three months of treatment may be required for the full suppressive effect of the agonist to occur. GnRH analogs should be reserved for use in women who do not respond to combination hormonal therapy or those who cannot tolerate OCs. GnRH analogs should be used cautiously with particular attention to possible long-term consequences (e.g., hot flushes, atrophic vaginitis, and demineralization of bones).[21] However, due to its high cost and adverse hypoestrogenic side effects, it is generally not recommended for the treatment of hirsutism.

FOLLOW-UP

To be able to draw any conclusion about the effectiveness of any therapy, at least 6 months of treatment is required, which is the average life span of a hair follicle. If adequate response after 6 months is not seen, then we may consider switching the agents or using a combination therapy. The rationale of measuring serum androgen levels is not convincing, but if a decrease in serum androgen levels is documented during the treatment, then it may increase the patient's confidence in the therapy, especially while waiting for the clinical response to be evident.

KEY POINTS

- Hirsutism needs to be evaluated, especially if rapidly progressing, although may be idiopathic at times.
- A thorough history-taking, including history of medications and complete physical examination, needs to be done in all cases of hirsutism.
- The investigations that need to be done depend on the finding in history and examination to make a final diagnosis.
- Management again depends on the severity of symptoms and definitive diagnosis and includes both nonpharmacological and pharmacological measures.
- Any pharmacotherapy needs to be given for at least 6 months to draw any conclusion about its effectiveness.

CHAPTER 13

Luteal Phase Defect

Deepti Sharma

INTRODUCTION

- Luteal phase of menstrual cycle starts after ovulation and leads to formation of corpus luteum (CL), which produces progesterone as a major hormone.[1]
- If pregnancy is not achieved, there is a drop in progesterone levels after failure of CL, leading to onset of menses.[2]
- However, whenever there is establishment of pregnancy, CL is rescued by luteotropic effect of human chorionic gonadotropin (hCG) produced by implanting embryo. hCG supports production of progesterone from CL by upregulating steroidogenic acute regulatory (StAR) protein and vascular endothelial growth factor (VEGF) gene expression.
- The progesterone produced from CL is essential for maintenance of early pregnancy until placental function is established.
- The concept of luteal phase defect (LPD), also known as luteal phase deficiency, was first described by Georgeanna Seegar Jones in 1949 as decreased production of progesterone during the luteal phase.[3]
- The potential causes of LPD include inadequate progesterone levels, inadequate progesterone duration, or resistance of endometrium to progesterone.[4]
- Luteal phase defect leads to dysfunctional endometrial development during the interval when embryo is present in uterine cavity, which in turn leads to impairment of implantation or maintenance of pregnancy.[5,6]
- LPD has been a controversial topic with doubts regarding its clinical relevance, due to a lack of reliable diagnostic criteria and treatment options.[7]
- As of now, LPD has not been proven as an independent cause of infertility or recurrent pregnancy loss.[4]

DEFINITION

- Luteal phase defect or luteal phase deficiency is a condition in which endogenous hormone production from ovaries is not of enough quantity or for enough duration so as to maintain the secretory endometrium for embryo implantation and growth.[4]
- *Clinical LPD* is defined as a luteal phase length of ≤10 days.[8]

INCIDENCE AND PREVALENCE

- The incidence of LPD is between 6.6 and 51%, estimated by endometrial biopsy in normally fertile women.[9] Endometrial biopsy timed during luteal phase and analyzed according to Noyes criteria remains the gold standard for many years.[10]
- Its prevalence is 8.1% in normo-ovulatory primary or secondary infertile patients.[11]
- In women with recurrent miscarriages, it is about 32.5%.[12]

PHYSIOLOGY OF LUTEAL PHASE

Corpus Luteum Formation

- Luteinizing hormone (LH) surge leads to resumption of meiosis in primary oocyte in dominant follicle and release of the first polar body and secondary oocyte, and the follicle remnant forms the CL.
- Corpus luteum contains steroidogenic cells along with immune cells and endothelial cells.[13] Steroidogenic cells are derived from granulosa and theca cells of follicle.[14]
- Formation of CL is characterized by neovascularization of granulosa cells. After ovulation, tissue remodeling takes place, and blood vessels from thecal vasculature invade granulosa cells.[15] This leads to formation of CL, which is the most vascular organ with blood flow of 6–10 mL/g/min, which is highest in the body.[16]

Progesterone Production

- Following LH surge, during luteinization, granulosa cells start expressing set of genes necessary to encode for progesterone production, which includes those required for side-chain cleavage for cholesterol esters (P450scc) and 3β-hydroxysteroid dehydrogenase (3β-HSD).[17]

- Steroidogenic acute regulatory protein is required for transfer of cholesterol from outer to inner mitochondrial membrane.[18] *StAR* gene is expressed in granulosa cells only after LH surge, thus enabling them to synthesize progesterone.[19]
- For progesterone biosynthesis, CL uptakes low-density lipoprotein (LDL) and high-density lipoprotein (HDL) from blood while cholesterol esters from intracellular stores. All these are then transported inside mitochondria with the help of StAR protein, where they are converted to pregnenolone with action of enzyme P450cc, which enters cytoplasm and gets converted to progesterone by 3β-HSD.[13]
- Daily production rate of progesterone during midluteal phase is 25 mg/day[20] and is under the control of LH pulse frequency (177/min) and amplitude (0.26 mIU/mL/min).[21]
- Progesterone acts on estrogen-primed endometrium to induce secretory changes, which are necessary for implantation of embryo. During these changes, glands become tortuous and secretory, and there is increased stromal vascularity.[22]

Estrogen Production

- During luteal phase, LH acts on small luteal cells for androgen production, which is then converted to estrogen in large luteal cells with the help of enzyme P450 aromatase expressed by follicle-stimulating hormone (FSH).[23]
- In luteal cells, steroidogenic action of FSH is augmented by LH and insulin-like growth factors.[24]
- The exact role of luteal estrogen is unknown; however, in primates, it appears to play a role in luteolysis.[25] But in humans, due to the presence of both types of estrogen receptors, estrogen is supposed to have local action also in luteal function.[26]
- Daily estradiol production is 0.25 mg/day during the midluteal phase.[20]

Luteolysis

- Corpus luteum undergoes a process of regression known as luteolysis in nonfertile cycles **(Fig. 1)**. It includes loss of functional as well as structural integrity of the gland.[27]
- Functional luteal regression consists of reduced production of progesterone levels, which in turn is due to decreased expression of *StAR* gene. Other molecules, including prostaglandin F2α, tumor necrosis factor-α, interleukin-1β, endothelin, monocyte chemoattractant-1, estrogens, and reactive oxygen species, have been implicated in the luteolytic process.[28]
- For structural regression, apoptosis is one of the mechanisms along with autophagy and necrosis.[29,30] So unscheduled activation of luteolysis can lead to LPD.

Corpus Luteum Rescue

- In a fertile cycle after implantation of blastocyst, CL is rescued structurally and functionally with the help of hCG secreted by the trophoblastic cells.
- It has been shown in vitro in CL that there is increased expression of *StAR* gene expression when hCG is administered in mid- and late luteal phase, not in early luteal phase.[31] In clinical terms, it means that for luteal phase support (LPS), hCG should be given from midluteal phase.[32]
- In addition, hCG rescues CL by stimulating angiogenesis so that the second wave of vascular development takes place.[33]
- The molecular mechanism by which hCG rescues CL is not completely understood. It has been postulated that it prevents apoptosis by interfering at various stages of apoptotic process, which includes inhibition of *Fas* and *Bax* gene expression and stimulating that of B-cell lymphoma-2 (Bcl-2) and increasing survivin, a molecule that inhibits action of caspases-3.[34]

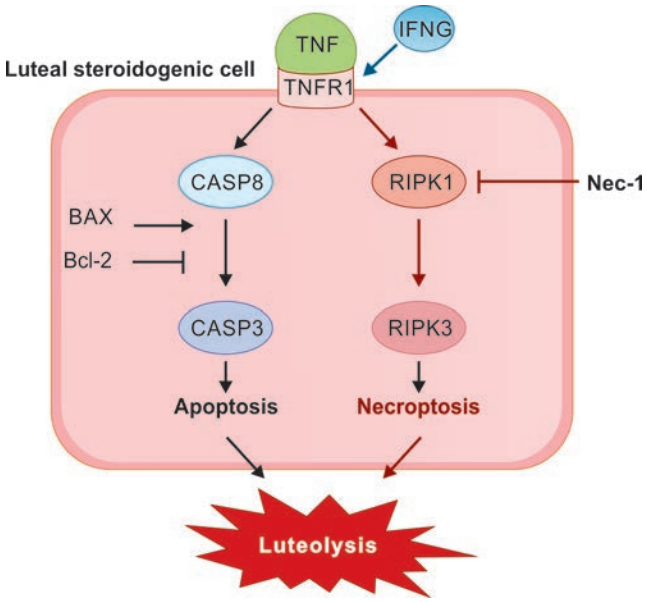

Fig. 1: Schematic representation of possible mechanisms to induce cell death in the bovine LSCs. Proinflammatory cytokines, tumor necrosis factor (TNF) and interferon-gamma (IFNG), can induce at least two cell death pathways, i.e., caspase (CASPs)-dependent apoptotic pathway and receptor-interacting serine/threonine protein kinase (RIPKs)-dependent necroptotic pathway, in the bovine luteal steroidogenic cells (LSCs). Apoptotic pathway is mediated by CASP8 and CASP3; Bcl2-associated X protein (BAX) and B-cell lymphoma-2 (Bcl-2) can play as inducer and inhibitor of apoptotic pathway, respectively. In necroptotic pathway, RIPK1 and RIPK3 play a central role to induce cell death. RIPK1 inhibitor, Nec-1, can inhibit necroptotic pathway. (BAX: Bcl2-associated X protein; Bcl-2: B-cell lymphoma-2; CASP: caspase; IFNG: interferon gamma; RIPK1: receptor-interacting serine/threonine protein kinase 1; TNF: tumor necrosis factor; TNFR1: tumor necrosis factor receptor 1.
Source: Principles and Practices of Assisted Reproductive Technology; second edition;166.

PATHOPHYSIOLOGY OF LUTEAL PHASE DEFECT IN NATURAL CYCLES

Several different mechanisms may be involved.

- *Abnormal follicular phase* leading to lower levels of luteal phase estrogen and progesterone: A follicular phase with low levels of FSH and estrogen, altered FSH/LH ratio and abnormal FSH and LH pulsatility was found to be associated with short luteal phase[8] and also with low levels of estrogen and progesterone in luteal phase.[35]
- *Endometrial resistance to progesterone:* The endometrium of patients with underlying diseases, e.g., polycystic ovarian syndrome (PCOS) and endometriosis, has been found to have altered the response to progesterone, which may lead to infertility.[36,37]
- *Abnormal luteal phase:* Various physiologic and pathologic conditions (as mentioned in **Box 1**) that lead to altered gonadotropin-releasing hormone (GnRH) and LH pulsatility can lead to abnormal luteal phase and hence to LPD.

BOX 1: Factors associated with luteal phase defect in natural cycles.[6,38-51]

- Short menstrual cycles
- Unexplained infertility
- Endometriosis
- First-trimester pregnancy loss
- Premenstrual spotting
- Excessive exercise
- Stress
- Starvation
- Eating disorders
- Extremes of reproductive ages
- Postpartum and lactation
- Renal transplant
- Thyroid and prolactin disorders
- Increased β-endorphin levels
- Obesity
- Hyperandrogenism
- 21-Hydroxylase deficiency

- *Idiopathic LPD or true isolated LPD:* It is the pathologic condition of luteal phase when no underlying disease process could be identified that is responsible for negatively affecting the normal LH support of CL.[4] However, it has not been found that idiopathic LPD can lead to infertility.[39]

PATHOPHYSIOLOGY OF LUTEAL PHASE DEFECT IN CONTROLLED OVARIAN STIMULATION CYCLES

Following the advent of controlled ovarian stimulation (COS) cycles, it was soon recognized that luteal phase was defective in COS cycles **(Flowchart 1, Fig. 2)**. Both gonadotropin-releasing hormone agonist (GnRH-a) and GnRH antagonist cycles are associated with LPD **(Box 2)**. An LPS is a must in all COS cycles to optimize the outcome.

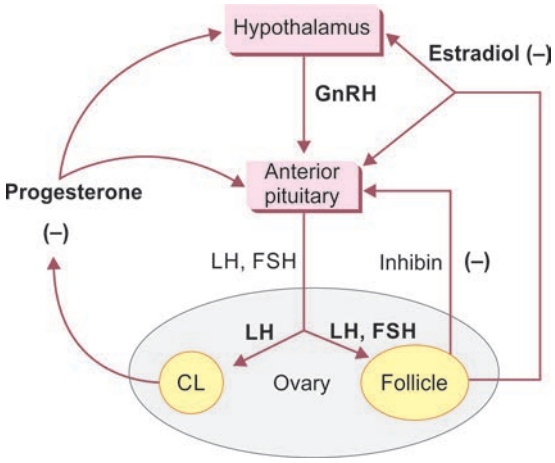

Fig. 2: Luteal phase defect due to supraphysiological steroid levels in controlled ovarian stimulation cycles. (CL: corpus luteum; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)

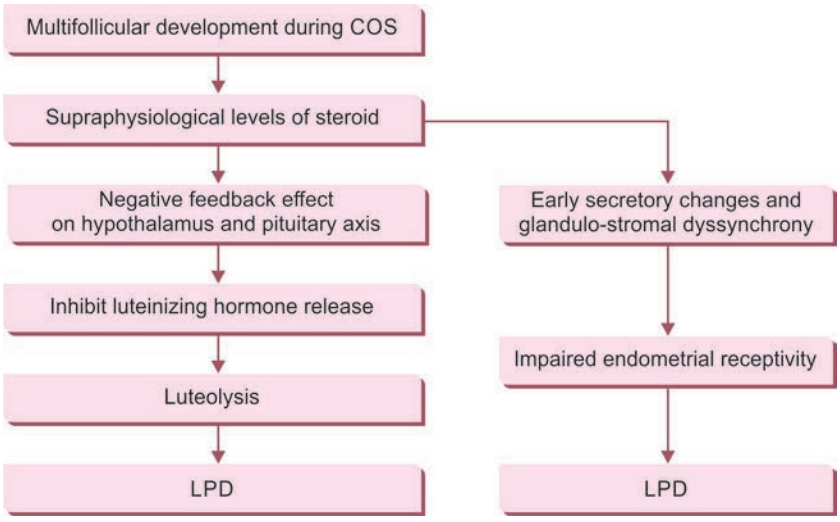
Flowchart 1: Luteal phase defect (LPD) in controlled ovarian stimulation cycles (COS).[59,60]



BOX 2: Theories regarding luteal phase defect (LPD) in controlled ovarian stimulation (COS) cycles.

- Destruction of granulosa cells during follicular aspiration, which was destined to form CL[52]
- In GnRH-a cycles, LPD is supposed to be due to prolonged suppression of pituitary LH secretion; usually for up to 3 weeks after downregulation has been achieved[53]
- In GnRH antagonist cycles, it has been found to have low levels of LH in early and midluteal phases irrespective of agent used for final oocyte maturation[54]
- Further adding GnRH-a as a trigger in antagonist cycles leads to short LH surge, which is not sufficient enough to support CL, thus leading to early luteolysis, and diminished estrogen and progesterone levels, and thereby LPD[55,56]
- Multifollicular development in COS leading to supraphysiological steroid levels leads to suppression of LH secretion from the pituitary; hence, a sufficient amount of LH is not available to support CL, thus leading to LPD[57,58]
- Various studies comparing the endometrium in COS cycles with natural cycles have demonstrated early secretory changes and glandular-stromal dyssynchrony in COS cycles leading to impaired endometrial receptivity[57]

(CL: corpus luteum; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)

DIAGNOSIS OF LUTEAL PHASE DEFECT

According to the American Society for Reproductive Medicine (ASRM) 2021 guidelines, LPD is a clinical diagnosis.[4] Various diagnostic tests have been described to diagnose, ranging from clinical to biochemical to histological.

- *Length of luteal phase of menstrual cycle*
  - Luteal phase length can be assessed by monitoring basal body temperature (BBT) or by urinary LH surge detection as they substantiate ovulation.
  - BBT method is based upon the rise in body temperature following ovulation[61] and because of its inaccuracy and inconvenience, it is no longer practiced, and the recent studies have used LH surge detection kits to detect the time of ovulation.
  - Length of luteal phase ranges from 11 to 17 days, with an average duration of 14 days.[62] A duration of <9–11 days from the day of LH peak to the onset of menses has been described as "short luteal phase" in various studies.[4,8,42]
  - In one of the recent studies, luteal phase of <10 days was found in 13% of ovulatory menstrual cycles.[8]
  - In another prospective time to pregnancy cohort study, a short luteal phase of ≤11 days was found in 18% of menstrual cycles.[63]
  - Further in this study, it was noted that women with a short luteal phase have low chances of pregnancy in their immediate next menstrual cycles, but their cumulative fecundity for over 12 months was not lower.[63]
  - Given the various durations of short luteal phase described in literature, ASRM 2021 has considered LPD as clinical when the luteal phase duration is <10 days.[4]
- *Serum progesterone levels*
  - Measurement of serum progesterone levels in response to LH during the luteal phase is one of the proposed diagnostic methods for LPD.
  - Progesterone secretion occurs in pulses in normal ovulatory cycles, and its level may fluctuate up to eight times in 90 minutes;[64] therefore, single random serum progesterone value is not of any significance.
  - In one of the recent studies, it was shown that even in ovulatory cycles 8.4% times luteal progesterone is <5 ng/mL, which is called "biochemical LPD" and 31.3% times it is <10 ng/mL.[8]
  - Although it was suggested that the sum of three midluteal levels taken between 5 and 9 days post ovulation when >30 ng/mL has 100% sensitivity and 80% specificity,[65] this has neither been clinically validated nor is clinically practical.
  - Furthermore, the function of CL varies from cycle to cycle in fertile women, so progesterone levels cannot be taken as a diagnostic tool for LPD.[4]
- *Menstrual cycle length and luteal serum progesterone levels combined together*
  - In BioCycle study, it has been proposed to diagnose LPD by combining clinical LPD (luteal phase length <10 days) and biochemical LPD (midluteal serum progesterone <5 ng/mL), which had an 8.2% prevalence in the study.[8]
  - This study has paved the path for future clinical research in the direction of this diagnostic tool for LPD.
- *Endometrial biopsy and other endometrial markers*
  - Histological analysis of endometrial biopsy tissue is considered a means to determine the presence of adequate progesterone production during the luteal phase.
  - Any abnormality in this has been considered as a gold standard for LPD diagnosis in previous studies.[66]
  - With time, as the research has advanced, it has been shown that for implantation, it is not only the microscopic endometrial appearance that is important it also involves various other factors, e.g., cytokines, pinopodes, growth factors.[67,68]
  - Further, endometrium maturation may vary from one endometrial region to other; hence, the clinical criteria that define luteal phase endometrial development accurately are still evolving and under research.[4]
  - A randomized controlled study (RCT), which has included regularly cycling fertile females, concluded

that histological endometrial dating has considerable intrasubject, intersubject, and interobserver variabilities. It does not have accuracy to provide as a method to diagnose luteal phase insufficiency or to guide in the management of females with reproductive failures.[69]
- Another multicentric RCT that included 847 women with regular menstrual cycles to assess the ability of histological dating to discriminate between the women of fertile and infertile couples has shown that out-of-phase biopsy results poorly discriminate between women in fertile and infertile couples in either midluteal or late luteal phase.[70]
- Hence, these studies have confirmed that histological endometrial dating via endometrial biopsy is neither a valid diagnostic tool for identification of infertile population nor suitable for diagnosis of LPD.
- As far as markers for endometrial receptivity are concerned, there has been no RCT that is validated to differentiate fertile and infertile women. It is still experimental and not a valid tool to diagnose LPD.[4]

Hence,

- According to ASRM practice committee guidelines 2021, at present, there is no reproducible and clinically practical and gold standard method to diagnose LPD and to differentiate infertile and fertile women.[4]
- It does not recommend the luteal phase progesterone, endometrial biopsy, or other tests to diagnose LPD.[4]

COLOR DOPPLER IN LUTEAL PHASE DEFECT

- During normal menstrual cycles, resistance index (RI) of preovulatory follicle (0.4–0.48)[71] decreases following ovulation (RI 0.35–0.50),[72] and it further decreases till late luteal phase, when it again increases in nonconception cycles.
- RI of CL is suggested to correlate with plasma progesterone levels as an index of luteal function.[73]
- In LPD, RI of CL is increased (RI: 0.52–0.60) and maintained throughout the luteal phase.[74]
- In LPD, endometrium appears thin and nonechogenic with increased resistance in spiral arteries (RI 0.66–0.72). This may be an underlying mechanism in unexplained infertility.[75]

TREATMENT OF LUTEAL PHASE DEFECT

- The first and foremost thing to consider in the treatment of LPD is to identify any underlying cause for it (e.g., thyroid dysfunction, hyperprolactinemia) and to treat accordingly. If, however, no underlying cause is found (i.e., idiopathic or true isolated LPD), the treatment becomes empirical and has very minimal reliable data available.
- Empirical treatment consists of treatment to promote endometrial maturation, enhance endometrial receptivity, support implantation and development of early pregnancy.
- It includes:
  - Supplementation in the form of luteal phase progesterone, estrogen, hCG, and GnRH-a
    or
  - Ovulation induction: It has been postulated that there is a continuity between follicular and luteal phases, and improved preovulatory follicular development leads to improved CL function.

Clomiphene Citrate

- Luteal phase LH levels were found to be higher in clomiphene citrate (CC) cycles as compared to that with gonadotropins.[76] When CC is administered, it causes occupancy and depletion of estrogen receptors in the hypothalamus. This leads to increase in endogenous FSH and LH secretion resulting in higher estrogen (E) and progesterone (P4) levels in the luteal phase. The ability of CC to augment CL function has led to its potential use as a treatment modality for patients with inadequate luteal phase endogenous P4 secretion.[12,77]
- In a systematic review and meta-analysis by Hill et al., it has been concluded that there is no role of luteal phase progesterone supplementation in patients undergoing ovulation induction with CC.[78]
- However, in a study by Cook et al., it has been concluded that CC use may be associated with a high risk of LPD induction as diagnosed by endometrial biopsy, except in women with PCOS.[79]
- However, ovulation induction has not been found to be a treatment modality for LPD.[80,81]

Progesterone

- Besides inducing secretory changes in endometrium, progesterone also:
  - Improves endometrial receptivity in estrogenized endometrium[82]
  - Stabilizes lysosomal membrane, which leads to quiescent uterus[82]
  - Leads to uterine relaxation by blocking chemokines which cause inhibition of prostaglandin synthesis, reduce calcium intracellularly, and help in nitric oxide synthesis[82]
  - Has immunomodulatory effect, and it prevents the conceptus from rejection along with hCG and cortisol[82]
  - Regulates natural killer cells, HOX10, and human leukocyte antigen (HLA) genes, thus, positively shifting to TH2 cell type[83]

- It is thus considered the mainstay of treatment for LPD.
- Cochrane systematic review 2015 has established the beneficial effect of progesterone on live birth and ongoing pregnancy rates in in vitro fertilization (IVF) cycles, irrespective of its route of administration.[84]
- European Society of Human Reproduction and Embryology (ESHRE) Ovarian Stimulation for IVF/intracytoplasmic sperm injection (ICSI) 2019 guidelines has recommended progesterone for LPS in IVF/ICSI cycles.[85]
- Also, Cochrane Database of Systematic Reviews 2019 has shown that progesterone supplementation therapy in women with unexplained recurrent miscarriages may reduce the risk of miscarriage in subsequent pregnancies.[86]
- However, in a multicentric, double-blind, placebo-controlled, and randomized trial, progesterone use in first trimester has not been shown beneficial in terms of live births in women with unexplained recurrent miscarriage.[87]
- Progesterone can be given orally, intramuscularly, vaginally, subcutaneously, and rectally.
- As of now, the only well-documented evidence of intramuscular or vaginal progesterone in luteal phase is in assisted reproductive technology (ART), GnRH-a, and antagonist cycles.[88,89]
- There is no evidence that progesterone use is beneficial in unstimulated cycles.
- Intramuscular or vaginal route of natural progesterone administration yields better results than oral micronized form of natural progesterone due to less bioavailability of oral progesterone.[90]
- ESHRE ovarian stimulation for IVF/ICSI 2019 guidelines recommends the use of any of the above-mentioned routes except the oral, for natural progesterone as LPS.[85]
- Oral synthetic form of progesterone is now emerging as an option for LPS.
- A recent meta-analysis including eight randomized controlled trials (RCTs) with 3,386 women has reported similar reproductive outcomes of oral dydrogesterone as compared to vaginal progesterone in terms of live birth/ongoing pregnancy rate.[91]
- Lotus I trial, a multicentric RCT, has shown noninferiority of oral synthetic progesterone in a dose of 10 mg TDS as compared to micronized vaginal progesterone (MVP) (200 mg thrice daily) in terms of clinical pregnancy and live birth rates.[92]
- Lotus II trial, a randomized multicentric trial conducted in 10 countries, has also demonstrated the noninferiority of 30 mg daily of dydrogesterone to 8% MVP gel (90 mg daily) for the presence of fetal heartbeat at 12 weeks of gestation in fresh IVF cycles.[93]
- ESHRE guideline has recommended the probable use of dydrogesterone as LPS.[85]
- Progesterone supplementation is to be started in the window from the evening of the day of oocyte retrieval till day 3 after it[85,94] and is usually administered until the first positive β-hCG test.[85,95]

Human Chorionic Gonadotropin

- Due to structural similarity of hCG with LH, supplementation with hCG in luteal phase stimulates corpora lutea to secrete endogenous estrogen and progesterone in ART cycles.
- It has been documented that delivery rates are more and miscarriage rates are less in ART cycles supplemented with hCG as compared with those without hCG.[88,89]
- However, hCG supplementation is associated with the risk of ovarian hyperstimulation syndrome (OHSS). Cochrane 2015 has shown that the risk of OHSS is less with progesterone as compared to hCG.[84]
- ESHRE 2019 guidelines do not recommend hCG as LPS in hCG-triggered ovarian stimulation cycles.[85]

Estrogen

- As after luteolysis, there is deficiency of estrogen also; it has been postulated that estrogen along with progesterone is required in IVF cycles.
- A recent meta-analysis has shown the beneficial effect of progesterone plus estradiol on clinical pregnancy rates [odds ratio (OR) 1.617; confidence interval (CI): 1.059–2.471; $p = 0.026$] as compared to progesterone alone.[96]
- In an RCT by Turgut et al., it has been concluded that in ART cycles with GnRH-a protocol, addition of 4 mg of estrogen along with progesterone in luteal phase leads to significantly increased pregnancy and implantation rates and decreased miscarriage rates as compared to progesterone alone.[97]
- However, Cochrane Systematic Analysis 2015 has shown no significant benefit of adding estrogen in terms of ongoing pregnancy rate and live birth rates.[84]
- ESHRE 2019 guidelines do not recommend the addition of estradiol to progesterone as LPS.[85]

Gonadotropin-releasing Hormone Agonist

- Various hypotheses of beneficial effect of GnRH-a in ART cycles are:
  - Direct support of CL by secretion of LH from pituitary or by acting at GnRH receptors on endometrium[98]
  - Direct effect of GnRH on embryo has also been postulated as there is evidence of increased hCG secretion[99]
- In a study by Bar-Hava et al., intranasal GnRH-a (nafarelin 400 μg/day) was found to be an effective LPS in itself without progesterone; in GnRH-a triggered fresh embryo transfer cycles in high responders and it also helps in avoiding OHSS.[100]

- In an RCT, it was found that administration of 0.1 mg Decapeptyl bolus on day 6 after oocyte retrieval, in addition to routine LPS, can lead to improved implantation and pregnancy rates in women with previous IVF failures.[101]
- A recent meta-analysis by Song et al. including eight RCTs has shown that administration of a single dose of GnRH-a on day 5/6 after oocyte retrieval along with regular LPS led to higher clinical, ongoing, and even multiple pregnancy rates per transfer in GnRH antagonist downregulated IVF cycles but not in long-acting GnRH-a cycles.[102]
- Another evidence is from Cochrane Systematic Review 2015, including seven RCTs and 1,708 women, which has shown that the live birth and ongoing pregnancy rates were lower in the progesterone-only group than the progesterone plus GnRH-a group (OR 0.62, 95%; CI 0.48–0.81).[84]
- ESHRE 2019 guidelines recommend the use of GnRH-a as LPS in hCG-triggered IVF/ICSI cycles only in clinical trials.[85]

IN NATURAL CYCLES

- According to ASRM practice committee guidelines of 2021, there is no treatment of LPD to improve pregnancy rates in natural and unstimulated cycles.[4]
- There is no evidence that progesterone use is beneficial in fertility treatment in natural cycles and in the LPD treatment.[4]
- As of now, there is no evidence to support routine use of progesterone to prevent miscarriage in early and mid-pregnancy, although some benefit is found in unexplained recurrent miscarriage patients.[86]

IN INTRAUTERINE INSEMINATION CYCLES

- Systematic review and meta-analysis by Katherine et al., including 11 RCTs, have demonstrated benefit of supplementing progesterone in intrauterine insemination (IUI) cycles in terms of clinical pregnancy rate and live birth rate.[103]
- Furthermore, benefit of progesterone in luteal phase has been found only in IUI cycles where ovulation induction was achieved with exogenous gonadotropins and not with CC or both gonadotropins and CC.
- This can be explained by the effect of exogenous gonadotropins on ovaries leading to increased serum estradiol levels, which will exert negative feedback effect on the hypothalamus–pituitary axis leading to abnormal LH secretion and thereby reduced progesterone secretion from CL.[59]
- While in CC cycles, due to antiestrogenic effect of CC on hypothalamus, there is increased LH secretion from pituitary.[104]

IN CONTROLLED OVARIAN STIMULATION CYCLES

- For LPS in IVF cycles, vaginal progesterone is the mainstay of treatment because of the ease of administration and efficacy equivalent to intramuscular form.[105]
- It is directly absorbed avoiding first-pass metabolism and having higher progesterone concentration in the endometrium as compared to serum.[106]
- However, vaginal progesterone use may lead to vaginal irritation, discharge, and bleeding[84] and hence there is emerging research to use oral synthetic progesterone.
- In Lotus I and II trials, oral synthetic progesterone has been proven noninferior to vaginal progesterone in fresh embryo transfer IVF cycles and is probably recommended for LPS in IVF/ICSI cycles.[85,92,93]
- Progesterone can be started from the day of oocyte retrieval to 2 or 3 days thereafter without affecting the ongoing pregnancy rates,[107] and usually continued till 8 weeks of pregnancy or longer; most studies have shown no benefit of progesterone support after positive hCG.[85,95]
- Although hCG can be used, it is better avoided in patients having a higher risk of OHSS.[89]

IN FROZEN EMBRYO TRANSFER CYCLES AND DONOR–RECIPIENT CYCLES

- There are various protocols for frozen embryo transfer (FET) cycles depending upon the method of endometrial preparation used.
- Natural cycle FET does not involve exogenous hormone use for endometrial preparation.
- Whereas in artificial FET cycles and in donor–recipient cycles, exogenous estrogen is given for endometrial proliferation, and exogenous progesterone is given to induce secretory changes.
- In these artificial and donor–recipient cycles as there is no CL, there is no source of progesterone to support pregnancy.
- After embryo transfer, progesterone and estrogen supplementation is given.
- As evidenced by a randomized trial, there is no difference in ongoing pregnancy rate while comparing intramuscular to vaginal progesterone in donor–recipient cycles.[108]
- However, in a recent meta-analysis, it has been shown that the use of vaginal progesterone in natural FET cycles does not improve clinical pregnancy rates.[109]

CONLUSION

- Although LPD has been proposed as a clinical entity 70 years back that may lead to infertility and early pregnancy loss, there is still a controversy regarding its definition,

diagnosis, and clinical relevance apart from known pathological conditions suppressing LH pulses.

- Until further research is done, at present true isolated LPD is not considered as a clinical entity that causes infertility or early pregnancy loss.
- At present, testing and treatment of LPD is not recommended in non-IVF cycles.

CHAPTER 14

Anovulation

Ashwini Sidhmalswamy G

INTRODUCTION

"The key to growth is the introduction of higher dimensions of consciousness into our awareness"

—Lao Tzu

Anovulation is one large spectrum in reproductive endocrinology. To know everything of a big spectrum is so much more of a challenge. Anovulation presents itself with various clinical manifestations that include amenorrhea, infertility, hirsutism, and menstrual irregularities.

Anovulation accounts for infertility in 15–20% of infertile women.[1] Infertility caused by anovulation can be classified according to the deficiency of the hypothalamic–pituitary–ovarian (HPO) axis at different levels **(Box 1)**. Anovulation is defined as a state where there is no release of oocyte due to failure of rupture of a mature follicle.[2] This is the working definition of anovulation accepted at present. Ovum release involves many steps and any blockage during one of these stages could lead to anovulation.

BOX 1: World Health Organization (WHO) classification of anovulation.

WHO class I: Hypogonadotropic hypogonadal anovulation (hypothalamic amenorrhea)

These women have low or low-serum follicle-stimulating hormone (FSH) concentrations and low-serum estradiol concentrations due to decreased hypothalamic secretion of gonadotropin-releasing hormone (GnRH) or pituitary unresponsiveness to GnRH

WHO class II: Normogonadotropic normoestrogenic anovulation

These women may secrete normal amounts of gonadotropins and estrogens. However, FSH secretion during the follicular phase of the cycle is subnormal. This group includes women with polycystic ovary syndrome (PCOS). Some ovulate occasionally, especially those with oligomenorrhea

WHO class III: Hypergonadotropic hypoestrogenic anovulation

The primary causes are premature ovarian failure (absence of ovarian follicles due to early menopause) and ovarian resistance (follicular form)

Hyperprolactinemic anovulation

These women are anovulatory because hyperprolactinemia inhibits gonadotropin and therefore estrogen secretion; they may have regular anovulatory cycles, but most have oligomenorrhea or amenorrhea. Their serum gonadotropin concentrations are usually normal

CLASSIFICATION

The World Health Organization (WHO) classification[3] offers a useful frame for diagnosis and treatment of anovulation. **Box 1** shows the WHO classification of anovulation.

ETIOPATHOGENESIS

The complex interaction of neuroendocrine and intra-ovarian mechanism that regulates the normal ovulatory cycle is controlled by the HPO axis **(Fig. 1)**. Disruption at any level of this axis causes anovulation.

Anovulation can be one of the earliest symptoms of functional or organic hypothalamic diseases, pituitary disease or inappropriate feedback by the peripheral hormones, and primary ovarian insufficiency. Ovarian dysfunction in relation to anti-Müllerian hormone (AMH), inhibin B, and follicle-stimulating hormone (FSH) is depicted in **Figure 2**.

In women of reproductive age group, there are multiple causes of anovulation; these are shown in **Box 2**. Anovulation is managed according to the causes as discussed later.

Hypogonadotropic Hypogonadism Causes (WHO Group I)

The main feature of hypogonadotropic hypogonadism is that there is no luteinizing hormone (LH) and FSH release as there is no production of these hormones by pituitary. There is physiological decrease in the production of gonadotropin-releasing hormone (GnRH) from hypothalamus, which causes amenorrhea.

The most common cause is overexercising usually seen in athletes and the other common cause is being underweight with low body mass index (BMI).

Sheehan's syndrome (panhypopituitarism), usually occurring after severe postpartum hemorrhage or trauma, causing infarction of the anterior pituitary venous complex causes hypogonadotropic hypogonadism. Kallmann syndrome, wherein amenorrhea is present along with anosmia, is caused by congenital absence of production of GnRH by hypothalamus. Cerebral irradiation, which affects hypothalamus or the pituitary, in children treated for a craniopharyngioma or leukemia can cause secondary hypogonadotropic hypogonadism.

Normogonadotropic Normogonadism (WHO Group II)

Ovarian causes are included in this group. The most common is the polycystic ovary syndrome (PCOS).

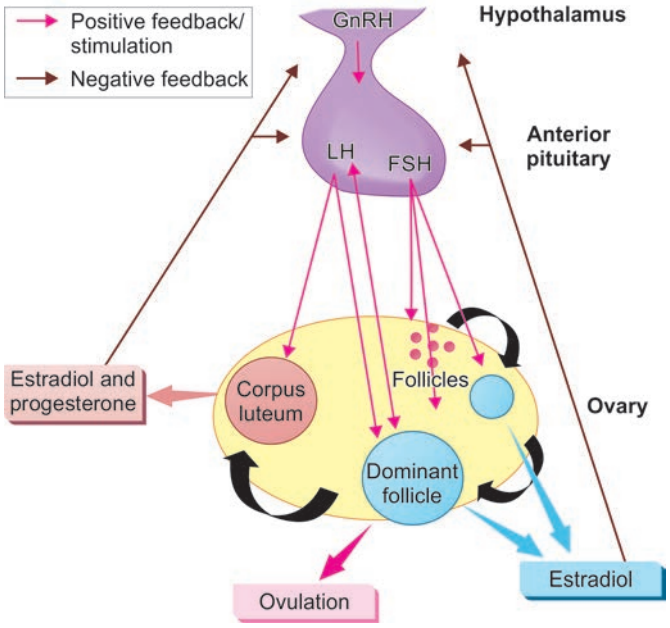

Fig. 1: Hypothalamic–pituitary–ovarian axis.
(FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone)
Source: Fairley DH, Taylor A. Anovulation. BMJ. 2003;327(7414):546-9.

BOX 2: Causes of anovulation according to the World Health Organization (WHO) classification.

Hypogonadotropic hypogonadism (WHO group I)
- Functional hypothalamic dysfunction (e.g., excessive exercise, over stress, weight loss such as in anorexia nervosa, drug intake, iatrogenic)
- Pan-pituitary infarct as in Sheehan's syndrome, pituitary tumor
  - Kallmann syndrome where there is isolated gonadotropin deficiency along with anosmia
  - Idiopathic hypogonadotropic hypogonadism

Normogonadotropic normogonadism (WHO group II): Polycystic ovary syndrome (PCOS)

Hypergonadotropic hypogonadism (WHO group III)
- Iatrogenic as in postradiotherapy, surgical menopause, or chemotherapy
- Genetic disorders such as Turner syndrome
- Infectious cause such as mumps oophoritis
- Autoimmune causes
- Idiopathic

Other various endocrinopathies: Such as thyroid disorders, including hyperprolactinemia, congenital adrenal hyperplasia, ovarian and adrenal tumors, which are secreting androgens, are to be considered cause of anovulation

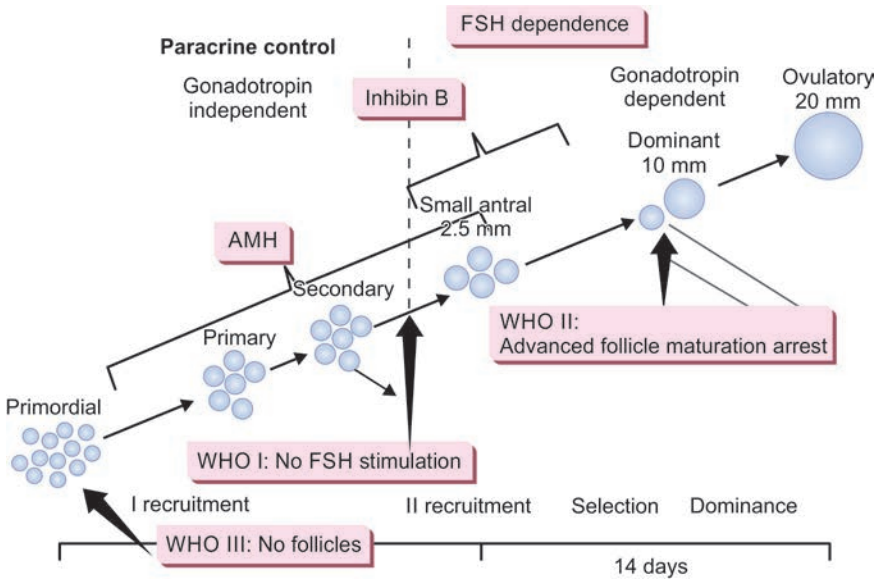

Fig. 2: Ovarian dysfunction in relation to anti-Müllerian hormone (AMH), inhibin B, and follicle-stimulating hormone (FSH).
(WHO: World Health Organization)

Polycystic Ovary Syndrome

Polycystic ovary syndrome accounts for 70% of infertility occurring due to anovulation.[4] In PCOS, the excess production of androgens within the ovary results in recruitment of increased numbers of preovulatory follicles. No dominant follicle is produced. Insulin resistance is the main pathophysiological abnormality and is seen in only 10–15% of PCOS women who are slim and 20–40% of PCOS women who are obese.[5]

The prevalence of polycystic ovary syndrome depends on the criteria used to diagnose PCOS and it also depends on what population the study is conducted. Previously, the National Institutes for Health consensus[6] definition was used and prevalence was about 7%.[7] When Rotterdam consensus[8] was used for diagnosis of PCOS, the prevalence rate was around 20–25%. According to Rotterdam 2003 criteria, PCOS is defined as presence of (1) oligo- or anovulation, (2) clinical and/or biochemical signs of hyperandrogenism, or (3) polycystic ovaries (PCO) after excluding related disorders such as thyroid disorders, hyperprolactinemia, and congenital adrenal hyperplasia. If any two of the above features are present, then the woman is diagnosed to have PCOS.

Serum FSH concentration can be normal, but majority of times FSH is reduced in women with PCO when compared to women whose ovaries are normal.[9] FSH action in women with PCOS is inhibited. It is shown that AMH counteract the actions of FSH;[10,11] it is also in a way involved in causing anovulation in these women. the severity of the ovulatory dysfunction is greater when there is increased concentration of AMH.[9,12] Another contributory factor of AMH to anovulation is its direct relation with LH concentrations.[9,13] PCOS is separately dealt with in a separate chapter.

Obesity and Anovulation

In obese women, peripheral conversion of androgens to estrogens increases, causing imbalance in the secretion of gonadotropins. There is also decrease in the sex hormone-binding globulin in the blood, along with decrease in growth hormone secretion, and also decrease in insulin-like growth factor binding proteins and increase in leptin levels, causing alteration in the HPO axis. This causes ovulatory dysfunction.

Increased BMI is associated with infertility,[14-16] which causes ovulatory disorders in obese women. Obesity plays an adverse role in causing anovulation in PCOS.[17] However, not every woman who is obese suffers from PCOS, and not every woman diagnosed with PCOS is obese.[18,19] So, obesity may present with anovulation regardless of PCOS. This shows that there might be other factors causing an anovulatory disorder.[20,21]

Hypergonadotropic Hypogonadism (Ovarian Failure) (WHO Group III)

Premature Ovarian Failure

This condition cannot be reversed. This can only be treated by in vitro fertilization (IVF) with donor oocytes. Hormone replacement therapy is given for menopause symptoms and to prevent loss of bone density.

Genetic Abnormalities

One of the most common genetic abnormalities is Turner syndrome (45,X), in which the ovaries are underdeveloped (streak) and so there is primary ovarian failure. In this case, hormone replacement is done for the uterus to be adequate for implantation, so that the woman can conceive with IVF by using donated eggs. Some X chromosome translocations and deletions can also cause ovarian failure.

Androgen insensitivity syndrome, also called testicular feminization, can cause primary amenorrhea. These women have testes, but they are phenotypically female. The karyotype is 46,XY with intra-abdominal gonads. The androgen receptors are either absent or nonfunctioning. Pregnancy is impossible as there is absence of uterus and the vagina ends blindly.

Other Endocrinopathies

Hyperprolactinemia

The WHO classification did not include hyperprolactinemia in any of the category. *The cause of this condition* is usually pituitary microadenoma. In hyperprolactinemia, the pulsatile secretion of GnRH is hindered and this in turn impairs normal ovarian function. This leads to a decrease in pituitary LH production and also decrease in FSH. Secondary amenorrhea is usually the presenting symptom; some women may have galactorrhea. AMH levels to some extent can be used further to categorize women as the AMH levels are low in typical class I and class III WHO classification and the levels are high in class II.

DIAGNOSIS

Anovulatory infertility is a condition with several underlying causes. This can be systematically evaluated by proper history, physical examination, and basic investigations along with hormonal status. **Flowchart 1** shows schematic representation of hormonal status in relation to classification of anovulation.

History and Physical Examination

Women with ovulatory disorder present with history of infertility. Apart from this, anovulatory women present with scanty menses or oligomenorrhea, they can also present with amenorrhea, and few of the women can have regular

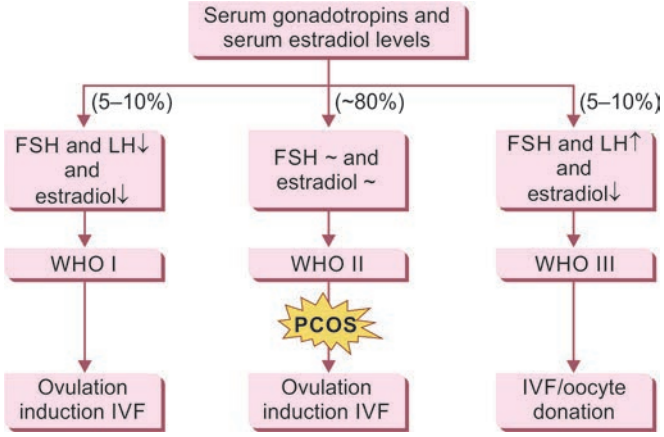
menstrual cycles as well. So, menstrual history has to be taken properly. Hyperprolactinemia symptoms such as galactorrhea, headache, and visual disturbance have to be looked for. Symptoms of thyroid dysfunction are asked for. History of any drug intake or any other relevant medical history pertaining to menstrual cycle disturbance is to be noted. Hyperandrogenic symptoms such as hirsutism, acne, and male-pattern baldness are looked for in PCOS women.

Physical examination has to be done to note development of secondary sexual characteristics, and calculation of BMI is done. Abnormal genital development is also noted if any.

Apart from routine blood investigation that includes thyroid-stimulating hormone (TSH), free T4, and serum prolactin, further specific investigations are done to diagnose a particular type of anovulation. They are as follows:

- *Hypogonadotropic hypogonadism (WHO group I):* In these conditions, serum estradiol value is <40 pg/mL,[3] there is no withdrawal bleeding after progesterone challenge, and the endometrium is thin and atrophic, which measures <5 mm on ultrasound.[22]
- *Normogonadotropic anovulation (WHO group II):* These patients are more likely to have PCO. In these women, serum values of FSH may be normal and LH values are either raised or are within normal limits. Sometimes, there is some disturbance in the secretion pattern of GnRH.[23] They will have withdrawal bleeding in response to progesterone challenge.
- *Hypergonadotropic hypogonadism (WHO group III):* In these conditions, the plasma level of FSH is usually >20 mIU/mL on repeated measurements.[24] The women are hypoestrogenic and do not respond to the progesterone challenge; the most important test is karyotyping. If there is presence of Y chromosome, removal of the gonad through surgery is suggested as there is a risk of malignant transformation.[25]

Flowchart 1: Schematic representation of hormonal status in relation to classification of anovulation.



(FSH: follicle-stimulating hormone; IVF: in vitro fertilization; LH: luteinizing hormone; PCOS: polycystic ovary syndrome; WHO: World Health Organization)

Further Evaluation to Exclude Other Disorders

- *Autoimmune evaluation:* This should be done in young women with premature ovarian insufficiency, who are also usually at a high risk of developing autoimmune hypothyroidism. So, apart from regular thyroid testing with TSH, the levels of thyroid-peroxidase autoantibodies should also be checked. Other disorders associated with autoimmune polyglandular syndrome should be kept in mind and evaluated accordingly depending on the symptoms of the woman.
- *Karyotype:* This is done to evaluate chromosomal abnormalities specifically in women with premature ovarian insufficiency. Secondary infertility cases who have delivered one normal child may also develop premature ovarian insufficiency. This happens in women with X chromosome abnormalities, so it becomes necessary to evaluate the women with a karyotype. Any chromosomal abnormality on karyotyping mandates change in the treatment. Presence of Y chromosome material mandates oophorectomy as there is a high risk of gonadal malignancy.

TREATMENT

Treatment of anovulation is done according to the cause. **Box 3** shows the types of anovulation that are treatable and **Box 4** shows conditions that are not amicable to the treatment.

Flowchart 2 shows the treatment in relation to causative factors of anovulation.

Lifestyle Changes and Weight Management

Numerous studies have shown improvement in the hormonal levels and reproduction with weight loss in obese women. Losing weight improves insulin sensitivity, up to 5–10% of

BOX 3: Causes of anovulation treatable with ovulation induction.

Hypogonadotropic hypogonadism causes (WHO group I)
- *Hypothalamic*
  - Low concentration of gonadotropin-releasing hormone (hypogonadotropic hypogonadism)
  - Weight or exercise-related amenorrhea
  - Kallmann syndrome
  - Stress
  - Idiopathic
- *Pituitary*
  - Pituitary failure (hypogonadotropic hypogonadism)
  - Sheehan's syndrome
  - Craniopharyngioma or hypophysectomy
  - Cerebral radiotherapy

Normogonadotropic anovulation (WHO group II)
- *Ovarian*
  - Polycystic ovaries
- *Other endocrinopathies*
  - Hypothyroidism
  - Hyperprolactinemia
  - Congenital adrenal hyperplasia

(WHO: World Health Organization)

loss in total body weight can decrease up to 30% of central fat, and there can be ovulation.[26,27] Lifestyle modification is a key component in overweight anovulatory women.

Hyperprolactinemia

There are three ways to increase fertility in women with anovulatory hyperprolactinemia—surgery, treating with dopamine agonists, and release of ovum by ovarian stimulation. For idiopathic disease and prolactinoma, the treatment of choice is dopaminergic agents. Bromocriptine is the most common drug used. It is given as 2.5–20 mg in two or three divided doses per day.[28] This brings back the serum prolactin level to normal in about 80% of patients with microprolactinoma, leading to normalization of ovarian function in about 85% of women. In about 65% of patients with macroprolactinoma, the prolactin level becomes normal, with normalization of gonadal function in over 50%. The effective dopaminergic agent is cabergoline.[29] This is given in the dose of 0.5–1.0 mg/week. In women who do not ovulate with prolactin concentration being normal, bromocriptine can be given along with antiestrogens.[30]

BOX 4: Causes of anovulation not treatable with ovulation induction.

Ovarian failure
- Idiopathic
- Radiotherapy or chemotherapy
- Surgical removal
- Genetic
- Autoimmune

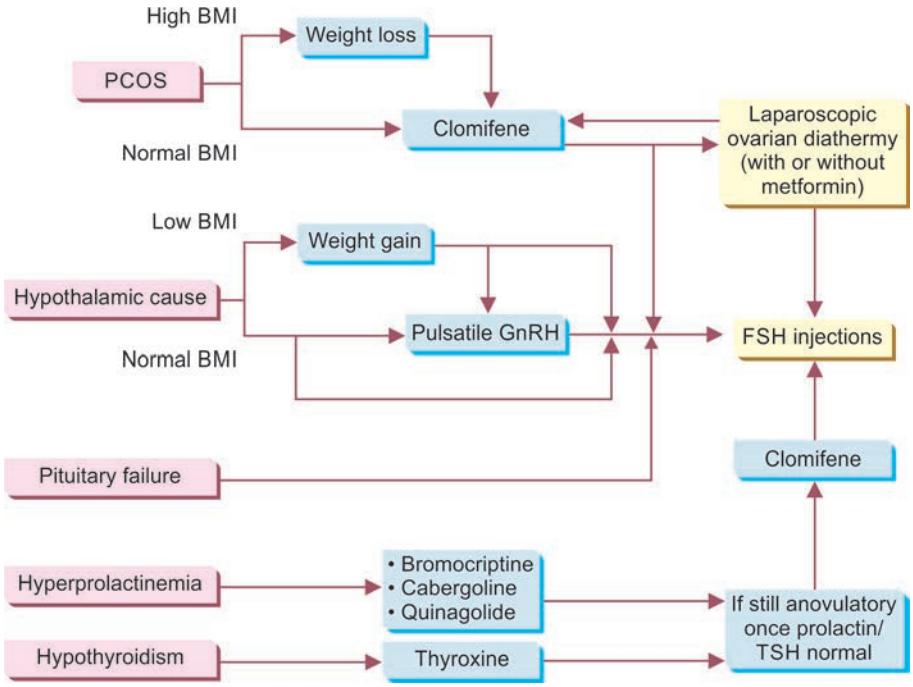
Chromosomal
- Turner syndrome (45,X)
- Androgen insensitivity syndrome (46,XY)

Hypogonadotropic Anovulation (WHO Group I)

Acute or chronic emotional stress is associated with acquired forms of hypogonadotropic amenorrhea. A proportion of fat tissue is needed to initiate menarche and maintain ovulation in women, which is about 27% of body weight. Thorough counseling is required when anovulation is associated with behavioral conditions and with weight issues such as underweight or overexercise.

Surgery is recommended for space-occupying tumors in the central nervous system (CNS). Proper counseling and reassurance are the initial steps of the treatment. GnRH given in pulsatile fashion induces ovulation in women with anovulation due to overweight. Other alternatives are menotropins. The advantages of pulsatile GnRH over menotropins are that the risk of hyperstimulation is minimal and the need for monitoring is also lessened.[31] In case anovulation is caused due to pituitary failure, ovulation is induced with gonadotropins. Human menopausal gonadotropin (hMG) is used as LH activity is required to stimulate proper estrogen production.[32] Serial ultrasonography is necessary to monitor the follicular growth.

Flowchart 2: Treatment in relation to causative factors of anovulation.



(BMI: body mass index; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; PCOS: polycystic ovary syndrome; TSH: thyroid-stimulating hormone)

Normogonadotropic Anovulation (WHO Group II)

Women in this group, when stimulated, have a greater risk of ovarian hyperstimulation and sometimes there also can be a decreased response. Treatment with antiestrogen is most effective; the drugs usually used are clomiphene citrate or tamoxifen. Clomiphene citrate is started in the dose of 50 mg/day for 5 days, starting from the second day of menses for 5 days, after induced or spontaneous bleeding. If no dominant follicle is developed, the dose can be increased by 50 mg each cycle. The treatment is monitored by serial ultrasound. Ultrasound monitoring is necessary as there can be development of more than one follicle leading to twins and triplets due to uncontrolled ovarian stimulation with clomiphene. If adrenal androgens are high [dehydroepiandrosterone sulfate (DHEAS) >30 ng/L], the addition of dexamethasone to clomiphene may be helpful.[33] The pregnancy rate is increased by 5.5-fold with clomiphene.[34]

The second line of treatment with normogonadotropic anovulation is ovarian stimulation with hMG preparations. The risk of ovarian hyperstimulation and multiple pregnancies is high. Low-dose regimen that is modification to the traditional regimen of gonadotropin treatment has been suggested for these patients.[35-37] With these regimens, the FSH threshold exceeds marginally, recruiting and selecting only few follicles leading to one or rarely two follicles to attain dominance. Multiple pregnancies are lower and even the abortion rate is minimal.

If the medical line of treatment fails, then ovarian drilling[38] is the next line of management. The sensitivity of the ovary to the gonadotropins is increased post this procedure, increasing the ovarian response to stimulatory drugs.

Medical Options for Ovulation Induction

Antiestrogens

Clomiphene citrate: This is the treatment of choice for WHO group II anovulation. Through its antiestrogenic effect, it displaces endogenous estrogen from estrogen receptors in the hypothalamic–pituitary axis; this in turn reduces its negative feedback and hence increases the secretion of endogenous GnRH and gonadotropins, which therefore induces ovulation.[39]

The starting dose is 50 mg daily for 5 days and can go up to 150 mg/day. The treatment is started on the second day of menses after a spontaneous or withdrawal bleeding. Follicular monitoring and endometrial response are studied by transvaginal pelvic ultrasound. The ovulation rate is 73%, and pregnancy and live birth rates are 36 and 29% per woman, respectively. Treatment is usually done for six ovulatory cycles.[40] The adverse effects may occur with clomiphene. Rarely these require discontinuation of treatment in some patients.

Tamoxifen: This mimics clomiphene citrate structurally; it is a triphenylethylene derivative. It is used in the dose of 20–40 mg/day for 5 days after a spontaneous period or withdrawal bleeding. According to a meta-analysis,[31] both tamoxifen and clomiphene citrate have similar ovulatory and pregnancy rates per cycle.

Insulin-Sensitizing Agents

In women with PCOS, there is insulin resistance. Insulin-sensitizing agents are used in these cases to increase the insulin responsiveness in tissues, which reduces the hyperinsulinemic condition. This improves ovulatory function. Metformin, a biguanide, is the common insulin sensitizer used; the dose is 850 mg twice daily with meals. According to a Cochrane review,[41] metformin used alone improves the ovulation rate and clinical pregnancy rate when compared with placebo or no treatment, but there was no significant change in live birth rate. When compared with clomiphene citrate, metformin has a lower ovulation rate, and there was no significant change in live birth rate.

Aromatase Inhibitors

Aromatase inhibitors block the production of estrogen by hindering the conversion of androstenedione to estrone and testosterone to estradiol, and the negative feedback to the hypothalamic–pituitary axis is decreased, causing increase in endogenous FSH secretion. It is used for ovulation induction in women with PCOS.

Letrozole, a third-generation aromatase inhibitor, is used for ovulation induction. It has a shorter half-life, so the endometrium suppression is minimal. It is used in the dose of 2.5–5 mg/day for 5 days starting on the second day of spontaneous or induced bleeding,[42] or as a single dose of 20 mg on day 3 of the period.[43] Serial ultrasound is done to monitor follicular growth. Letrozole is usually used in women who are resistant to clomiphene citrate. With this regimen, 70–84% women achieved ovulation and the pregnancy rate achieved was about 20–27% per cycle. Letrozole showed teratogenicity that has been described only in animal studies. On a larger sample size, a retrospective study was done, which found no difference in the rates of major and minor congenital malfo`rmations in newborns of mothers who took letrozole or clomiphene citrate treatments.[44]

Gonadotropin-Releasing Hormone

In hypogonadotropic anovulation caused by hypothalamic dysfunction, GnRH is given for the treatment, but this is of no help in the pituitary problem; it is given in a pulsatile fashion using a battery-operated pump, which causes growth of a dominant follicle. It is given subcutaneously or intravenously. An 80% cumulative pregnancy rate is noted after six cycles and 93% has been noted after 12 cycles of treatment.[44] The risk of multiple pregnancy is between 3.8 and 13.5%.

Gonadotropin

A combined preparation containing both FSH and LH gives a better outcome than only FSH in women with hypogonadotropic hypogonadism because LH activity is required for steroidogenesis in ovary to achieve optimal proliferation of endometrium. Exogenous gonadotropins are used to overcome the FSH threshold required for follicular development.

Chronic Low-Dose Step-Up Protocol

Chronic low-dose step-up protocol is the recommended protocol. The principle is to avoid excessive stimulation and aim at monofollicular development by determining the FSH threshold gradually. Follicle stimulation is started with a low dose (37.5–75 IU/day) of gonadotropins for at least 10–14 days,[26] and if there is no response, the dose is stepped up by 37.5 IU at weekly intervals, up to a maximum of 225 IU/day. Once follicular growth is observed, which is monitored by serial ultrasound scans, the same dose is maintained. Human chorionic gonadotropin (hCG) is given to trigger ovulation when one or two follicles are 18–20 mm in size. Once the maximum dose for follicular response is known, in subsequent cycle, the stimulation can be directly started with the maximum dose. **Figure 3** shows the low-dose step-up protocol.

Step-Down Protocol

The step-down protocol is more physiological. Gonadotropin is started from day 2 or 3 of the menstrual cycle at a dose of 150 IU/day, and the ovarian response is monitored by serial ultrasound every 2–3 days until one of the follicle size is 10 mm, and follicular growth is monitored by ultrasound every 2–3 days. Once there is response, the dose is reduced to 112.5 IU/day for 3 days and it is then further reduced to 75 IU/day until the follicle attains the size of 18–20 mm, and then ovulation trigger is done by hCG. The duration of stimulation in this protocol is shorter than the step-up protocol, but ovarian hyperstimulation syndrome risk is increased, and also there is a lower ovulation rate. There is no significant change in the pregnancy rate between the two regimens.[45]

With low-dose gonadotropin regimens, there is development of monofollicle and the ovulation rate is about 70% and the pregnancy rate is about 20% with a cumulative pregnancy rate of 55–70%. Multiple pregnancy rates are about 6% and ovarian hyperstimulation syndrome accounts to 1%. This is better than the conventional regimens of gonadotropin, in which there is a significant higher risk of multiple pregnancy and severe ovarian hyperstimulation syndrome.[26]

It is important to do strict ultrasound monitoring with titration of the gonadotropin dosage. When there is development of more than two dominant follicles, the cycle should be abandoned and the starting dose for stimulation in subsequent cycles should be reduced. **Figure 4** shows the step-down protocol.

A recent randomized-controlled trial[46] suggested that with low-dose FSH as the first-line treatment in women with PCOS, the outcome in terms of live birth rate for first cycle, time to pregnancy, and cumulative live birth rate over three cycles was significantly better than with clomiphene citrate. Further studies are required to know the cost effectiveness of such treatment and to choose between the two treatment modalities.

Laparoscopic Ovarian Drilling Surgery

Another way to induce ovulation in anovulatory women, especially with PCOS, is ovarian drilling by diathermy or laser through laparoscopy. A Cochrane review found that the cumulative ongoing pregnancy rate of 6–12 months post laparoscopic drilling is similar to ovulation induction with gonadotropins for three to six cycles.[47] However, the rate of multiple pregnancies is low in women who conceived with ovarian drilling.

As in all cases surgical methods carry more risk than the medical management, so they are reserved and used only when medical treatment fails or in selective women, where other fertility factors are properly assessed and where it mandates the use of laparoscopic ovarian drilling.

Hypergonadotropic Anovulation (WHO Group III)

There is no treatment available for women with hypergonadotropic anovulation. Fertility in these patients can be obtained by IVF with egg donation program.

*Absence of withdrawal bleeding after progestogen challenge in typical cases.
†Presence of withdrawal bleeding after progestogen challenge.

Flowchart 3 summarizes the treatment options for fertility in patients with chronic anovulation.

KEY POINTS

- Most of anovulatory patients can be successfully treated after proper diagnostic procedures.
- There are effective treatments available.
- A few women respond poorly to specific stimulation; in such a case, simpler and milder forms of individualized ovarian stimulation programs are being developed.
- The positive and added effect resulting from normalization of body weight in obese and underweight patients is very encouraging.
- Better ovarian stimulation depends on carefully choosing the available drugs to improve ovarian response in women who are poor responders and also to avoid multiple pregnancies.

CHAPTER 15

Declining Fertility

Mahesh Koregol, Soumya Mahesh Koregol, Navya N

INTRODUCTION

Over the past 70 years, fertility rates have decreased worldwide, with nearly a 50% decline overall. Increased life expectancy, along with lower fertility rates, is creating an aging population which in turn puts pressure on healthcare systems globally. The total fertility rate (TFR) is the total number of offspring that would be born to each woman if she were to live to the end of her fertile age. In the last 50 years, there has been a consistent fall in the global TFR markedly in the more developed nations of the world.

TOTAL FERTILITY RATE TRENDS

Until 1870, the global TFR had been relatively static at around 5.7 children per woman. After 1870, there was a gradual decline that was made up for by the relative prosperity following World War II. The fertility rates gained momentum during the 1950s and peaked around the 1960s. Thereafter, there has been an astounding downward trend in global TFR.

Replacement level fertility is the level of fertility at which a population exactly replaces itself from one generation to the next. In simple words, it is the minimum fertility needed to keep the population unchanged from one generation to the next. The TFR should be at least 2 to ensure replacement for the parents. An additional 0.1 has been included to account for the infant mortality rate. Shockingly in 2017, TFR was only just above replacement levels.[1,2]

THE INDIAN SCENARIO

The Indian numbers are not very different from those of the more developed countries. There has been a striking decline in TFR from 2.2 (reported in 2015–2016) to 2.0 at the all-India level. This is as per the latest National Family Health Survey of India-5 (NFHS-5) (phase 2) released by the Union Health Ministry.[3] TFR is currently 1.6 in urban areas, 2.1 in rural areas, and an average of 2.0 all over India. The NFHS-5 for 2019–2021 was conducted in about 6.1 lakh sample households from 707 districts of India. This covered 724,115 women and 101,839 men to provide the estimates up to district level.

MAJOR CAUSES OF FERTILITY DECLINE: SHORT TERM AND LONG TERM

There are two major factors responsible for the fall in TFR. The "*short-term*" decline in human TFR is mainly a result of social, economic, and educational factors. This may be addressed by changes in policy, support to pregnant working women, and attitude of people in general. In parallel, there are more challenging "*long-term*" changes occurring, driven by a combination of drastic environmental, lifestyle, and genetic factors. These have the potential to result in permanent damage to the fertility of the human species and are less malleable to human interventions.

EDUCATION—"THE MOST EFFECTIVE CONTRACEPTION"

One of the biggest causes of large families is illiteracy, or more specifically, the lack of awareness and knowledge. The World Bank has found a negative correlation between women's education and fertility. It has been observed across countries and time. Literacy has been proven to be one of the most effective ways to achieve gender parity at a global level. There is a clear association between female education and reduced fertility.[4] The reasons behind this strong link are complex. Reduced fertility means that there are fewer children and all, including the daughters, get the advantage of gaining better education. This somewhat reduces the gender disparity level as there are increased job opportunities and independence for women.[5] Higher education comes with increased economic autonomy. These empowered women are more likely to make major decisions concerning fertility and family.[6] On the flip side, a relatively negative consequence of female education and career development is that women contemplate having a family at a later age at which fertility declines naturally.

The average age of women attending in vitro fertilization (IVF) clinics is around 36 years, when fertility is beginning its irrevocable age-dependent decline via mechanisms that assisted reproductive technology (ART) cannot reverse.[7]

WORKING WOMEN AND THE MYTH OF "HAVING IT ALL"

The present generation of men, women, and families has high aspirations for life. Having children will lead to a conflict with these aspirations. In fact, professional women find it challenging even to be married—for most cultures, a prerequisite for having children. Postponement of childbearing is a new behavioral change seen in many countries. A wide range of complex personal, psychological, and social factors affect the decision to have children. There is a lack of social and structural support for women to have their children at a time in their lives when their fertility is likely to be more viable. This will in turn mean women will have to compromise their education, career, and economic goals, which is also likely to peak in the same time period of their lives. Mostly a pause in career to have and raise children will result in an invariable struggle to reengage in the professional world.[8]

ECONOMY—"MONEY MAKES MANY THINGS"—DOES IT HOLD TRUE FOR HAVING CHILDREN

As nations become more prosperous, healthcare facilities and life expectancy improve. This increases the confidence of couples to have a smaller family as the risk of unexpected infant and childhood mortality rate decreases. This results in a decline in TFR which is temporarily unchanged by a parallel rise in life expectancy. As a result of this trend, we are seeing "super-old" populations like in Japan, Finland, Italy, or Germany. In these countries, over 20% of the society is over the age of 65 years.[9] As a consequence of these changes, these affluent nations are seeing their population pyramid turn on its head. In the long term, this is likely to build huge economic stress on these countries.

CHANGING RELATIONSHIP DYNAMICS—IT IS SIMPLY COMPLICATED

Marriage is a social institution that has been around for thousands of years. It ensures a stable relationship which is a prerequisite for expanding the family. We would assume that this social ritual is unlikely to change over time. However, developments since the middle of the 20th century show that this assumption is wrong. Marriage is no longer considered as a priority or even relevant to today's society. All over the world, fewer couples are becoming married. For example, plots of marriage rate against TFR for the Netherlands have revealed a drastic decline in the incidence of marriage as the TFR falls to a sub-replacement level.[10] The decrease in marriage rates have been accompanied by an increase in the age at which people are getting married in several countries. So, marriages are becoming less common, people are marrying much later, and unmarried couples are increasingly choosing to live together. There is also a shocking phenomenon in several countries where we are seeing a "decoupling" of parenthood and marriage. This will definitely cause a fall in fertility rates at present;[10] however, in future, it seems likely that more and more children will be born out of wedlock. This might become common and might not affect couples' decisions to bear children.

IS ASSISTED REPRODUCTIVE TECHNOLOGY GENETICALLY AFFECTING HUMAN FECUNDITY? LESSONS FROM THE CATTLE INDUSTRY

The mechanism of evolution heavily relies on the principle of "natural selection." Organisms that are more adapted to their environmental challenges are most likely to survive and pass on the genes that aided their survival. This process causes species to evolve and diverge over time toward better sustenance. In the early stages of human evolution and propagation on this planet, high rates of mortality essentially meant that natural selection involved choosing individuals with higher fertility genes. One had to be fertile enough to bear several offspring as high mortality would mean that only the best one or two would survive to pass their genetic material to the next generation.

Over the past few decades, the use of ART has increased rapidly, and the reasons for treatment are gradually broadening as more same-sex couples, single women, and surrogates are making use of advanced fertility treatments. While this is indeed a boon to many infertile couples, there is a long-term interference in nature's rule of selecting the best possible genotypes for the propagation of the human species. The spread of low fertility genotypes will be subsequently encouraged by the IVF industry itself, thereby setting off a vicious cycle of fertility problems. This might sound very theoretical, but the experience in the dairy industry has already proven this to be a real problem. There is a conscious effort to choose the most fertile domestic animals for breeding; otherwise, there is a subsequent decrease in the fertility of the next generation of the breed. A similar phenomenon may be expected in humans that will not be noticed for a few decades, but if we do not actively select for fertility, we will ultimately lose it in decades to come.[11] The fertility rates may remain unaffected by this in the immediate future as ART is responsible for <0.5% of births worldwide. However, it has been already noticed in most developed countries that one of the inadvertent consequences of ART is that, when conducted at a large scale, ART will help poor

fertility genes be retained within the population and will get passed on to the next generation.

A shocking instance of ART facilitating the propagation of low fertility genotypes is seen in the management of severely oligozoospermic men with azoospermia factor c (AZFc) deletions on their Y-chromosome. These individuals need intracytoplasmic sperm injection (ICSI) to conceive, and the sons inherit the same male factor infertility. So, they will also require the same intervention once they wish to have a family.[12] There is already enough evidence to suggest that male offspring conceived by ICSI have lower sperm counts than their naturally conceived children of the same generation.[13] Of course, these data will need lot of substantiation, but they are quite consistent with the ability of ART to promote the transmission of poor fertility genotypes in humans. This situation is complex as any mutations that compromise fertility by acting on the quality of gametes or fertilization and early embryogenesis will potentially persist within the human population by the upsurge in the practice of ART, particularly ICSI.[14-16] The offspring born out of ART are more likely to carry aneuploidies[17] and abnormal DNA methylation profiles[18] as well as genetic mutations,[19] which are very much likely to be passed on to the upcoming generations.

The ART industry is indeed putting conscious efforts to avoid such problems through the development of high-end embryo selection processes and increasing use of genetic screening protocols.[20] The increased application of ART may also discourage research into the effect of environmental and lifestyle factors on human fertility by treating and achieving pregnancy in subfertile individuals. This will obscure the serious problem of falling human fecundity and fail to create political pressure to address these larger issues.

DECLINE IN MALE FERTILITY

There are several lifestyle and environmental factors acting to suppress human fecundity; the impact is likely to be more permanent. This is most evident in the rising incidence of male infertility. Human semen quality is consistently degrading all over the world.[21] The sperm counts have almost decreased by 50% over the last 50 years in both the West and the East.[22] This rapid and widespread change cannot be attributed to genetic causes alone. There must be a more generalized environmental cause.

The mechanism by which the environmental factors are affecting male fertility is being studied and there are few interesting observations. One such finding is simultaneous decline in serum testosterone levels. The fall in circulating testosterone levels might, in turn, be caused by increased exposure to estrogenic compounds from various sources.[23] Obesity is a pandemic known to be associated with low testosterone and high estrogen levels. This is due to a rise in aromatase activity, particularly in people with long tetranucleotide TTTA repeat polymorphisms in their aromatase gene.[24] Dairy products, such as milk and cheese, are known to contain significant quantities of natural estrogens. The increased intake of dairy along with phytoestrogens via the diet has been shown to lower serum testosterone levels in some studies.[25] Also, the exposure to synthetic estrogens in our environment, such as ethinyl estradiol or xenoestrogens, including bisphenol A or phthalate esters, is known to have a dual effect of suppressing gonadotropin production and reducing testosterone levels in humans.[26]

A reduction in sperm counts may not necessarily be associated with a simultaneous decrease in fecundity. Nevertheless, if the current trends continue, then, as Shanna Swan has pointed out, human fertility will become compromised due to poor sperm numbers.[22] The seriousness of the condition is emphasized by the rising incidence of testicular cancer which, according to the testicular dysgenesis syndrome hypothesis, has a similar origin to the global decline in sperm counts. Both share the common etiology of environmental endocrine disruptors with estrogen-like activity.[27]

ROLE OF FERTILITY SPECIALISTS: INCREASE AWARENESS AND OPTIMIZE NATURAL FERTILITY

As clinicians, we frequently encounter nonpregnant women, men, and couples in their reproductive age, which is an opportunity for us to create awareness in them about wellness and healthy habits to optimize their reproductive outcomes. The fact that the likelihood of conception is generally highest in the first few months of unprotected intercourse and declines gradually thereafter is unknown to many.[28] They are under the wrong assumption that pregnancy can be planned any time and fail to understand that modern ART techniques will not be able to overcome the effect of age on fertility. Fertility varies among populations, may be related to other health-based and environmental factors, and declines irreversibly with age in both sexes, the effects of age being much more pronounced in women.[29,30] There is a well-recognized age-related decline in the chances of pregnancy and live birth in older women. Also, there is a higher risk of aneuploidies, miscarriage, and medical complications of pregnancy with maternal aging, which further lowers fecundity.[31]

Apart from increasing awareness regarding the declining fertility, we should also inculcate a healthy "reproductive routine." Intercourse every day or alternate days during the fertile window should help maximize fecundability. Recreational drugs and smoking should be discouraged in couples attempting pregnancy. Caffeine and alcohol use should be limited to a minimum to moderate use while trying to conceive. There is no substitute for a healthy lifestyle and

diet for couples attempting to achieve pregnancy and also for their general well-being. They should be encouraged, to the extent possible, to limit their exposure to endocrine-disrupting chemicals in food, air, water, and personal care products and exposure to air pollution. The limitations in the available options of ART should be frankly discussed.

KEY POINTS

- Over the past 70 years, fertility rates have declined worldwide.
- TFR is defined as the total number of children that would be born to each woman if she were to live to the end of her reproductive years.
- A TFR of 2.1 ensures the replacement for the couple giving birth to her offspring.
- The *short-term* decrease in human TFR is mainly a result of socioeconomic and educational factors that are relatively easier to tackle with change in attitude of the society.
- The *long-term* changes are driven by a combination of drastic environmental, lifestyle, and genetic factors, which could potentially result in permanent damage to the fertility of the human species.
- With large-scale ART practice, we may encourage the persistence of poor fertility genotypes within the population.
- As clinicians, we frequently encounter nonpregnant women, men, and couples in their reproductive age, which is an opportunity for us to create awareness in them about wellness and healthy habits to optimize their reproductive outcomes.

CHAPTER 16

Evaluation of Infertility

Dipti Das, Kamini A Rao

INTRODUCTION

Since ancient times, humankind has been obsessed with fertility. With both biological and social imperatives driving us to have children, it is no surprise that, even today, the lack of fertility is perceived by many, especially the infertile, as a curse. In India, this has resulted in many social evils such as stigmatization and isolation and, in turn, has caused much trauma in the affected individuals. Further compounded by ignorance, this situation has engendered much quackery. Thus, the proper diagnosis of infertility is of paramount importance not only to the physical well-being of an affected couple but also to their mental and social well-being.

DIAGNOSIS OF INFERTILITY (MALE)

Definition

Infertility is the inability of a sexually active, noncontracepting couple to achieve spontaneous pregnancy in 1 year.[1]

About 8–12% of couples in the reproductive age group do not achieve pregnancy within 1 year and seek medical treatment for infertility. Eventually, <5% remain unwillingly childless.[2] The age-standardized prevalence of infertility has increased annually by 0.370% in women and by 0.291% in men.[3]

Male Infertility

- Male factor infertility may be explained by:
  - Abnormal semen analysis
  - Sperm function defects
  - Functional male defects.

A male factor is solely responsible in about 20–30% of infertile couples and contributes in another 20% of couples.[4]

Goals of Evaluation

There are various conditions causing male infertility, of which, many—but not all—can be identified and treated. Further, in cases of males who were previously fertile, the current condition of infertility implies that a newly acquired secondary factor of male infertility may be present, thus necessitating identical sequences of evaluation for either type of infertility—primary (having never caused a pregnancy) or secondary (having previously caused a pregnancy).[5]

The aims of evaluation, as per the American Urological Association (AUA) guidelines, are to correctly identify the following:[6]

- Potentially reversible conditions contributing to male infertility due to either obstruction within the reproductive tract or treatment of endocrinopathies
- Irreversible conditions amenable to assisted reproductive techniques using the sperm of the male partner
- Irreversible conditions that are not open to the above, and for which donor insemination or adoption is a possible option
- Life- or health-threatening conditions that may underlie the infertility and require medical attention
- Genetic abnormalities that may affect the health of offspring if assisted reproductive techniques are to be employed.

History

The reproductive history should cover the following:

- Sexual history, including:
  - Timing of puberty
  - Frequency and timing of coitus
  - Type of lubricants used
  - Libido, erectile, and ejaculatory dysfunction
  - Duration of infertility and previous fertility
  - Sexually transmitted infections
- Medical history, including:
  - Medical illnesses
    - Neurological conditions (spinal cord injury and multiple sclerosis), diabetes mellitus
    - Infections (urinary infections, epididymitis or prostatitis, tuberculosis, and mumps orchitis)

- Cryptorchidism and anosmia
- History of testicular torsion
- History of testicular trauma
- Previous surgery
  - Orchidopexy, herniorrhaphy, vasectomy, and prostatic surgery
  - Medications and allergies
  - Childhood illnesses and developmental history
  - Exposures to gonadotoxins (including environmental and chemical toxins and heat)
  - Malignancy
- Social history or lifestyle, including:
  - Current and/or past use of anabolic steroids, recreational drugs, tobacco, and alcohol
- Family history:
  - Infertility
  - Cystic fibrosis (CF)
  - Androgen receptor deficiency.

Physical Examination

Obviously, a general physical examination is a basic part and a starting point of the evaluation of infertile men. This should include the following:

- Calculating the body mass index (BMI)
- Examining the penis and noting the location of the urethral meatus
- Palpating and measuring the testes (normal volume 12–30 mL)
- Noting the presence and consistency of the epididymis and both vasa
- Noting the presence or absence of a varicocele
- Noting secondary sex characteristics, including physique (including arm span, muscle development), voice, hair distribution, and/or breast development
- Digitally examining the rectum for cysts, seminal vesicles, and prostate
- Diagnosing for the congenital bilateral absence of the vas deferens (CBAVD).

Varicocele

Varicoceles, defined as abnormally dilated scrotal veins, are present in almost 15% of the normal male population and in approximately 40% of infertile men. Primarily diagnosed by palpating the scrotum of the patient in both upright and recumbent positions, a palpable varicocele feels like a "bag of worms," which disappears or is significantly reduced when the patient is recumbent. Since only clinically palpable varicoceles have been clearly associated with infertility, in cases where physical examination has been inconclusive, scrotal ultrasonography is sufficient to confirm the presence of a varicocele.[7] Classification of varicoceles is shown in **Table 1**.[7]

TABLE 1: Classification of varicoceles by Dubin and Amelar.[7]

Grades of varicoceles	
Grade	***Characteristics***
1	Palpable only with Valsalva maneuver
2	Palpable without Valsalva maneuver
3	Detectable by visual inspection

Timing of Evaluation

Once the couple meets the definition for infertility, they should be referred for further investigations. The American Society for Reproductive Medicine (ASRM)[6] and the European Association of Urology (EAU)[8] both recommend an initial evaluation consisting of a reproductive history and at least two semen analyses.

However, there are certain circumstances where earlier evaluation may be required:

- Female partner is >35 years
- Predisposing factors for infertility
- Imminent treatment is planned for malignancy that may result in infertility (chemotherapy/radiotherapy).

Semen Analysis

The lynchpin of the diagnosis of infertility in men, semen analysis forms the basis of an evaluation of the male partner in subfertile couples and allows planning of further investigation and management **(Flowchart 1)**. The body stores sperm in the pair of epididymides as a concentrated suspension, which is mixed only during ejaculation with fluids from the other accessory sex glands—the prostate gland, the seminal vesicles, and the bulbourethral glands. The fluids amount to around 90% of the total semen volume, much of it from the prostate gland and the seminal vesicles with the remaining from the bulbourethral glands.

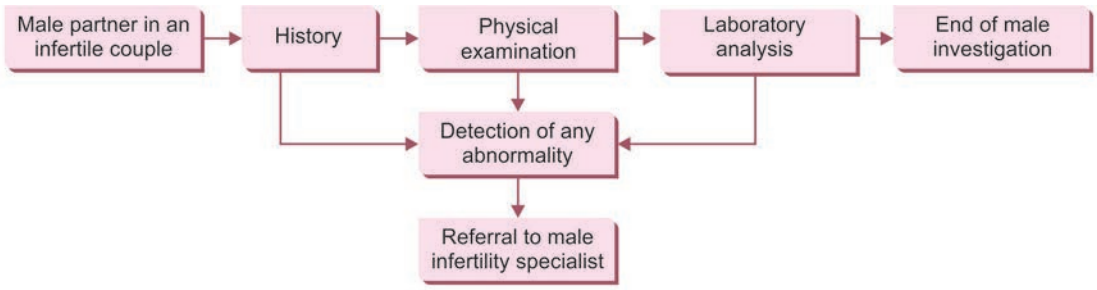
The analysis is done on the semen ejaculated, which is collected as a result of either:

- Masturbation into a sterile wide-necked container (at home or in a room close to the laboratory) or
- Intercourse using a special nonspermicidal condom (at home)

The quality of the ejaculated sample and, thus, the interpretation of the analysis vary as per:

- *Method of producing ejaculate:* The ejaculate produced by masturbation tends to be of lower quality than that produced by intercourse, perhaps due to a difference in the arousal level.
- *Completeness of the sample:* Ejaculation is done in a series of spurts, the first of which contains most of the sperm, while the subsequent ones contain very little.
- *Period of sexual abstinence:* The body stores the sperm in the epididymides which, when filled, allow the sperm to overflow into the urethra, to be passed out with urine.

Flowchart 1: Diagnosis algorithm of male partner in an infertile couple.



History	Physical examination	Laboratory analysis
Including, but not limited to: 1. Medical illness and medications 2. Surgical interventions in the past 3. Sexual ability/limitation 4. Cryptorchidism and scrotal infections 5. Testosterone/anabolic usage 6. Lifestyle factors a. Obesity b. Smoking 7. Supplement usage a. Vitamins b. Oral antioxidants 8. History of malignancy	Including, but not limited to: 1. Overall body habitus a. Obesity b. Muscular development c. Virilization 2. Testes a. Location, size, and consistency 3. Ductal structures ("vas" and epididymis) a. Presence/absence b. Normal/obstructed 4. Spermatic cord a. Varicocele b. Hydrocele	Including, but not limited to: 1. Semen analysis 2. Hormonal assays, if necessary 3. Genetic assays, if necessary a. Karyotype b. YCMD c. CFTR analysis

(CFTR: cystic fibrosis transmembrane conductance regulator; YCMD: Y chromosome microdeletions)

TABLE 2: Macroscopic examination of semen.

Liquefaction	The complete semen sample usually liquefies within 15 minutes and sometimes, up to 60 minutes
Viscosity	Viscosity is estimated after liquefaction; the sample should be aspirated into a pipette of around 1.5 mm diameter and then allowed to drop due to gravity while watching for threads. Normal semen usually forms small individual drops; the presence of threads longer than 2 cm indicates abnormal viscosity
Semen volume	Volume is best measured by collecting directly in a graduated measuring container. Decanting from the collection container into the measuring container or even aspirating into a pipette or syringe would cause a loss in volume
Semen pH	The seminal vesicle secretions are alkaline, while the prostatic secretions are acidic; thus, the pH value demonstrates the equilibrium between the secretions of the accessory sex glands. A sample of low volume combined with azoospermia and a pH below 7 strongly indicates the congenital bilateral absence of the vas deferens (CBAVD) or other ejaculatory duct obstruction(s). Semen pH increases with time, reducing the clinical usefulness of the value

- *Size of the testes:* The size of the testes affects both the total number of sperm per ejaculate and the morphology of the sperm.
- *Age of the male patient:* The total number of sperm and the total volume of semen ejaculated tend to reduce as age increases.
- For optimum results, physicians should give their patients a standardized set of instructions for semen collection, advising sexual abstinence—for 2 days at a minimum and 5 days at a maximum—prior to semen collection, and careful collection of the whole ejaculate.

The primary characteristics of semen are the total sperm number and the total semen volume. The total sperm number is a function of the sperm-production capacity of the testes. The total semen volume is a function of secretion capacity of the accessory sex glands. Both these characteristics are also a function of the degree of openness of the respective ducts of the reproductive tract.

Routine Tests

Macroscopic Examination

Table 2 shows the macroscopic examination of semen.

Microscopic Examination

Table 3 shows the microscopic examination of semen.

Many textbooks go into detail about available methods of semen analysis, but the gold standard is the World Health Organization (WHO) Laboratory Manual for the Examination and Processing of Human Semen.

TABLE 3: Microscopic examination of semen.

Agglutination	Though sperm move vigorously, they sometimes clump together.  (*Courtesy:* Dr. Sarita Suresh, Aaradhya Fertility Center) The degree of agglutination is expressed using grades 1 through 4: • Grade 1, isolated—many free sperm; <10 per clump • Grade 2, moderate—quite a few free sperm; 10–50 per clump • Grade 3, large—a few sperm are free; >50 per clump • Grade 4, gross—no free sperm; all are clumped The site of attachment should be recorded, whether they are head-to-head, tail-to-tail, tail-tip-to-tail-tip, mixed, or tangled
Motility	Progressive sperm motility is linked to pregnancy rates. To reduce errors due to deterioration of the sample with time, motility should be determined soon after liquefaction, within 30 minutes or at most within 60 minutes. Motility is graded as: • Progressive motility (PR): Active movement, linear, or circular • Nonprogressive motility (NP): Any other pattern of movement • Immotility (IM): No movement Fast progressive (1), slow progressive (2), nonprogressive (3), and immotile (4)
Vitality	Sperm vitality is an estimate based on the percentage of sperm cells with an intact plasma membrane. Vitality is particularly important in the cases of samples with less than about 40% progressively motile sperm,[9] because the percentage of dead sperm should not be greater than the percentage of immotile sperm. Either of two methods is usually used: • *Dye exclusion—eosin-nigrosin one-step technique:* The plasma membrane of live sperm cells does not allow dyes such as eosin (yellow in color) to permeate into the cell. However, the membrane of a dead sperm cell is damaged and allows the eosin dye to stain the cell. Nigrosin (black in color) increases the contrast between the background and the sperm heads, making it easier to discern the dead sperm cells. Slides can be stored, allowing for reevaluation and quality control • *Hypoosmotic swelling (HOS):* On the other hand, the HOS test is used to discern live sperm cells because, in a hypotonic solution, only the cells with their plasma membranes intact would swell. This is an advantageous alternative because spermatozoa staining must be avoided in some cases, such as choosing spermatozoa for intracytoplasmic sperm injection (ICSI)
Sperm concentration	Sperm are counted per slide, then concentration and number are calculated for the sample
Sperm number	
Round cells number	Calculation of round cells is done relative to the number of sperm
Morphology	Like the "strict criteria" detailed by Dr. Thinus F. Kruger (Tygerberg Hospital, South Africa), the World Health Organization (WHO) criteria classify rather few sperm as having normal morphology, even in semen collected from fertile men. Morphological anomalies can be found—in more than one part—in the head, neck, mid-piece, and tail. Defective spermatogenesis and epididymal pathologies may increase the percentage of abnormal sperm morphology. Sperm with abnormal morphology generally have a lower ability to cause fertilization

TABLE 4: Lower reference limits (fifth centiles and their 95% confidence interval) for some semen characteristics.

Parameter	*WHO 5th edition*[9]	*WHO 6th edition*[1]
Semen volume (mL)	1.5 (1.4–1.7)	1.4 (1.3–1.5)
Total sperm number (10^6/ejaculate)	39 (33–46)	39 (35–40)
Sperm concentration (10^6/mL)	15 (12–16)	16
Total motility (PR + NP, %)	40 (38–42)	42 (40–43)
Progressive motility (PR, %)	32 (31–34)	30 (29–31)
Nonprogressive (NPR, %)	1	1 (1–1)
Immotile	22	20 (19–20)
Vitality (live spermatozoa, %)	58 (55–63)	54 (50–56)
Sperm morphology (normal forms, %)	4 (3.0–4.0)	4 (3.9–4)

(WHO: World Health Organization)

TABLE 5: Consensus threshold values for other semen characteristics.[1]

Parameter	*Threshold value*
pH	7.2
Peroxidase-positive leukocytes (10^6/mL)	≥1.0
Mixed antiglobulin reaction (MAR) test (% motile spermatozoa with bound particles)	<50
Immunobead test (% motile spermatozoa with bound beads)	<50
Seminal zinc (μmol/ejaculate)	≥2.4
Seminal fructose (μmol/ejaculate)	≥13
Viscosity	≤2 cm thread after liquefaction
Sperm agglutination	Absent

TABLE 6: Basal hormone levels in various clinical states.[11]

Clinical condition	*FSH*	*LH*	*T*	*PRL*
Normal spermatogenesis	Normal	Normal	Normal	Normal
Hypogonadotropic hypogonadism	Low	Low	Low	Normal
Abnormal spermatogenesis	High/normal	Normal	Normal	Normal
Complete testicular failure or hypergonadotropic hypergonadism	High	High	Normal/low	Normal
PRL-secreting pituitary tumor	Normal/low	Normal/low	Low	High
Androgen excess	Normal/low	Normal	High	Normal
Hypothyroidism	Low	Low	High	
Hyperthyroidism	High	High	Low	
Insulin disorders	Decreased spermatogenesis, reduced vacuolization in the Sertoli cells, decreased fertility, decreased semen parameters, decreased Leydig cells count, decreased testosterone			

(FSH: follicle-stimulating hormone; LH: luteinizing hormone; PRL: prolactinomas; T: testosterone)

Note that the reference limits provided in **Tables 4 and 5** are from semen samples from men who had initiated natural conceptions; so, they represent the semen characteristics those are associated with the couples in the WHO study who achieved pregnancy during a 12-month period of unprotected sexual intercourse. Thus, these limits can only be used as guidelines and should not be used to distinguish between fertile and infertile men. Further, though these limits could indicate that a man needs treatment for infertility, they should not be used to ascertain the nature of the treatment.

Although each of the sperm parameters in **Tables 4 and 5** could be used to predict fertility and subfertility, the terms "normozoospermia," "asthenozoospermia," "necrozoospermia," and "teratozoospermia" are voluntarily removed in the WHO 6th manual as no single one is a powerful discriminator. Most importantly, these so-called normal values do not actually correspond to normal sperm concentrations in the general population, and, as such, the values cannot be considered as the minimum sufficient for conception. Men with out-of-range semen values could be fertile, while those with values within range could be infertile.[3] The male partner should be counseled for a repeat analysis if the result of the first is abnormal.

HORMONAL EVALUATION

One to two percent of male infertility is occasionally related to endocrinopathies.[10]

The international societies have evaluation limited to men with a sperm concentration below 10×10^6/mL or impaired sexual function, or if endocrinopathy is suspected.[6,8] However, a customized approach of the case would enable timely treatment and restoration of infertility.

Inhibin B: This is produced in males exclusively by Sertoli cells in the testis. It leads to negative feedback for follicle-stimulating hormone (FSH) secretion. Inhibin B, FSH, and testicular volume are important markers of the competence of Sertoli cells and spermatogenesis in a man. There is a positive correlation between sperm count and serum level

of inhibin B and testicular volume. The adult reference level of 170 pg/mL is standard. Inhibin B can be used as a discriminatory biomarker to differentiate nonobstructive azoospermia (NOA) patients from obstructive azoospermia patients.[12,13]

EXTENDED SEMEN ANALYSIS

Sperm function tests analyze the functional aspects of spermatozoa and therefore augment semen analysis **(Box 1)**.[14]

The clinical application of these tests:[15]

- Clinical varicocele
- Unexplained infertility or intrauterine insemination (IUI) failure or recurrent pregnancy loss
- In vitro fertilization (IVF) failure, or intracytoplasmic sperm injection (ICSI) failure, or both
- Borderline abnormal (or normal) semen parameters with risk factor.

However, with the development of ICSI, hemizona or acrosome function assays have lost their significance because the penetrating capability of sperm is bypassed by ICSI.

The most commonly applied deoxyribonucleic acid (DNA) integrity tests, none indicate the specific DNA sequences that might be affected; rather, each provides a semiquantitative estimate of the general state of the DNA being studied.

- *Sperm chromatin structure assay (SCSA):*[16] It utilizes flow cytometry of fluorescently labeled sperm to determine the proportion of sperm susceptible to DNA damage (red fluorescence) compared with normal sperm (green fluorescence). Sperm samples diluted with a 1× TNE buffer are exposed for 30 seconds to a 1.2 pH acid detergent solution. Acridine orange (AO), a DNA-binding fluorescent dye, is then added. Normal range is 25–27%.
- *Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) assay*: This utilizes flow cytometry of sperm fluorescently labeled at DNA strand breaks to determine the degree of DNA damage; the fluorescence intensity is proportional to the number of strand breaks. Normal is <36%.
- *Single-cell gel electrophoresis assay (SCGE, also known as comet assay):* Fluorescently labeled sperm cells are embedded in an agarose gel, lysed to relax the DNA, and electrophoresed. The electrophoresis causes structures resembling comets, hence the name. DNA damage is proportional to the displacement between the nuclear material and the tail material.
- *Sperm chromatin dispersion (SCD) test:* This utilizes fluorescence microscopy to discriminate between cells with intact DNA (large halo) and sperm cells with damaged DNA (small or absent halo).
- *Oxidation–reduction potential (ORP) assay:* ORP levels can lend support to routine semen analysis. In patients with idiopathic male infertility, abnormal ORP levels are particularly useful in pinpointing altered sperm function, thereby improving the accuracy of therapy management.[17]

Chemiluminescent or fluorescent techniques can have prognostic value in the evaluation of oxidation–reduction potential with a cutoff value of <102.2 RLU/s/10^6 sperm/mL to distinguish between men who are fertile and men with infertility.[18,19]

BOX 1: Sperm function tests.

- Sperm zona pellucida binding—hemizona assay
- Sperm DNA fragmentation—SCD, TUNEL, SCSA, comet assay
- Acrosome reaction–acrosome reaction
- Reactive oxygen species—chemiluminescence (luminometer) ORP (MiOXSYS)
- Mitochondrial function—mitochondrial membrane potential

(DNA: deoxyribonucleic acid; MiOXSYS: Male Infertility Oxidative System; ORP: oxidation–reduction potential; SCD: sperm chromatin dispersion; SCSA: sperm chromatin structure assay; TUNEL: terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling)

Genetic Screening

Fifteen percent of men with infertility can be attributed to genetic mutations in embryos leading to repeated ICSI failure, recurrent miscarriage, or vertical transmission of paternal genetic defects.[20]

International societies agree on recommending karyotype analysis for men with azoospermia or severe oligozoospermia (sperm count <5 × 10^6/mL).[21] EAU recommends the use of genetic screening also if there is a family history of recurrent spontaneous abortions, malformations, or intellectual disability,[22] regardless of the sperm concentration.

The most common genetic abnormalities associated with male factor infertility are:

- *Chromosomal abnormalities:* The most common chromosomal abnormalities in azoospermic men are abnormalities involving the sex chromosomes, which are found in approximately 4% of these men. Due to these abnormalities, proper chromosome pairing during meiosis is impaired, giving rise to spermatogenic disruption and the infertility phenotype. The most frequent abnormality is called Klinefelter syndrome, in which patients show a 47,XXY karyotype.
- *Karyotypic chromosomal abnormalities:* The incidence of chromosomal abnormalities is higher in infertile men and is inversely proportional to their sperm count; the incidence is 10–15% in azoospermic men, 5% in men with severe oligozoospermia (<5 million/mL), and <1% in men with normal sperm concentrations.[5]

For infertile men with such abnormalities, karyotype analysis is strongly recommended—either before

using ejaculated sperm in performing ICSI or before testicular sperm extraction/aspiration (TESE/TESA). Prior knowledge of a chromosomal translocation would beneficially alter therapeutic planning to include the use of preimplantation genetic screening in discarding chromosomally unbalanced embryos, thus allowing the transfer of balanced or normal embryos.

- *Y chromosome microdeletions (YCMD):* Over 40 years ago, in 1976, Tiepolo and Zuffardi first suspected Y chromosome involvement in male infertility when they detected obvious terminal deletions. At that time, they postulated that infertility resulted from defects in the gene controlling spermatogenesis; it was called the azoospermia factor (*AZF*) gene. In 1996, Vogt et al. discovered three separate deletion intervals named AZFa, AZFb, and AZFc. A meta-analysis by Kohn et al. showed that the majority of YCMD occur in men with sperm counts of $<1 \times 10^6$/mL.[23]

  The latest EAU guidelines recommend Y chromosome microdeletion testing if sperm concentrations are $<5 \times 10^6$/mL and make such testing mandatory for sperm concentrations of $<1 \times 10^6$/mL.[8]

  Y chromosome microdeletions transmitted from fathers to sons by ICSI may maintain the same characteristics and size; though, without single-cell amplification, the stability of the boundary of the deletion cannot be determined with certainty. Such men had higher incidence of abnormal sperm karyotypes, and spermatozoa of men with AZFc or partial AZFb deletions will successfully fertilize and generate offspring at the same rate as nondeleted infertile men. Though deletions in the AZF regions apparently do not adversely affect the psychological and physical development of the children, men with such microdeletions must be informed of the risk of transmission of genetic defects as well as their infertile testis phenotype.[24]

  Although standard Y-deletion screening can detect deletions of AZFa, AZFb, and/or AZFc, there might be other, as yet undetected, deletions on the Y chromosome. The availability of the complete Y sequence will facilitate more precise research on Y chromosome integrity. Further research into the other numerous testis-specific genes, which are not part of the Y chromosome, would definitely help to illuminate the complex spermatogenesis process while also enabling screening for genetic aberrations in male partners of couples planning for ICSI.

  All infertile males should be provided genetic counseling, irrespective of whether an abnormality is detected or whether Y-deletion testing has even been done. The frequency of detection of genetic aberrations in infertile males using karyotyping and standard Y-deletion screening is <15%. Even so, some deletions might remain undetected because standard screening needs much improvement. Also, some suspected deletions may turn out to be polymorphisms, thus having no clinical significance. Finally, despite the apparent lack of cytogenetic or Y chromosomal abnormality in an infertile male patient, a genetic cause for his azoospermia or severe oligozoospermia may well be present.[25]
- *Cystic fibrosis:* The cystic fibrosis transmembrane conductance regulator (*CFTR*) gene is responsible for the production of a protein called the cystic fibrosis (CF) transmembrane conductance regulator protein. This protein acts as a channel to allow ions such as those of chloride and sodium to cross the membranes of cells. The movement of chloride ions controls the movement of water in and out of tissues and thus is critical in the production of mucus. For men with structural abnormalities of the vas deferens, it is recommended that both partners be tested for *CFTR* mutations containing a minimal panel of common point mutations and the 5T allele.[8]

Antisperm Antibodies

An uncommon cause of male infertility, antisperm antibodies (ASAs) may be detected in the serum, in the seminal plasma or directly bound to sperm. Consequent to a rupture in the blood–testis barrier, ASAs can form if the immune system is exposed to large quantities of sperm antigens. Risk factors for ASA formation include trauma, torsion, biopsy, orchitis, testicular cancer, and vasectomy.

Testing for ASAs is usually done when the semen analysis shows sperm agglutination or isolated asthenospermia (while sperm concentration is normal). ASAs in the serum or seminal plasma are detected using indirect antibody agglutination assays, while ASAs (immunoglobulin G and A) bound to the sperm head or tail are detected using a direct immunobead test. Sperm-bound ASAs could be important in clinical practice because of their cascade of effects—decreased motility, reducing the penetration of the cervical mucus, in turn reducing fertilization, and thus, greatly decreasing the likelihood of conception.

Antisperm antibodies are usually managed using ICSI. Therefore, if ICSI has been planned, testing for ASAs is unnecessary since its helpfulness in practice is unclear.[26] ASA testing should not be a part of routine male infertility evaluation. ASAs do not hamper the pregnancy rates of IVF or ICSI, which, therefore, become treatment options.[27]

Microbiological Assessment

Conditions indicating microbiological assessment include abnormal urine samples, urinary tract infections, male accessory gland infections (MAGIs), and sexually transmitted diseases. The combination of low ejaculate volume and the presence of white blood cells in the semen could

mean ejaculatory duct obstruction, perhaps partial, resulting from an infection of the prostate or seminal vesicles. Genital tract obstruction can also result from *Neisseria gonorrhoeae* and *Chlamydia trachomatis* infections. Further, genital infections could provoke the production of spermatotoxic oxygen radicals. Antibiotic procedures for MAGI might improve sperm quality but not the probability of conception.

Viral Screening

Screening for human immunodeficiency virus (HIV), hepatitis B surface antigen, and hepatitis C virus should be offered to couples undergoing IVF or opting for semen freezing.

Ultrasonography

Almost the entire male genital tract can be easily and accurately imaged using ultrasonography; therefore, it is used to detect abnormalities that adversely affect fertility. However, it is required only in a minority of cases.

Transrectal Ultrasonography

Usually, seminal vesicles are <1.5 cm in the anteroposterior diameter. Thus, when dilated seminal vesicles or ejaculatory ducts and/or midline cystic prostatic structures are seen in transrectal ultrasonography (TRUS), this suggests—without establishing by itself—partial or complete ejaculatory duct obstruction. Typically, the ejaculate is low-volume and acidic, containing neither sperm nor fructose. Similar findings are seen for men with CBAVD because they often have absent or atrophic seminal vesicles. Unsurprisingly, partial ejaculatory duct obstruction often manifests low-volume ejaculate, oligoasthenospermia, and poor progressive motility. Outside of consensus, a few experts advocate routine TRUS for men with normal testicular size and normal serum T but with oligospermia, low-volume ejaculate, and palpable vasa.

Scrotal Ultrasonography

Most scrotal pathology, such as varicoceles, spermatoceles, absent vasa, epididymal induration, and testicular masses, can be identified via careful physical examination. Though scrotal ultrasonography can be used to identify varicoceles that are not palpable, they have no clinical significance because only palpable varicoceles have been linked with infertility. However, scrotal ultrasonography is more useful in clarifying vague or ambiguous physical examination findings or abnormalities such as apparent masses. It is also useful in cases with testes located in the upper scrotum, a small scrotal sac, or anatomy hindering examination. Further, scrotal ultrasonography is recommended for men with infertility and risk factors for testicular cancer, such as cryptorchidism or a previous testicular neoplasm, but not as a routine screening procedure.

Conclusion

Knowing the prevalence of a disease is central in the endeavor to manage patients, provide resources, estimate impact, present rational research questions, and effectively make arguments on the health economy. However, on a global level and across all health economies, there is a severe lack of clinical data on the extent of reproductive health problems and infertility in men.

The best estimates on infertility are based on demographic health studies which depend on heterosexual women to self-report a problem with becoming pregnant, and which further assume female infertility (due to minimal reporting of clinical diagnosis), or possibly, an infertile relationship. This, coupled with an even more severe lack of male diagnosis and management of infertility in low- and middle-income countries, renders any male infertility prevalence values which are based upon demographic health reports or reports from small private clinics to be, at best, greatly extrapolated and highly inaccurate. Consequently, and unsurprisingly, there is inadequate information on basic but crucial indicators such as the socioeconomic impact of infertility and other diseases or disorders on the individual as well as the society as a whole.

Improving the care of couples and expanding the collective knowledge of the scale of the problem depend on highlighting the criticality of male partner engagement in the assessment of the infertile couple and public awareness and education about male infertility. Equally crucial is the need to ascertain the potential consequences of male infertility; this is an extensive investigation which goes beyond the confines of the couple and their immediate relationships, to find out, for example, the relationship of infertility with other diseases and the associated impact.

RECOMMENDATIONS

- *Assess several ejaculate parameters:* For a more accurate prediction of fertility success
- *A single ejaculate is sufficient:* To determine the most appropriate investigation and treatment pathway (can repeat semen analysis if abnormalities are found)
- *Perform karyotype and YCMD testing:* On all males with severe oligozoospermia (<5 × 10^6/mL) or NOA prior to any therapeutic procedure
- *Offer CFTR mutation analysis:* To all males with CBAVD or CF.[10]

DIAGNOSIS OF INFERTILITY (FEMALE)

Female Infertility

Failing to achieve pregnancy after 12 months or more of regular and unprotected sexual intercourse is an indication for couples to undergo diagnostic evaluation

for infertility. As roughly 85% of couples usually achieve an unassisted natural pregnancy in 12–18 months, around 15% of couples would require evaluation for infertility. A couple in which the woman is over 35 years of age, after 6 months of attempting to conceive naturally, should soon undergo evaluation. This may also be necessary in cases with:

- History of oligo- or amenorrhea
- Known or suspected uterine/tubal/peritoneal disease or stage III–IV endometriosis
- Known or suspected male subfertility.

When appropriate for the couple, both partners should undergo evaluation at the same time. Women who intend to attempt pregnancy by donor insemination would benefit by undergoing evaluation before starting treatment.[28,29]

History and Physical Examination

Preferably, this should be done during the first consultation, allowing enough time for gathering a complete history (medical, reproductive, family, and social/lifestyle), carrying out a detailed physical examination, and counseling the patient about preconception care and about screening for any pertinent pathological and/or genetic conditions.

History

A comprehensive history should cover and document the following:

- *Sexual history, including:*
  - Frequency and timing of coitus
  - Sexual dysfunction
  - Previous methods of contraception
  - Duration of infertility and previous fertility
  - Previous evaluation and treatment
  - Menstruation (menarche, cycle, molimina, and dysmenorrhea)
  - Pregnancy (gravidity, parity, outcome, and complications).
- *Medical history, including:*
  - Surgery (procedures, indications, and outcomes), hospitalizations, serious illnesses or injuries, pelvic inflammatory disease, or sexually transmitted infections
  - Thyroid disease, galactorrhea, hirsutism, pelvic or abdominal pain, and dyspareunia
  - Previous abnormal Pap smears and any subsequent treatment
  - Current medications and allergies
  - Family history of birth defects, mental retardation, early menopause, or reproductive failure or compromise.
- *Social/lifestyle history, including:*
  - Occupation
  - Exposures to gonadotoxins (including environmental and chemical toxins and heat)
  - Use of tobacco, alcohol, and recreational drugs.

Physical Examination

A thorough physical examination should cover and document the following:

- Weight, BMI, blood pressure, and pulse
- Thyroid enlargement and presence of any nodules or tenderness
- Breast secretions and their character
- Signs of androgen excess
- Vaginal or cervical abnormality, secretions, or discharge
- Pelvic or abdominal tenderness, organ enlargement, or masses
- Uterine size, shape, position, and mobility
- Adnexal masses or tenderness
- Cul-de-sac masses, tenderness, or nodularity.

Diagnostic Evaluation

Evaluation should progress according to the couple's preferences, partner ages, duration of infertility, and significant features of their medical history and physical examination.

Ovulatory Function

Between 15 and 45% of cases of infertility in women arise from ovulatory dysfunction. Common causes of anovulation include polycystic ovary syndrome (PCOS), excess weight gain, thyroid disorders, and strenuous exercise. Though the detection of ovulation is of use, it is eminently more useful for the practice of assisted reproduction to identify the fertility window, which starts, due to sperm lifespan, about 3–5 days before ovulation, and ends, due to oocyte lifespan, about 1–2 days after ovulation.

Methods of evaluating ovulatory function are discussed below.

Menstrual History

A regular 25–35-day cycle indicates normal ovulation. Amenorrhea and oligomenorrhea indicate anovulation.

Basal Body Temperature

Ovulatory cycles typically exhibit a biphasic pattern of temperature change of dip followed by a rise, whereas anovulatory cycles show a single pattern. However, predicting ovulation using basal body temperature (BBT) is not reliable.

Serum Progesterone

Traditionally, the serum progesterone test has been considered to reliably predict ovulation. The adrenal glands produce progesterone and, prior to ovulation, provide a

steady baseline serum progesterone value between 1.5 and 3 ng/mL. After ovulation, a corpus luteum forms and starts producing progesterone, raising the value over 3 ng/mL to a peak between 10 and 20 ng/mL on day 21 of a regular 28-day cycle (or, for longer cycles, 7 days before the start of the next cycle). Serum progesterone >3 ng/mL indicates ovulation, whereas serum progesterone >10 ng/mL indicates the quality of luteal function. However, since the corpus luteum secretes progesterone in pulses, the figures may vary depending on the time of day when the blood is drawn.[30,31]

Luteinizing Hormone Detection Kits

The dominant follicle produces the serum estradiol (E2), which, after reaching a threshold concentration level of over 200 pg/mL and being maintained for about 50 hours, causes the pituitary gland to abruptly release luteinizing hormone (LH) into the bloodstream, this is called the LH surge, and it is followed by ovulation in a day or two. A study of 35 women over 155 cycles found that, in the majority (85%), the LH surge begins between midnight and 8 am. Detecting the LH surge, whether in urine or in serum, can sensitively and reliably indicate ovulation.

Obviously, the detection of urinary LH is noninvasive and preferable to multiple drawings of blood. Urinary LH concentrations during the surge vary from 20 to 100 mIU/mL. Highly sensitive over-the-counter kits, detecting as little as 22 mIU/mL, make it extremely convenient for women to inexpensively test themselves in the privacy and comfort of their homes. For a reliable prediction of the ovulation day, women should test themselves over several menstrual cycles—starting on the 10th or 11th day of each cycle, once or twice a day for 5 days.[32]

In a study of 951 cycles of IUI, urine samples taken at four different times of the day were tested for LH. The distribution of the first positive test is shown in **Table 7**.[33]

Endometrial Biopsy

Lacking precision, endometrial biopsy is not an acceptable test of ovulation; thus, it is no longer recommended.

Transvaginal Sonography

Transvaginal sonography (TVS) is considered the standard reference examination for determining the time of ovulation, using signs such as:

- Collapse of follicle or abrupt decrease in size
- Increase in echogenicity of both follicle and endometrium
- Free fluid in the pelvis.

TABLE 7: Distribution of the first positive test.

Early morning 04:00–10:00	*Lunch time 11:00–15:00*	*Tea time 16:00–20:00*	*Bed time 21:00–00:00*
27%	44.5%	15.7%	12.8%

Further, it allows the identification of the number and size of growing follicles as well as the identification of any uterine and/or adnexal pathologies. However, TVS is expensive because it must be performed by an experienced professional (radiologist or gynecologist) and requires the patient to come to the clinic for a series of examinations. As such, it is slightly invasive, somewhat uncomfortable, and quite inconvenient.

Other tests include thyroid stimulating hormone (TSH) and prolactin.

Ovarian Reserve

Ovarian reserve is generally explained as the number of oocytes in a female at any given time. Formally, it is the concept that reproductive potential is a result of the number and quality of extant oocytes in a female.[34] In practice, ovarian reserve is assessed on the consideration that the number and quality of antral and mature follicles that form in response to endogenous or exogenous ovarian stimulation are proportional to the available reserve of oocytes in the ovaries of a woman.[35] Thus, when regularly menstruating women of reproductive age are found to have a poor response (less than three to four dominant follicles with a diameter >12 mm) to ovarian stimulation (using a minimum of 150 IU of FSH) than other women of comparable age, they are classified as having "poor ovarian reserve/diminished ovarian reserve (POR/DOR)."[36]

Established ovarian reserve tests (ORTs) include day 3 measurements of serum FSH, E2, and inhibin B; clomiphene citrate challenge test (CCCT); and the two most sensitive—antral follicle count (AFC) and serum anti-Müllerian hormone (AMH)—levels.

The tests may have predictive value for women at increased risk of DOR, such as those:

- Over 35 years of age
- With unexplained infertility
- Whose family has a history of early menopause
- Demonstrating poor response to gonadotropin stimulation
- Planning treatment with assisted reproductive technology (ART)
- With a single ovary or a history of previous ovarian surgery, chemotherapy, or pelvic radiation therapy.

It is important to remember that, rather than substantiating a diagnosis of DOR, ORTs help predict ovarian response to exogenous gonadotropin stimulation and, to a smaller degree, the prospect of pregnancy using ART. Equally importantly, poor test results are not an indication of an inability to conceive. Although ORTs are widely applied, there is an ongoing debate over their ability to predict three outcomes, which are linked but quite separate—quality of oocytes, quantity of oocytes, and fecundity. Ovarian reserve testing aims to provide additional prognostic information

useful in counseling and planning, thus helping couples choose among treatment options.

Follicle-stimulating Hormone

Follicle-stimulating hormone is the first hormone to be linked with declining ovarian function. It is secreted by the anterior pituitary gland and stimulates the growth of antral follicles into dominant follicles. As the age of a woman increases, so do the concentrations of her basal serum FSH of the second, third, or fourth day of the menstrual cycle.[37]

However, though many studies have found that, independent of age, women with high FSH concentrations respond poorly to ovarian stimulation and thus have lower pregnancy rates, a lack of consensus in defining "high FSH concentration" has caused difficulties in test interpretation.[38] Further, considerable inter- and intra-cycle variability in the assays for FSH limits their reliability. Thus, high values are linked to but cannot be used to predict poor ovarian response and lack of conception.[37]

For clinicians trying, in their practice, to apply FSH cutoff points in medical literature, additional confusion arises due to a change in standard, from International Reference Preparation (IRP)-human menopausal gonadotropin (hMG) to the World Health Organization (WHO) Second International Standard (IRP 78/549). Cutoff point values of the two standards are compared in **Table 8**.

Assays which have been standardized against the WHO second International Standard exhibit high specificity (83–100%) in prediction of poor ovarian response to stimulation (<2–3 follicles or ≤4 retrieved oocytes) using several cutoff points over 10 IU/L (10–20 IU/L). Nevertheless, for the purpose of identifying poor responders, FSH assay sensitivity varies too widely (10–80%), decreasing with increasing FSH cutoff points.[37]

A study of 293 patients found that over 90% of those achieving a live birth lacked a high FSH.[38] Many studies have concluded that the utility of basal FSH is, at best, limited to that of a screening test.[37,38]

Estradiol

Like FSH, basal E2 of the second, third, or fourth day of the menstrual cycle has poor reliability as an ORT because it has diurnal, inter-, and intra-cycle variation. Additionally, test results can be misinterpreted because reproductive aging typically features increased serum E2 concentrations which may produce feedback suppression of FSH, lowering the level into the normal range. The presence of seemingly "normal" basal FSH concentration but too low or too high (<20 or >60–80 pg/mL) E2 level early in the follicular phase has been linked with the poor ovarian response, though *not* with lower pregnancy rates. Further, with a substantial majority of studies finding no difference in basal E2 values between normal women and women with DOR, the test has no predictive value and, thus, is not recommended for routine clinical practice.[34,37,39]

TABLE 8: Comparison of cutoff point values of the International Reference Preparation-human menopausal gonadotropin (IRP-hMG) to the World Health Organization (WHO) second International Standard (IRP 78/549).

Reference standard	*Cutoff point*		
	High	*Moderately high*	*Normal*
IRP-hMG	25	17	<15
IRP 78/549	16.7	11.4	<10

Inhibin B

Inhibin B, a heterodimeric glycoprotein secreted by the granulosa cells of growing follicles, downregulates pituitary FSH. Upon gonadotropin-releasing hormone (GnRH) or FSH stimulation (the basis of dynamic tests of ovarian reserve) during the luteal-follicular transition, inhibin B serum levels rise, peaking halfway through the follicular phase, while also varying significantly between menstrual cycles, thereby exhibiting high intra- and inter-cycle variability. Further, though, with age, the inhibin B levels taper off and perhaps cause the subsequent rise in FSH levels. It is a late marker of ovarian reserve decline. The cutoff point for low inhibin B as a marker of poor response varies widely among studies (40–141 pg/mL).[37,40]

With most studies proving that inhibin B, by itself, is of little value in predicting ovarian reserve and response, it is not recommended for routine use. Due to the low accuracy, attempting to use the levels as a diagnostic or screening test for ART programs will lead to needless rejection of patients. At best, the information can be used for counseling.[37,39-41]

Clomiphene Citrate Challenge Test

Clomiphene citrate, a synthetic compound, is an ovulation-inducing fertility drug that, taken orally, binds to estrogen receptors in the brain, thereby binding the hypothalamus–pituitary axis to the circulating endogenous estrogen, consequently stimulating the pituitary gland to release FSH and attempting to normalize the luteal phase.[42] Therefore, the CCCT is both a treatment and a test. It involves measuring serum FSH on cycle day 3, dosing the patient daily with 100 mg of clomiphene citrate on cycle days 5–9, and measuring serum FSH again on cycle day 10.[41]

While the group of growing follicles produces increasing inhibin B and E2 levels, which suppress FSH in women with responsive ovaries, the smaller follicles that respond in women with DOR generate less inhibin B and E2, reducing negative feedback inhibition of FSH secretion and, consequently, increasing stimulated serum FSH levels. Thus, a high serum FSH level after clomiphene stimulation suggests DOR.[37,41]

However, systematic reviews of the CCCT found that, though the test has higher sensitivity than basal FSH in predicting poor ovarian response, it has lower specificity and significant inter-cycle variability, leading them to conclude that the test does not improve prediction accuracy.[37,40] Additionally, clomiphene citrate has a list of side effects:

- Formation of cysts
- Development of multiple follicles (superovulation), thereby increasing the risk of multiple pregnancies (when fertilized in vivo)
- An adverse peripheral antiestrogenic action on the cervical mucus and endometrium (reduction in thickness), significantly reducing pregnancy rates
- Development of resistance to it (25% incidence), forcing poor responders to use another drug for fertility treatment.[42]

Further, although the drug itself is cheap, the CCCT is expensive and time-consuming to conduct. Thus, it has relatively little value in clinical practice.[39,42]

Anti-Müllerian Hormone

Performing a fundamental role in sex differentiation, the AMH is a glycoprotein and, such as inhibins and activins, is a member of the transforming growth factor-β (TGF-β) superfamily of tissue growth and differentiation factors.[43]

In women, ovarian AMH production starts around birth; however, it is barely detectable in the serum.[44] The levels rise during puberty, peak between 20 and 25 years, then taper off with age, becoming undetectable by menopause.[45] Many studies have confirmed age-related AMH serum level decline.[46]

Since AMH is produced mainly by the granulosa cells of preantral and antral follicles, serum levels are a significant marker of ovarian reserve.[47] A study involving 42 women undergoing oophorectomy found a high correlation of both AMH and AFC with the number of primordial follicles in their ovaries. Further, during normal menstrual cycles, follicular phases do not affect AMH serum levels. Whereas, inhibin B, E2, and FSH are not only menstrual-cycle-dependent, but also comparatively late in marking primordial follicle pool depletion. Thus, AMH is easier to use clinically.[46]

In the context of ART, AMH testing can be used to predict an individual woman's response to controlled ovarian hyperstimulation (COH). The accumulating evidence suggests that, of the available ORTs, the AMH test is the most sensitive and specific.[28,29] Analysis of results of the first IVF treatment cycle of 4,700 women proved the accuracy of a single AMH test for individual women.[36]

When attempting to predict follicular status and responsiveness to COH, there are two noteworthy points regarding AFC: (1) Ultrasound technology cannot differentiate between atretic and healthy follicles and (2) common clinical practice counts follicles as small as 2 mm and as large as 12 mm.[41,48] Atretic follicles neither respond to FSH stimulation nor produce AMH. Thus, the AMH test is a better predictor of responsive follicles. In the ovary, AMH exerts an inhibiting role on many follicular functions, including granulosa cell sensitivity to FSH. Supporting this, antral follicle responsiveness to exogenous gonadotropins, clinically assessed by the Follicular Output RaTe (FORT), is inversely correlated with serum AMH.[49]

Antral Follicle Count

Antral follicle count is done by counting the antral follicles observed early in the follicular phase using transvaginal ultrasonography. AFC has good inter-cycle reliability and, with experienced radiologists and doctors, interobserver reliability as well. Studies vary in defining the size of the antral follicles: 2–6 mm, 3–8 mm, 7–10 mm, 2–10 mm, and 2–12 mm.[37,41,48]

A study of 474 subfertile, ovulatory patients found that the number of smaller follicles (2–6 mm) reduced with age, whereas the number of larger follicles (7–10 mm) remained constant. The study had also conducted other ORTs—basal FSH, basal inhibin B, clomiphene citrate challenge, and, after dosing with clomiphene citrate, inhibin B. The study found that the number of larger follicles correlated only with basal inhibin B, while the number of smaller follicles, independent of age, correlated highly with all the other ORTs used. The study concluded that the smaller follicles (2–6 mm, the ones mainly producing AMH) better represent the ovarian reserve.[48]

The consensus cutoff counts for ovarian stimulation are 3 AFC as poor response, 8–10 as normal, while 14 and over is hyperresponse. Other than AMH, AFC is viewed as the best discriminator for poor ovarian response. However, AFC has not proved reliable in predicting failure to conceive. Thus, AFC should not be the sole measure used in ART practice.[37]

Ovarian Volume

Measuring the three perpendicular dimensions (D1, D2, and D3) of an ovary and using the formula for the volume of an ellipsoid ($D1 \times D2 \times D3 \times \pi/6$) yields the ovarian volume. Total basal ovarian volume (BOV) is the sum of the volumes of both ovaries. Mean ovarian volume is, obviously, BOV/2. Ovarian volume is not a reliable test of ovarian reserve. Average ovarian volume does decline a little with age but only in the perimenopausal period (over 40 years), and thereby, it is a late marker of ovarian reserve, adding no predictive value to other ORTs.[37,39]

Ovarian Response

The ORTs reviewed above facilitate assessment of the ovarian reserve at a particular time in a woman's life, whereas the ovarian response is dynamic and depicts the performance

of a woman's ovaries following endogenous or exogenous stimulation. A poor ovarian response is defined as a reduced follicular response to maximal stimulation, with a subsequent reduction in the number of oocytes retrievable for use in IVF. At their Bologna convention, the working group of the European Society for Human Reproduction and Embryology (ESHRE) standardized the definition by proposing that the presence of any two of the criteria below is required to classify a specific low response to stimulation as poor ovarian response:

- Advanced maternal age or other poor ovarian response risk factor
- A previous poor ovarian response
- An abnormal ORT[37]

According to a retrospective study of 1,190 patients <40 years old, definitions of poor response should include the degree of ovarian stimulation used. The study found that if <3,000 IU FSH/cycle was sufficient to cause the ovaries to produce oocytes 18 mm in diameter, pregnancy (detected fetal heartbeat) rates were an encouraging 29% even if <4 oocytes were retrieved, and 33% when >4 were retrieved. On the other hand, when >3,000 IU FSH/cycle was required, pregnancy rates were 25% only if >4 oocytes were retrieved, compared to a mere 7% when <4 were retrieved.[50]

Combined Ovarian Reserve Testing

Since any ORT lacks 100% sensitivity and specificity in identifying women with DOR, some investigators have attempted to improve test characteristics by combining biochemical and imaging assays.[37,51]

Using a mean of two cycles of day 3 FSH and one of day 10 inhibin B, one study achieved a sensitivity of 71%, a specificity of 98%, and a receiver operator characteristic (ROC) curve of 0.92. Similarly, another study, using a combination of day 3 FSH, basal inhibin B, and AFC, achieved 75% sensitivity, 95% specificity, and 0.92 ROC. Though these were better characteristics than those of any single ORT, the results did not explain the prevalence of DOR in women of different ages.[51]

Standardizing ORT combinations is difficult because of variations in assay selection and cutoff points across studies, affecting their validity and reliability for use in clinical practice. In one review,[52] it can be seen that, while some combinations improved sensitivity, they decreased specificity, and other combinations did the reverse. Further, it can be observed that, for the same combination of ORTs, there is wide variation between studies. Thus, using >1 ORT does not consistently improve the prediction of ovarian reserve.

Tubal Evaluation of Infertility

Tubal disease accounts for 25–35% of female factor infertility with more than half of cases due to salpingitis. Proximal tubal disease accounts for 10–25% of tubal obstruction, and distal tubal obstruction accounts to 75–90% of cases.

Hysterosalpingography

The traditional and standard method for evaluating tubal patency, hysterosalpingography (HSG) is an invasive radiological procedure done by injecting a water-soluble contrast media (WSCM) or a lipid-soluble one (an iodine-based dye)[53] into the uterine cavity (delivered by a catheter pushed through the vaginal canal and past the cervix) and using either X-ray film or a fluoroscopy to visualize the travel of the contrast material through the fallopian tubes, Which if open, allows the contrast medium to spill into the peritoneal cavity. The medium sometimes flushes out blockages in the tubes and contributes to a higher pregnancy rate. According to a review of 13 trials that analyzed 2,494 women, those who underwent HSG with oil-soluble contrast media (OSCM) had a higher rate of live birth (odds ratio 3.09) and ongoing pregnancy (odds ratio 3.59) compared to women who did not undergo HSG. The review found no evidence that WSCM had a similar effect.[54]

Hysterosalpingography can prove salpingitis isthmica nodosa and can help reveal tubal architectural detail of potential prognostic value, such as proximal and distal tubal occlusion. Also, HSG may suggest the presence of fimbrial phimosis or peritubular adhesions when escape of contrast is delayed or becomes loculated, respectively. Findings suggesting proximal tubal obstruction (PTO) require further evaluation to exclude artifacts resulting from transient tubal/myometrial contractions or relating to catheter position.

Hysterosalpingography had a high specificity for proximal obstruction, but a low sensitivity. Distal obstruction, absence of hydrosalpinx, and adhesions had a poor accuracy. The likelihood ratio for the presence of hydrosalpinx was high. In conclusion, PTO detected on HSG changes the pretest probability of PTO from 16 to 50%. Proximal tubal patency detected on HSG changes the pretest probability of proximal tubal patency from 16 to 9%.

In conclusion, we can say that HSG has limited use in detecting tubal patency, defined as the absence of PTO and distal tubal obstruction. However, it is able to detect proximal tubal occlusion. The lack of sensitivity is not caused by a lack of reproducibility. The usefulness of HSG for detecting distal tubal obstruction is also limited. HSG is a good test to detect hydrosalpinx, but not very useful in ruling out this condition.

Saline Infusion Sonography

Saline infusion sonography (SIS) enhances visualization of the endometrial lining. It can also be used as a test to determine tubal patency using fluid and ultrasound,

though of limited utility because the normal fallopian tube lacking the defined interfaces that produce clear organ outlines relative to catheter position is a poor reflector of ultrasound. Although tubal patency can be observed by the appearance of fluid in the cul-de-sac with the saline infusion, the test does not differentiate between unilateral and bilateral patency.

Laparoscopy

Laparoscopy with chromopertubation is widely accepted as the "gold standard" method for evaluating tubal patency. At present, it is considered the most accurate diagnostic test available for evaluating tubal-related subfertility. Its advantages include an ability to simultaneously evaluate the abdominal cavity and other pelvic structures for an enhanced diagnostic evaluation of other etiologies of subfertility. The National Institute for Health and Care Excellence (NICE) recommends that women who are thought to have comorbidities should be offered laparoscopy and dye so that tubal and other pelvic pathology (such as pelvic inflammatory disease, previous ectopic pregnancy, or endometriosis) can be assessed at the same time.[55] According to a meta-analysis by Jacobson et al. (2004b), the ablation of endometriotic lesions with adhesiolysis to improve fertility in minimal and mild endometriosis is effective compared to diagnostic laparoscopic surgery (DLS) alone.

Unilateral and bilateral tubal occlusion, as per HSG and laparoscopy, are linked to treatment-independent pregnancy. HSG-visible one-sided tubal occlusion had an adjusted fecundity rate ratio (FRR) of 0.80, whereas two-sided tubal occlusion had an FRR of 0.49. With laparoscopy, one-sided and two-sided tubal occlusion had FRRs of 0.51 and 0.15, respectively. In 5% of the patients, a laparoscopy showing two-sided occlusion after a normal or one-sided occluded HSG was found; the treatment-independent conception rate was practically zero. In 42% of patients, a normal laparoscopic examination after two-sided occluded HSG was found; in these cases, fertility prospects were only slightly impaired with a 3-year cumulative ongoing intrauterine pregnancy rate of 9%.

Hysterosalpingo-contrast Sonography

Hysterosalpingo-contrast sonography (HyCoSy) is an ultrasound contrast technique that uses the instillation of an echogenic contrast medium into the uterine cavity through a catheter inserted through the cervical os. Saline mixed with air, which produces a contrast fluid due to the presence of air bubbles, is a cost effective option or ex-foam (created by diluting gel containing glycerol and hydroxyethyl cellulose) can be used. HyCoSy is usually done in the mid-proliferative phase (days 6–10 of a 28-day cycle) of the menstrual cycle.

The NICE recommends where appropriate expertise is available, screening for tubal occlusion using hysterosalpingo-contrast-ultrasonography should be considered because it is an effective alternative to HSG for women who are not known to have comorbidities.[55]

Hysteroscopy

Hysteroscopic tubal catheterization in patients with PTO can be used both as a diagnostic method and, considerably effectively, as a therapeutic one. First, efforts using hysteroscopic proximal tube catheterization and balloon dilatation for recanalization were intraoperatively successful in >80% of the cases. With laparoscopy, the hysteroscopic approach enables tubal cannulation and evaluation of the entire pelvis.

Falloposcope

Falloposcope has been successfully used without complications to characterize normal and abnormal epithelial changes, document endo tubal lesions ranging from accumulated debris, nonobstructive intraluminal adhesions, stenosis, polyps, to total fibrotic obstruction, as well as the identification of the segmental location of tubal pathology. Falloposcopic cannulation has been performed hysteroscopically under laparoscopic guidance by dilation and coaxial catheters, and nonhysteroscopically with the linear eversion cannula (LEC). Higher recanalization success rates have been reported with falloposcopic cannulation using the LEC compared with those achieved with coaxial cannulation.

Peritoneal Factors

Endometriosis, pelvic or adnexal adhesions, and other such peritoneal factors may play a role or may result in infertility. History and/or physical examination findings could evoke suspicion, but are hardly ever sufficient for diagnosis. Peritoneal factors may be causative in women with otherwise unexplained infertility. Transvaginal ultrasonography could uncover an endometrioma and other such previously unidentified pelvic pathology with reproductive implications.

Thus, it is evident that laparoscopy is necessary for women who have no other clear indications for ART (e.g., severe male factor infertility) but have symptoms, risk factors, or an abnormal HSG or ultrasonography; it has low utility for asymptomatic women with normal imaging. Diagnostic laparoscopy may benefit certain individuals, such as young women who have been infertile for longer than 3 years, but without recognized abnormalities.

Cervical Factors

Abnormalities of cervical mucus regarding production or its interaction with sperm are seldom the only cause of

infertility. Nevertheless, examination of cervical mucus could provide confirmation of chronic cervicitis requiring treatment.

The traditional method for diagnosing cervical factor infertility has been the postcoital test (PCT). As the name suggests, within hours after intercourse just prior to expected ovulation, a cervical mucus specimen is extracted and then examined under a microscope for the presence of motile sperm.

However, the PCT is not recommended anymore as an evaluation of infertility for three reasons. Firstly, the test is inconvenient to the patient; secondly, since it is subjective and has poor reproducibility, it is unable to predict the inability to conceive; finally, it seldom influences clinical management.

Chlamydial Antibody Testing

Chlamydial antibody testing (CAT) helps in avoiding unnecessary and invasive diagnostic testing and long-term expectative management, because in CAT-positive women, further testing can be performed early.[56] A conventional meta-analysis reported that accurate estimates of CAT for individual studies ranged between 21 and 90% for sensitivity and between 29 and 100% for specificity, with a summary ROC estimating the accuracy of CAT to be moderate and comparable to that of HSG.[57] Tubal pathology is linked to chlamydia antibody presence; although a positive test requires follow-up evaluation if the test is negative, tubal pathology at laparoscopy is unlikely (7–12%).

Conclusion

Female factors are a common cause of subfertility, which are often multifactorial and may be lifestyle related. Delay in childbirth that has a strong impact on the outcome of fertility treatment. Ovarian reserve testing may inform patients regarding their reproductive lifespan and also aid in counseling and treatment strategy. Though controversies persist regarding the diagnostic modalities and management of female infertility, the advances in the field of ART has given hope to women with the rising success rates.

KEY POINTS

- Both partners of a couple should be involved in counseling, and they must be investigated together.
- Investigations can identify the cause(s) of infertility and guide them about necessary treatment.
- The investigations and treatment cause a lot of stress in a couple, and therefore, they require a lot of support and care.
- Evaluation of ovulatory function should be an initial diagnostic step in the evaluation of all infertile women.
- If the menstrual history is obviously abnormal, further evaluation is *not* required to diagnose anovulation. If not, an objective measure of the ovulatory function is necessary. Properly timed, a serum progesterone concentration above 3 ng/mL provides reliable objective evidence for recent ovulation.
- In anovulatory infertile women, failure to achieve pregnancy after three to six cycles of successful ovulation induction should be viewed as an indication to perform the additional diagnostic evaluation or, if the evaluation is complete, to consider alternative treatments.
- Ovarian reserve should be assessed in select women at increased risk of DOR. Options include cycle day 3 FSH and E2, CCCT, ultrasound to assess AFC, or serum AMH.
- Histologic endometrial dating is not a valid method for the evaluation of luteal function.
- Examination of the uterine cavity is an important part of the evaluation of infertile women and can be accomplished using HSG, sonohysterography, or hysteroscopy.
- Evaluation of tubal patency is a key component of the diagnostic evaluation of infertile women. All methods for the evaluation of tubal patency have technical limitations that must be considered when interpreting test results. A second and different test should be considered when the diagnosis remains in doubt.
- Laparoscopy may be indicated when there is evidence or strong suspicion of advanced stages of endometriosis, tubal occlusive disease, or significant adnexal adhesions.
- Overall, FSH is the most commonly used screening test for DOR, but AFC and AMH exhibit less variability and therefore are promising predictors. A single FSH value has very limited reliability because of inter- and intracycle variability.
- Emerging evidence suggests that a low AMH level (e.g., undetectable AMH) has high specificity as a screen for poor ovarian response, but insufficient evidence to suggest its use to screen for failure to conceive.
- There is fair evidence to support that a low AFC (<6) has moderate-to-high specificity as a screening test for poor ovarian response and insufficient evidence to support the use of AFC as a screening test for failure to conceive.
- There is fair evidence against the use of basal inhibin B as a screening test for DOR.
- There is fair evidence against the use of ovarian volume as a screening test for ovarian reserve.
- There is fair evidence against the use of basal E2 concentration as a single screening test for DOR, but there is fair evidence that the basal E2 concentration helps in the accurate interpretation of basal FSH concentrations used to screen for DOR.

CHAPTER 17

Immunology and Infertility

Tity Chacko, Anupama Patil

INTRODUCTION

The immunology of pregnancy is complex and must allow the mother to not only remain immunocompetent to fight infections but also become tolerant to a semi-allograft fetus. Knowledge of the immunology of pregnancy helps us to understand this paradox. Maternal and fetal immune cells must actively participate for implantation, placental growth, and fetal development. During pregnancy, maternal and fetal cells come close to each other. Fetal cells have the potential to trigger an immune response in the mother.

IMMUNE SYSTEM

Our immune system consists of innate and adaptive immunity.

Innate Immunity

Natural Killer Cells

The natural killer (NK) is the most common leukocyte in the uterus during pregnancy. The decidual NK (dNK) cells are different from those present in peripheral blood. Most NK cells in blood (90%) have low CD56 and high CD16 expression ($CD56^{dim}/CD16^{bright}$); in the uterine decidua, dNK cells have high CD56 expression ($CD56^{bright}$). $CD56^{bright}$ cells produce cytokines, while $CD56^{dim}$ cells found in peripheral blood are cytolytic. Gravid uterus has high levels of $CD56^{bright}$ NK cells. NK cells also help in remodeling of spiral arteries and thus have a role in normal placentation.

Adaptive Immunity

Adaptive immunity consists of B and T cells (lymphocytes). Fetal cells express paternal genes, which are foreign to the mother's immune system.

Humoral Immune Response

B cells protect the body by secreting immunoglobulins. A unique population of B cells, called regulatory B (Breg) cells, produces interleukin (IL)-10, which is a powerful anti-inflammatory cytokine. Breg cells also inhibit production of the proinflammatory cytokine tumor necrosis factor alpha (TNF-α); hence, they help in preventing rejection of fetal allograft.

Helper T-cell Subsets

There are two types of T helper (Th) cells—Th1 and Th2 subsets. Regulatory T (Treg) cells play an important role in the maternal immune tolerance. Th1 cells threaten maternal tolerance of the fetus. In contrast, Th2 cells suppress Th1 cell differentiation. Maternal dendritic cells present antigens derived from fetal trophoblast apoptotic debris to the T cells in the maternal lymph nodes and the spleen. A mother's immune cells recognize "fetal" alloantigens of paternal origin before pregnancy in the lymph nodes draining the uterus after intercourse with genital tract exposure to the male partner's seminal fluid.

Progesterone

Progesterone, the important hormone of pregnancy, is initially produced by the corpus luteum. Subsequently, the placenta is responsible for almost all progesterone synthesis. Progesterone alters the ratio of Th1 to Th2 cells and inhibits the production of TNF-α. Treg cells, which are critical mediators of tolerance, become more numerous in pregnancy and produce IL-10, which appears to play a role in maintaining pregnancy. Human chorionic gonadotropin (hCG) in early pregnancy stimulates proliferation of Breg cells, whose action is similar to Treg cells. The implications of some of the immunomodulatory features of progesterone remain to be proven in the clinical setting; it is likely that dydrogesterone mimics the effects of progesterone through binding to progesterone receptors.

EXPLORING TREATMENT OPTIONS FOR TACKLING FETAL REJECTION

Adjuvant immunotherapies have been tried to improve the implantation rates in patients with recurrent implantation

failures. Immunotherapies may improve the immunological imbalance.

Aspirin

Aspirin causes vasodilation and tries to increase the blood flow to the uterus and hence increase the endometrial thickness and receptivity.[1,2] While four randomized controlled trials (RCTs) failed to show any benefit of aspirin on the implantation rate,[3-6] one trial showed an improvement which was statistically significant.[7] Recipients of oocyte donation, who had thin endometrium and so received Aspirin, had improved implantation rates but not the both rates.[8]

Summary Statement[9]

Routine use of low-dose aspirin in assisted reproductive technology (ART) cycles in the general population is not recommended.

Corticosteroids

Corticosteroids are produced in the adrenal cortex in response to adrenocorticotropic hormone from the anterior pituitary.[10,11] They decrease elevated androgen levels, which are detrimental to normal folliculogenesis and thus improve ovulation rates.[12,13] 290 patients were randomized to 1 mg dexamethasone or placebo in a double-blinded RCT. Although there was reduction in the rate of cancellation of cycle for poor response (2.8% vs. controls 12.4%, $p < 0.02$), there were no significant differences in fertilization, implantation, or clinical pregnancy rate per cycle start.

Peri-implantation Corticosteroids

Overactivity of NK cells has been hypothesized as one of the causes of implantation failure and early pregnancy loss.[14-17] Corticosteroids around the time of implantation have been tried to normalize NK cell activity and thereby increase endometrial receptivity.[14,18,19] Patients with anti-thyroglobulin and thyroid peroxidase antibodies ($n = 60$; age 38 years) were randomized to receive either 5 mg prednisolone daily from day of oocyte retrieval to pregnancy test or no treatment.[20] The treatment group had higher clinical pregnancy and live birth rates compared with the control group (clinical pregnancy: 46.6 vs. 16.6%, $p = 0.03$; live birth: 46.6 vs. 20%, $p = 0.055$).[21] Men with antisperm antibodies were randomized to receive 20 mg of prednisolone daily for 2 weeks before in vitro fertilization (IVF) and found that there was no improvement in the ART outcome.[22]

Summary Statements[9]

Routine use of corticosteroids during stimulation is not recommended in ART cycles in the general population. The routine use of corticosteroids during the implantation window to improve the outcome of live birth in ART cycles in the general population is not recommended. Subgroups that may benefit from peri-implantation corticosteroids need to be identified by additional studies.

Granulocyte Colony-stimulating Factor

Granulocyte colony-stimulating factor (G-CSF) and their receptors have been found in the reproductive system.[20] One level 1 study found no benefit of administering G-CSF during ovarian stimulation on the euploidy rate.[23] Another level 1 study found an increase in the endometrial thickness in women with a thin endometrium.[24] Another RCT of granulocyte-macrophage colony-stimulating factor (GM-CSF) treatment found an improvement in the implantation rate and live birth rate in women with recurrent miscarriage, and this was statistically significant.[25]

Summary Statement[9]

There is insufficient evidence to recommend for or against G-CSF or GM-CSF administered locally or systemically to improve IVF outcomes.

Intravenous Fat Emulsions

296 women with unexplained secondary infertility, recurrent spontaneous abortion, and elevated NK cell activity (>12%) were randomized to receive intravenous fat emulsions.[26] There was a statistically significant increase in the ongoing pregnancy rate and live birth rate. Another prospective cohort study on the effectiveness of intravenous fat emulsions on outcomes of women aged 40–42 years undergoing IVF-embryo transfer (ET) was terminated early because preliminary data showed no live births in the intravenous fat emulsion group and a 30% live birth rate in the untreated controls.[27]

Summary Statement[9]

There is no sufficient evidence to recommend routine intravenous fat emulsions for infertile women pursuing IVF.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) has anti-inflammatory activity. IVIG was associated with improved implantation rate [treatment group 8/45 (17.7%) vs. placebo 4/61 (6.5%), $p < 0.05$] but not live birth rate [treatment group 6/18 (33.3%) vs. placebo 4/21 (19.1%)].[28-30] Two cohort studies employed analysis of Th1:Th2 ratio in the peripheral blood for immune stratification of treatment and response.[31,32] One of these studies was observational, retrospective, and with an unusually high live birth rate. While the other study, also retrospective, demonstrated an improvement in implantation rate, specifically in patients with an elevated Th1:Th2 ratio (45% IVIG vs. 22% control).[32]

Summary Statements[9]

There is no sufficient evidence to recommend IVIG administration to improve IVF outcomes.

Subpopulations that benefit from treatment may exist, but additional RCTs are needed to define indications and to explore risks and benefits.

Adalimumab

Disease-modifying agents such as adalimumab (TNF-α blocking antibody) have been used to treat autoimmune diseases. It was investigated if patients with abnormally high TNF secretion may benefit from treatment in conjunction with IVF by a single collaborative group of investigators[33-36] on a heterogenous population. Adalimumab should only be used in the context trials.

Long-term use (>12 weeks) has been associated with an increased risk of serious infection and malignancy.[37]

Summary Statement[9]

There is insufficient evidence to recommend adalimumab treatment toimprove IVF outcomes.

Peripheral Blood Mononuclear Cells

The rationale of peripheral blood mononuclear cells (PBMCs) intrauterine infusion in patients with recurrent implantation failure was that maternal immune cells are necessary to achieve immune tolerance to embryo. One RCT investigated the efficacy of PBMCs[38] and they compared a group with recurrent implantation failure who received autologous PBMCs instilled into the endometrial cavity prior to transfer or to standard ET without pretreatment.[38] The treatment group experienced a significantly increased clinical pregnancy rate ($p < 0.05$) and reduced, but not significant, early pregnancy loss rate.

Summary Statement[9]

Sufficient evidence is not available to recommend intrauterine infusion of autologous peripheral mononuclear cells prior to ET.

Seminal Plasma

Instillation of seminal plasma into the uterus and/or cervix at the time of oocyte pickup for IVF has been investigated as a strategy to improve pregnancy rates in fresh ET cycles. A meta-analysis of seven RCTs showed a statistically significant improvement in clinical pregnancy rate but no significant improvement in ongoing pregnancy or live birth rate with seminal plasma insemination.[39]

Tacrolimus

Recurrent implantation failure is associated with a high peripheral blood Th1/Th2 ratio. A Th1 immune response is associated with allograft, as well as embryo, rejection.[40,41] A prospective study[42] evaluated the success rates of 1–3 mg of tacrolimus for 2 days prior to ET. Patients with recurrent implantation failure had elevated peripheral blood Th1/Th2 ratios. The treated cohort had significantly higher clinical pregnancy (per ET, treated 64% vs. untreated 0%, $p < 0.0001$) and live birth rates (treated 60% vs. untreated 0%, $p < 0.0001$).[42] But the study was subject to selection bias due to lack of randomization and a small sample size.

Summary Statement[9]

There is insufficient evidence to recommend tacrolimus to improve IVF-ET outcomes.

HARMS AND BENEFITS OF IMMUNOTHERAPY

Immunotherapies have their own adverse effects. For example, IVIG use has been associated with fever, hypotension, tachycardia, thromboembolic complications, and anaphylactic reactions.[43] As a pooled blood product, IVIG use is also associated with an inherent risk of infectious disease. While intravenous fat emulsion infusions are generally well tolerated, jaundice and hyperthermia have been reported.[44] Cytokines such as G-CSF are used in healthy donors in the setting of blood and marrow transplantation. In this setting, common side effects associated with systemic administration include bone pain and myalgias. Tacrolimus is most commonly used as an immunosuppressant to prevent whole-organ rejection. In this setting, known side effects include nephrotoxicity, neurotoxicity, hypertension, and diabetogenic effects. Medications such as aspirin and corticosteroids are inexpensive, while others such as IVIG and adalimumab are costly. Most of these therapies should only be used under Institutional Review Boards (IRB)-approved protocols.

CHAPTER 18

Cytogenetics and Subfertility

CV Kannaki Uthraraj, KS Mangayarkarasi

INTRODUCTION

Genetics plays an important and ever-expanding role in basic reproductive biological processes from gonadal sex determination, reproductive organ development, gametogenesis, fertilization, implantation, and early embryonic development. Various disruptions in the genetic profile resulting from chromosomal aberrations including microdeletions and microduplications, single-gene disorders, polygenic influences, or epigenetic mechanisms can in turn affect the reproductive functions. This chapter presents an overview of basic cytogenetics, its role in subfertility, and its application in the management of a subfertile couple.

ROLE OF GENETICS IN INFERTILITY

Subfertility affects about 1 in 10 couples in the reproductive age group and has a multifactorial basis. In nearly half of these, an underlying genetic cause is implicated. However, in the majority of cases, the etiology for subfertility remains unclear and linking basic research to clinical practice is the path that will offer solutions to the affected couples. An in-depth understanding and application of cytogenetics, molecular tools, and epidemiological studies are therefore essential in the management and treatment of an infertile couple.

BASICS OF CYTOGENETICS

Cytogenetics is the study of chromosomes and combines cytology and genetics.

Chromosomes

Chromosomes are thread-like structures that represent the genetic material contained in the nucleus of a cell. In humans, nearly all nucleated body cells contain a diploid set consisting of 23 pairs of chromosomes ($2n$) **(Fig. 1)**.

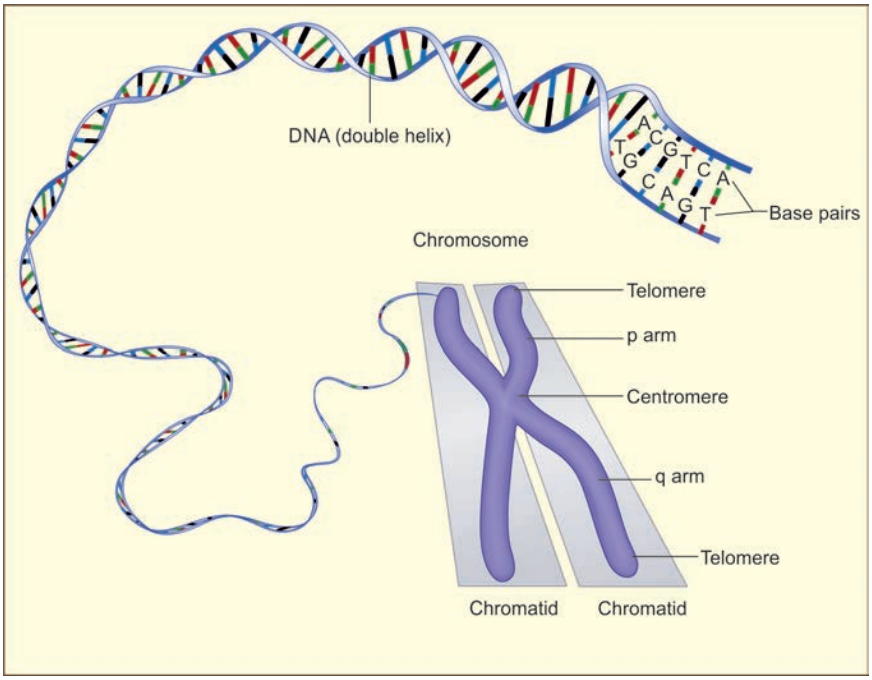

Fig. 1: Basic structure and subunits of a chromosome. (DNA: deoxyribonucleic acid).

In exception, the mature male and female gametes contain a haploid set containing half the number (n = 23) of chromosomes. The chromosomes 1–22 are the autosomes and the 23rd pair is the sex chromosomes, which is an X and X in females and an X and a Y in males. Chromosomes contain regions called genes. Genes code for proteins and are made up of deoxyribonucleic acid (DNA).

Cell Cycle

The genetic information present in each cell is transmitted in both mitosis and meiosis during cell division. The reason for the existence of two types of cell division is that somatic cells need a full diploid complement of chromosomes, whereas the gametes need only half the complement (haploid), as they will ultimately fuse with the other gamete during fertilization to become diploid in the zygote.

The transition from interphase to cell division (mitosis) and back to interphase is called cell cycle. The time when the cell is not dividing is called the interphase and this is the time when the nucleus is most metabolically active. Knowledge of the various phases of the cell cycle are important to understand the dynamics of cell division, segregation of chromosomes to daughter cells, and the processes of mitosis and meiosis in gametogenesis.

There are four distinct stages in the *interphase state* of the cell cycle **(Fig. 2 and Table 1)**:

1. G1 phase—9 hours
2. S phase (synthesis)—5 hours
3. G2 phase (interphase)—3 hours
4. M phase (mitosis)—1 hour.

M phase is itself composed of two tightly coupled processes:

1. *Karyokinesis:* Cell's chromosomes are divided.
2. *Cytokinesis:* Cell's cytoplasm divides into two daughter cells. Each phase for its activation depends on the proper development and completion of the previous one. Cells that have temporarily or irreversibly stopped dividing are said to have entered a state of quiescence called G phase (G_0).

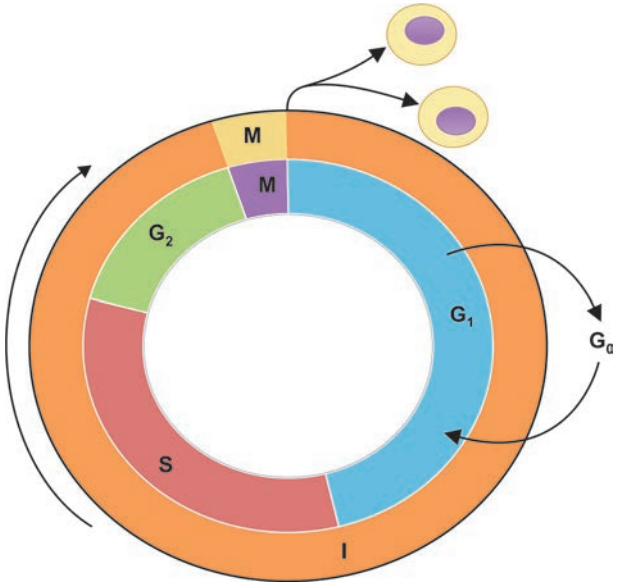

Fig. 2: Schematic of the cell cycle. Outer ring: I = interphase, M = mitosis; inner ring: M = mitosis, G_1 = gap 1, G_2 = gap 2, S = synthesis.

Cell Division—Mitosis and Meiosis

Meiosis, often called the reduction division, transforms primary spermatocytes and primary oocytes in the male and female into haploid spermatids and ova, respectively. Meiosis has two nuclear divisions, *meiosis I* and *meiosis II*.

In meiosis I, the homologous chromosomes separate, and in meiosis II, the chromatids separate. This results in four cells with a haploid set of chromosomes. In the female, only one of this becomes a viable ovum and the rest become polar bodies. In the male, all four spermatids mature into spermatozoa.

Compared with mitosis, meiosis is a lengthy and complicated process. Each stage of meiosis contains prophase, metaphase, anaphase, and telophase as in mitosis. Prophase I **(Figs. 3A and B)** is further divided into five consecutive substages: Leptotene, zygotene, pachytene, diplotene, and diakinesis.

There is no true prophase II in human meiosis; the cells pass directly into the second meiotic metaphase **(Fig. 2)**. The 23 chromosomes, each composed of two chromatids, move to the equatorial plate (metaphase II). Although only a haploid set of chromosomes is present, in one of each homolog, there is still a diploid amount of DNA since the replicated strands have not separated. In anaphase and telophase, the two chromatids have separated and go to two daughter cells, so that the end product of meiosis is four haploid cells, each with one complete but different set of genetic material. In females, the spindle is off-center, thus giving rise to a huge cell called the ovum and a second polar body. The first polar body also undergoes meiosis creating two additional polar bodies, but of the resulting four haploid cells only the ovum is theoretically viable gamete.

Chromosomal Variations

Chromosomal variations are commonly classified as follows:

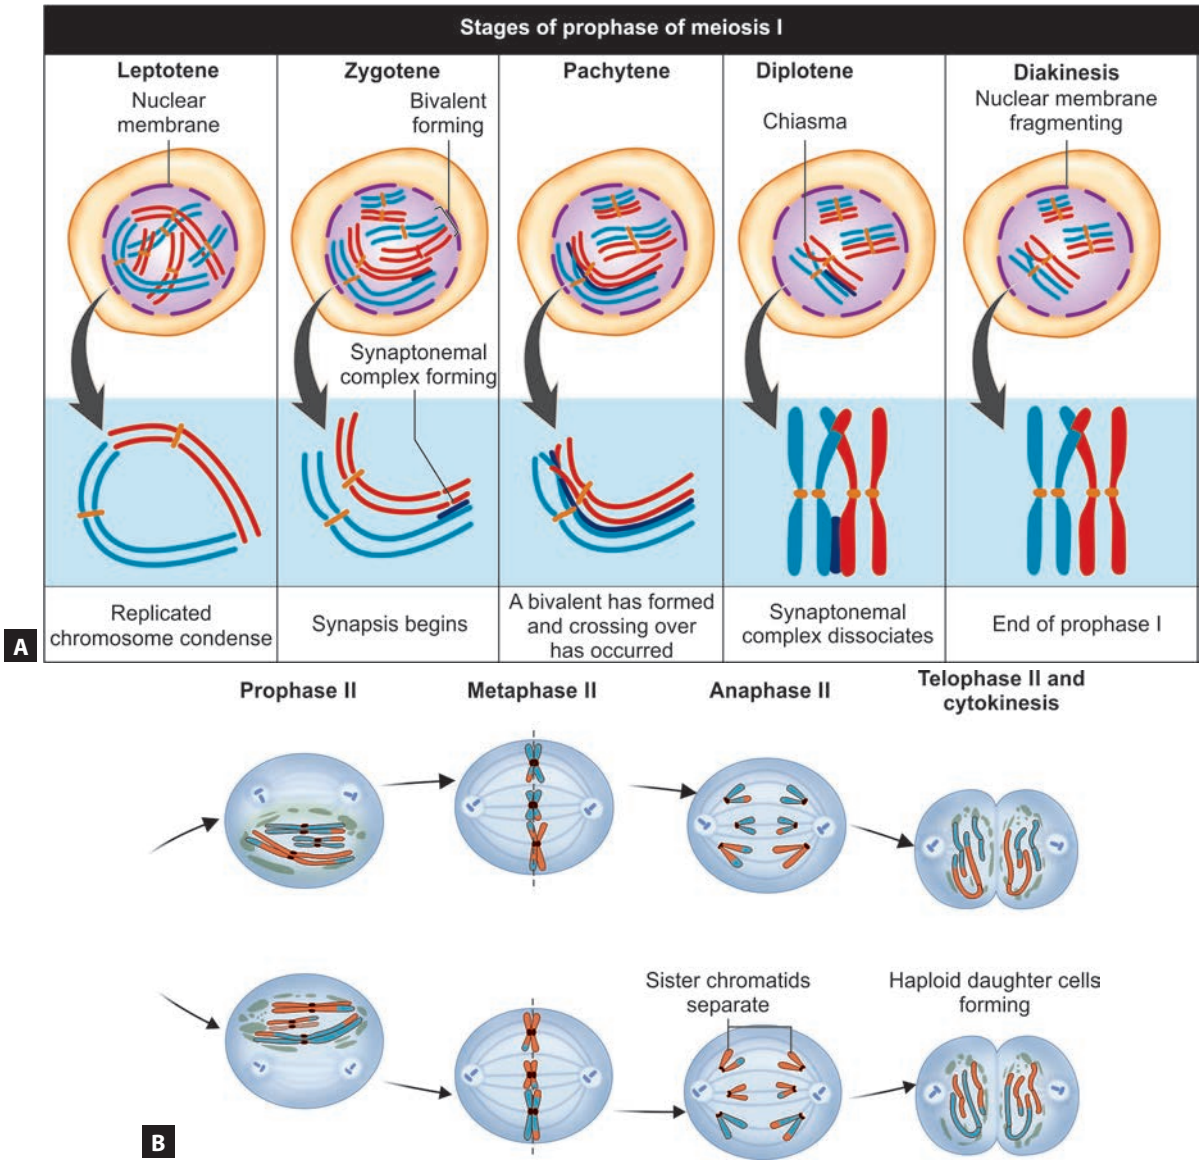
- Numerical
- Structural[1,2]

Numerical Abnormalities

Numerical abnormalities, also known as *aneuploidies*, are the most commonly encountered.[3] Aneuploidies are alterations in chromosome numbers, and the presence/absence of chromosomes in haploid or diploid is termed monosomy or trisomy. Aneuploidy is more prevalent in spontaneous abortions and developmental errors in

TABLE 1: Phases of cell cycle.

State	*Phase*	*Abbreviation*	*Description*
Resting	Gap 0	G_0	A phase where the cell has left the cycle and has stopped dividing
Interphase	Gap 1	G_1	Cells increase in size in gap 1. The *G checkpoint* control 1 mechanism ensures that everything is ready for deoxyribonucleic acid (DNA) synthesis
	Synthesis	S	DNA replication occurs during this phase
	Gap 2	G_2	During the gap between DNA synthesis and mitosis, the cell will continue to grow. The *G checkpoint* control mechanism ensures that everything is ready to enter the M (mitosis) phase and divide
Cell division	Mitosis	M	Cell growth stops at this stage and cellular energy is focused on the orderly division into two daughter cells. A checkpoint in the middle of mitosis (*metaphase checkpoint*) ensures that the cell is ready to complete cell division



Figs. 3A and B: Meiosis I and II.

humans.[4] Of the aneuploidies, *trisomy is more common than monosomy*.[1] In some cases, the chromosomal variations may be present in only a few populations of cells due to postzygotic occurrence, and the individual then has two populations of cells and is, therefore, *mosaic* for the normal complement and the variation.

Structural Abnormalities

Structural variations include several types of rearrangements:

- Translocations—balanced and unbalanced **(Fig. 4)**
- Inversion **(Fig. 5)**
- Insertion **(Fig. 6)**
- Deletion and duplication **(Figs. 7 and 8)**
- Ring chromosomes **(Fig. 9)**
- Microdeletions.

Cytogenetics includes the study of chromosomes under the microscope.

The various cytogenetic techniques are described below:

- *Karyotyping:* It is the gold standard in the basic workup of any genetic testing in spite of advanced technology. The karyotype of an individual is the microscopic description of their chromosome complement. Here, the chromosomes are visualized as colored bodies with a specific structure containing a central constriction called centromere to which are attached two linear arms, the shorter "p" arm and the longer "q" arm. The appearance of the chromosomes varies in the different phases of the cell cycle. In karyotype, the metaphase spread is analyzed. The metaphase spread is the collection of

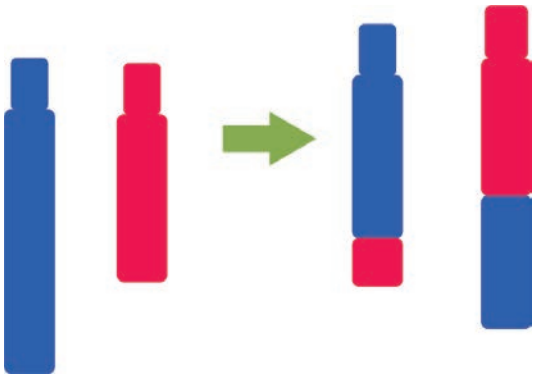


Fig. 4: Translocation of chromosomes.

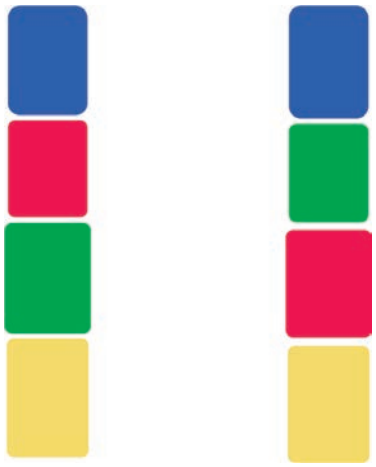

Fig. 5: Inversion of chromosomes.

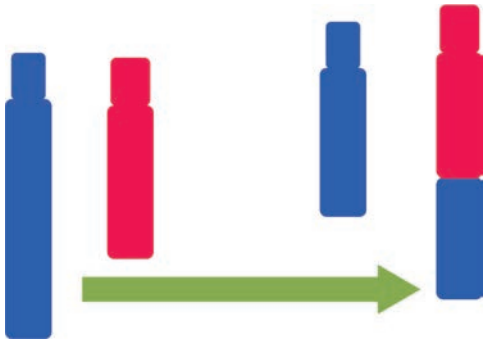

Fig. 6: Insertion of chromosomes.

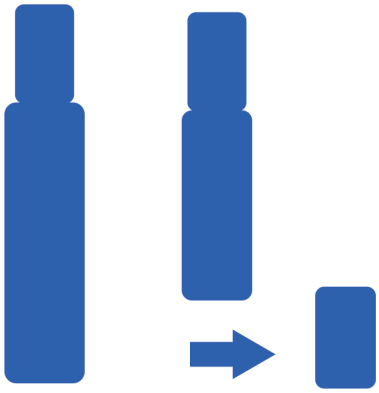

Fig. 7: Deletion of chromosomes.

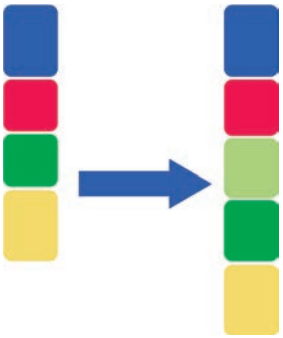

Fig. 8: Duplication of chromosomes.

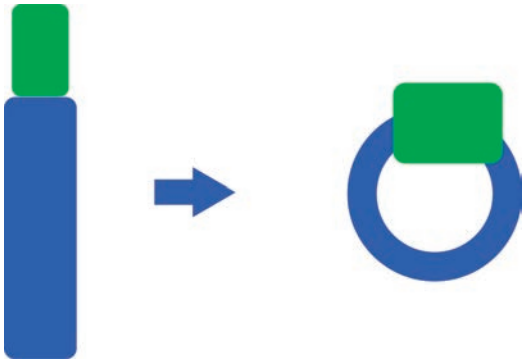

Fig. 9: Ring chromosomes.

chromosomes from one cell, visible in the condensed form that is assumed during metaphase. A karyotype study can be performed from various tissue samples such as blood, saliva, and skin fibroblast. Most commonly, the peripheral blood leukocytes are studied. A karyotype can detect chromosomal imbalances up to a resolution of approximately 5 megabases (Mb).

The peripheral blood sample is taken in a blood container containing sodium heparin, ensuring that the blood is mixed well soon after collection to prevent clots. Common causes for failed culture are lack of leukocytes, clotted blood, and inadequate sample, and therefore this may require a repeat sample.

This process involves cell culture, harvesting, slide preparation, staining, and analysis. Though manual processing is still necessary, much of the analysis has been automated with technological advances. Banding patterns are used to elucidate the breakpoints and chromosome constituents involved in chromosome translocations, deletions, and inversions within an individual chromosome can be identified and described using standard banding patterns. G-banding that utilizes trypsin and Giemsa allows visualization of banding patterns under bright field microscopy. Diagrams identifying the chromosomes based on banding patterns are called "idiograms."

- *Fluorescent in situ hybridization:* Fluorescent probes are for specific chromosomes in interphase. The following are modifications of the probes according to the indication:
  - Locus-specific probes
  - Repetitive sequence-specific probes
  - Whole chromosome painting (WCP) probes
  - Partial chromosome painting (PCP) probes.

  The above-mentioned probes use at least two-color fluorescent in situ hybridization (FISH) experiment, one probe as specific for the region of interest and the other as control probe. Multicolor FISH uses at least three different ligands and fluorochromes for the specific labeling of DNA, enabling staining of each of the 24 human chromosomes.

  Fluorescent in situ hybridization is done on metaphase spreads or interphase spreads, and at least 10–15 metaphases should be analyzed per probe. In case of suspected mosaicism, about 50–100 spreads are to be analyzed.

  The most commonly used FISH application in infertility is in preimplantation genetic testing and SRY locus detection in 46,XX males. Other applications include study of sperm nuclei to ascertain the aneuploidy rate, assessing the cytogenetic quality in post-chemotherapy scenarios, or to determine the percentage of unbalanced gametes in male balanced translocation carriers.

  Fluorescent in situ hybridization is a powerful tool due to its reliability and quickness; however, it should be offered only together with banding cytogenetics.
- *Single nucleotide polymorphism and comparative genomic hybridization:* Comparative genomic hybridization (CGH) is a molecular cytogenetic tool used to detect submicroscopic copy number changes. In this technique, the test and the control DNA are differentially labeled with fluorescent dyes and hybridized simultaneously in situ to normal metaphase spreads. Various array designs have been designed and used for diagnostic purposes and they include bacterial artificial chromosome (BAC)/P1-derived artificial chromosome (PAC) array, targeted array, and single nucleotide polymorphism (SNP) array.

  Array-CGH (a-CGH) is used to identify incidence of *mosaicism*, where routine chromosome analysis identifies as little as 3% of the cells on the basis of mitogen-induced metaphase counts. It finds applications in recognizing known and unknown chromosome syndrome by giving a detailed and comprehensive rearrangement pattern. a-CGH also helps in characterization of small supernumerary marker chromosomes (sSMC) that cannot be unambiguously recognized by conventional cytogenetics.

SPECIFIC INDICATIONS FOR CYTOGENETIC STUDIES IN A SUBFERTILE COUPLE

The pathological basis of infertility includes endocrine dysfunction, inflammatory diseases, genital tract abnormalities, gametogenesis failures, and implantation failures.[5] Lifestyle, environmental, and/or genetic factors are some of the reasons behind these pathologies. As 15–30% of the male infertility has a genetic origin, it is important to understand their genetic background. It may be chromosomal or single-gene anomalies[5] and around 2–14% of male infertility[4] and as much as 10% of female infertility[6] have a chromosomal origin.

In managing a couple with fertility issues, a karyotype may be needed in certain specific cases. This could be for either the partner or the couple or at times the product of conception depending on the clinical indication.

The following are the common indications for determining the karyotype in either partner presenting with infertility.

Male Factor Subfertility

Broadly this includes males with hypergonadotropic hypogonadism, idiopathic nonobstructive azoospermia, and severe oligospermia. Ascertaining the karyotype in these cases not only establishes the cause for the semen abnormalities, but it also helps in appropriate counseling and management.

For example, in case of males with Klinefelter syndrome (KS) (47,XXY), the chance of having male babies with an extra X chromosome exists and this needs to be explained.

Female Factor Subfertility

The most common indication for performing karyotype in a female partner is to investigate the cause for hypergonadotropic hypogonadism presenting as primary amenorrhea or premature ovarian failure (POF).

Couple Karyotype

Recurrent Pregnancy Loss

Screening for genetic causes in recurrent pregnancy losses (RPL) in the products of conception may reveal numerical or structural chromosomal abnormalities. The aim of investigating the chromosomes in a couple with RPL by karyotyping is to detect causative balanced structural chromosomal rearrangements in either of them that may have contributed to chromosomal imbalances in the conceptus. The incidence of balanced chromosomal translocations in couples with RPL is 2–5%, which is much higher compared to 0.2% incidence in the general population.

Generally, these are considered to have no phenotypic consequences in the individual carrying them as the exchange involves no loss or gain of genetic material. However, in some cases depending on the chromosomal breakpoints involved, there may be some clinical implications. For example, males with X autosome translocations are known to have low sperm counts.

There are, however, reproductive implications for carriers of balanced chromosomal translocations. In gametogenesis during meiosis, it is possible to have daughter cells with either a normal chromosome complement, or a balanced derivative chromosome number or unbalanced gametes with partial monosomy or trisomy in varying proportions. The latter two outcomes may result in abnormal embryos, which may subsequently result in miscarriage or an anomalous fetus.

Genetic counseling is recommended in such couples prior to testing and post-testing to discuss the recurrence risk, preconceptional and prenatal preventive options, and implications for the extended family. In each of their future pregnancy, prenatal testing by chorionic villi sampling or amniocentesis is recommended. Preimplantation genetic testing for aneuploidy (PGT-A) can be offered. The options of donor gamete may be considered by some couples.

Chromosomal Disorders in Male Infertility

Azoospermic men with severe oligospermia have a one in five chances of harboring a chromosomal aberration as a cause for their subfertility.[4,7] In males, autosomal ring chromosomes often cause oligospermia and azoospermia, probably due to gamete instability at meiosis.[8] Both numerical and structural variations are known.

Men with nonobstructive azoospermia have a greater incidence of aneuploidy in their chromosomes, particularly in their sex chromosomes with occasional fertilization and transmission of the defect to the progeny, e.g., KS 47,XXY karyotype or its variants.

NUMERICAL ABNORMALITIES/ ANEUPLOIDIES

Klinefelter Syndrome (47,XXY)

Klinefelter syndrome is the most common gonosomal (sex chromosomal) abnormality detected in 0.1–0.2% of newborns and 19% of men with severe oligospermia and in as high as 67% of azoospermic men.[9,10] Nondisjunction in male or female meiosis results in the extra X chromosome resulting in azoospermia in 74% of these men[11] **(Fig. 10)**. There are two variants of the syndromes:[12]

- Nonmosaic Klinefelter 47,XXY: 90% of KS falls into this category[13] and some can have sperms in the ejaculate.
- Mosaic Klinefelter 47,XXY/46,XY: 10% of the KS patients are mosaic and can have residual spermatogenesis.

In rare cases, more than two copies of X chromosome are found, for example, 48,XXXY and 49,XXXXY[13] resulting in severe conditions.

Clinically, features of androgen deficiency proven by a decline in serum testosterone levels and elevated follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels are noted along with germ cell degeneration in testicular biopsies.[11,12,14] As to their fertility potential, though the sperm of Klinefelter men have 23X or 23Y haploid genome, their offspring are reported to have an increased number of autosomal and sex chromosome aneuploidies.[15] The risk of transferring the abnormality by intracytoplasmic sperm injection (ICSI) with their sperms is present[16] though some studies have produced successful results with ICSI. Appropriate counseling should be offered for couples seeking treatment in such situations. Preimplantation

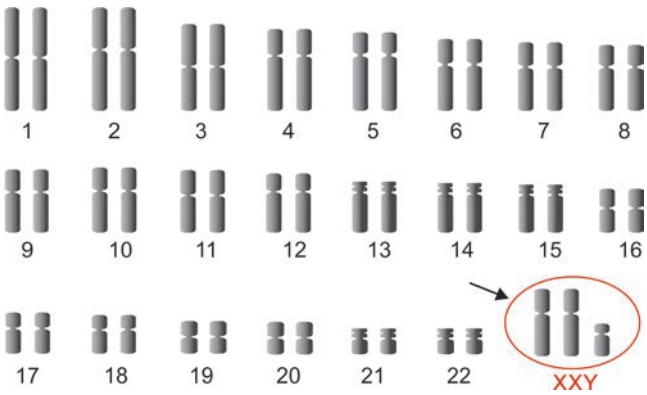

Fig. 10: Karyotype of a male with Klinefelter syndrome.

genetic diagnosis is indicated in such cases to ensure euploidy in the offspring.

47,XYY Syndrome/Jacob Syndrome

Jacob syndrome (JS) is the second most common gonosomal abnormality[17] occurring in 1:1,000 newborns. Most cases of JS are not inherited, but parental nondisjunction at meiosis II before conception leads to an additional Y chromosome 47,XYY in the affected offspring.[18,19] Extra Y chromosome in 47,XYY leads to infertility in adulthood, behavioral and cognitive disorders, facial dysmorphism, curved penis with nonpalpable testes, and decreased testosterone,[19] which eventually leads to sperm apoptosis and subsequent oligozoospermia and azoospermia[4,12,20] **(Fig. 11)**.

Some men expressing JS are fertile; here, additional Y chromosome is lost before meiosis, thereby preventing infertility.[18]

Translocations

Autosomal translocations are 4–10 times more in infertile men when compared to normal men, the most common being the Robertsonian translocation (RT) (0.8% prevalence in infertile men, 9 times higher than in general population).[21] RT results in a derivative chromosome (der) composed of two long arms from two acrocentric chromosomes.[22,23] Infertility, abortions, and aberrations in the child are the risks in RT carriers though they are healthy by themselves. The most frequent RTs are der (13;14) and der (14;21), with incidences of 1:1,000 and 1:5,000, respectively.[4,12,20,24,25] Nearly 20% of male carriers of der (13;14) are infertile.[24] Most mature spermatozoa with RT are normal or balanced (75–90%) as a result of alternate segregation. However, these translocations are associated with disrupted pairing in crossing over leading to trivalent formation and subsequent meiotic arrest, and result in oligozoospermia or azoospermia.[24,25] Male carriers of RTs involving chromosome 21 are more likely to have the disomic gametes that are likely to produce embryos with trisomy 21. Male RT carriers are often subfertile,[4] thereby reducing the chance of producing embryos. Loss of genetic material at breakpoints of genes can also occur due to translocations.

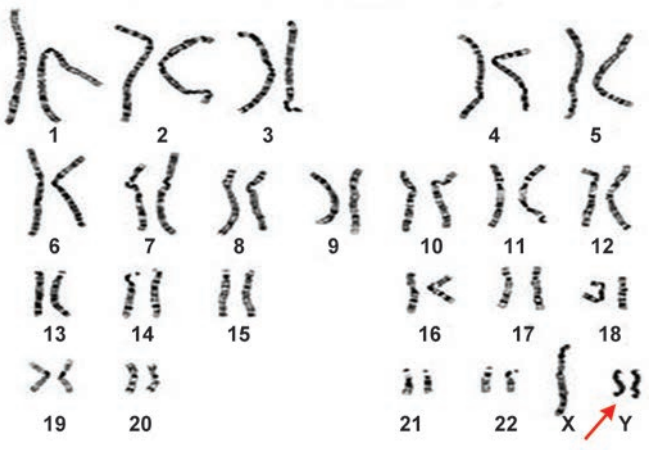

Fig. 11: Karyotype from a male with 47,XYY Jacob syndrome.

Y Chromosome Microdeletions (Table 2)

The critical genes that direct development of gonads and spermatogenesis are located on the Y chromosome, which is male-specific. This is the smallest of the human chromosomes and has a short arm (Yp) and a long arm (Yq) with a 60 Mb size and has the least number of genes.[14,23,26] Y chromosome microdeletions (YCMD) occur in 15% of azoospermic and 5% of oligozoospermic males **(Table 2)**. The genes identified are 27 in number, of which 9 are located in the Yp arm and 18 are located in the Yq arm. The male-specific region of the Y (MSY) is a complete sequence of the euchromatin segment. PAR represents the pseudoautosomal region and NRY, the region outside the PAR, represents the nonrecombining region.[27] The euchromatin lies in the Yp and the proximal part of Yq and the distal part of Yq is the heterochromatin segment. The mapping of the Y chromosome by molecular methods has shown deletion intervals and subintervals.[28] Tiepolo and Zuffardi[29] were the first to postulate the link between YCMD and infertility. It was proposed that at least one genetic Y factor required for male germ cell development is located on the distal Yq11.[30] It is defined as Y-borne fertile gene or azoospermia factor (AZF).

TABLE 2: Y chromosome microdeletions.[29,30]

Gene	*Location*	*Function*	*Deletion/shortening*
USP9Y	AZFa	Efficiency of spermatogenesis	Azoo/oligo/ oligoasthenospermia
DBY	AZFa	Premeiotic germ cell development	
RBMY	AZFb	RNA-binding protein/ testis splicing factor	Reduced expression in azoospermia
PRY	AZFb	Apoptosis regulation	
DAZ	AZFc	Regulation of translation, meiosis, and germ cell population; codes for RNA-binding proteins	Reduced expression in azoospermic men. Partial deletions related to oligospermia
sY153	AZFd	Spermatogenesis	Mild oligospermia/ normal semen parameters
CDY	Yq	Involved in histone replacement	
TSPY	Yp	Regulates timing of spermatogenesis	Greater copy number in infertile patients

(AZF: azoospermia factor; RNA: ribonucleic acid)

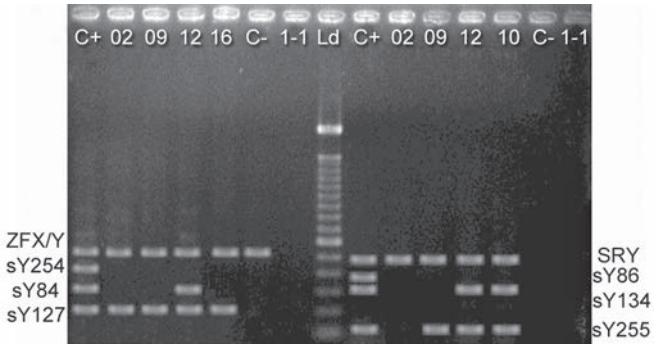

Fig. 12: Electrophoresis on a 1.5% agarose gel showing deletion in the azoospermia factor (AZF) region of the Y chromosome. Ld, molecular weight 100 bp (invitrogen); ZFX/Y, 495 bp; SRY, 472 bp; sY255, 126 bp; sY254, 400 bp; sY134, 301 bp; sY127, 274 bp; sY86, 320 bp; sY84, 326 bp. Lanes 02 and 09, azoospermic patients. Lanes 12 and 16, severe oligozoospermic patients.

Thus, deletions of genes of this region had a spectrum of impacts on spermatogenesis.[26] The deletion affects has three distinct regions—AZFa, AZFb, and AZFc.[30,31] AZFa is a nearly 0.8 Mb region that maps to proximal region Yq11.21. AZFb and AZFc map to regions Yq11.22 and Yq11.23, respectively **(Fig. 12)**.

AZFa region: The two main genes in AZFa are USP9Y and DBY (DDX3Y). When both are deleted, the result is Sertoli cell-only syndrome.[32] The *DBY* gene expresses in the testis and is involved in the development of the premeiotic germ cells.[33-35] The deletion or shortening of the *USP9Y* gene causes oligoasthenospermia, azoospermia, or oligospermia.[36-39] However, this gene is involved only in the efficacy of spermatogenesis because it can be carried to the offspring. Thus, the *DBY* gene plays a more important role in the spermatogenesis.

AZFb region: RBMY is the main gene of this region that codes for a ribonucleic acid (RNA)-binding protein,[15] a testis-specific splicing factor, conveyed in the nuclei of spermatogonia. A family of *PRY* genes in the AZFb region in regulation of apoptosis is for the regulation of abnormal sperms. However, if both are removed, arrest of spermatogenesis results indicating that both are vital for spermatogenesis.

AZFc region: The AZFc deletions cause approximately 12% of nonobstructive azoospermia and 6% of severe oligospermia.[31] The AZFa and AZFb regions are required to start spermatogenesis, but the process will not be completely normal without AZFc.[40] The AZFc deletion can be a result of a previous deletion or a de novo one, which when total may lead to a Y chromosome loss resulting in sexual reversal. Also, several studies have found this to be a permutation for 45,XO and for mosaic 45,X/46,XY.[15,20] Partial deletions may produce a wide variety of phenotypes from azoospermia to normospermia influenced by the background genetic makeup and the environment as exemplified by the ethnic variations.[41]

The three most frequent subdeletions are gr/gr, b1/b3, and g1/g3.[30,42] The deletions and their effects on spermatogenesis and fertility have not been uniform across ethnic groups and geographical regions illustrating the impact of environment on fertility genes.[43]

DAZ gene: Deleted in azoospermia (*DAZ*) genes having four copies are considered to play various roles in spermatogenesis because they are expressed in all stages of germ cell development.[44-46] They control code for germ cell-specific RNA-binding proteins, translation, and are involved in the control of maintenance of primordial germ cell population and meiosis. Thus, their deletion can cause a range of phenotypes such as oligospermia and azoospermia.[42]

Other genes on the Y chromosome: The CDY gene located on Yq is expressed exclusively in the testis and facilitates histone replacement spermatogenesis. It also grants the proteins that regulate transcription access to the postmeiotic sperm DNA. It is interesting to note that this gene has divulged from its homolog on chromosome 6 and subsequently migrated to the Y chromosome during evolution, reflecting the consolidation of the genes involved in spermatogenesis on the Y chromosome.[47] The *TSPY* gene, which is located on the short arm of the Y chromosome Yp, and has copies on the long arm, is expressed in the testis and its protein is identified in the spermatogonia. It may regulate timing of spermatogenesis and signaling of spermatogonia to enter spermatogenesis. More studies are needed on this gene as more copies of it were found in the infertile patients.

AZFd region: This is the region between AZFb and AZFc. No candidate gene has been identified till now, though sY153 has been implicated and patients with microdeletions in this region may present with mild oligospermia or even normal spermatogenesis.[48,49]

Recent genome-wide copy number variation (CNV) array studies using modern versions of the CGH technique began to uncover additional CNV linked to male infertility. Interestingly, a generally increased CNV burden seems to be associated with male infertility.[50-53] Several such aberrations including mutations within *TEX11* gene have been mapped to the X chromosome, which houses many germs cell-specific genes, and in analogy to the Y contains palindromic regions that facilitate rearrangements.[50]

Autosomal Genetic Aberrations

A number of candidate genes have been investigated for their role in male infertility. In patients with congenital bilateral absence of the vas deferens (CBAVD), *the cystic fibrosis transmembrane conductance regulator* (*CFTR*) gene on chromosome 7 is mutated in 60–90% of patients.[54,55] The F508del-CFTR is seen in 60–70% of patients with CBAVD, the male presenting with obstructive azoospermia. When shortening is seen on *SHBG* gene on chromosome 17, the

spermatogenesis was increased and showed higher sperm concentrations.

Gene Polymorphisms

ESR1 and 2 on chromosome 6 has many polymorphisms and the promoter region of *ESR1* has a variable number of tandem repeats TA *n*. The high number of repeats of TA *n* polymorphism is correlated with[33] lower levels of spermatogenesis. Further studies are needed. *FSHR* located on chromosome 2 may undergo changes due to SNPs and may have effects on spermatogenesis. The polymorphism *677C/T* interferes with the activity of methylenetetrahydrofolate reductase (*MTHFR*) gene located on the short arm of chromosome 1 affecting coding for folate synthesis, which in turn can affect the methylation of the genomic DNA important for spermatogenesis.

Mutations on the *INSL3* gene on chromosome 19 and its receptor *LGR8* on chromosome 13 have been linked to cryptorchidism seen in 5% of such patients.[56] The *INSLR 3* gene may also have a role in testicular dysgenesis syndrome (TDS) consisting of a variety of disorders such as cryptorchidism, hypospadias, testicular cancer, and infertility. TDS is thought to result from the combination of genetic environmental and lifestyle factors.[57]

X-linked Genes

Spermatogenesis is considered to be linked to many X-linked genes expressed in the testis. The *AR* gene, located on the long arm of X chromosome, has an important role to play in the conversion of spermatocytes to round spermatids. Mutations of *AR* gene can result in a spectrum of disorders ranging from oligoasthenospermia to androgen insensitivity syndrome and Kennedy syndrome (a neurogenetic disorder with abnormal spermatogenesis).[46] A synergistic effect of *SHBG* gene and *AR* gene can influence sperm motility. Variations in the *UPPS26* gene on the long arm of the X chromosome may influence spermatogenesis, resulting in azoospermia. The *TAF7L* gene expressed in the testis is related to the autosomal TAF gene and its role as a transcription factor in spermatogenesis is important for regulation. Thus, the SNP at exon 13 is a risk for an infertile phenotype combined with other polymorphisms.[58,59]

The idiopathic hypogonadotropic hypogonadism with anosmia—Kallmann syndrome is yet another condition which has X-linked and autosomal inheritance. Stunted sexual development, anosmia, cognitive impairments, ocular abnormalities, midfacial cleft, and renal agenesis constitute this syndrome. Two genetic deletions found in these patients are in KAL1 (KS1 sequence) located on the short arm of the X chromosome and directing gonadotropin-releasing hormone neuronal migration as well as coding for the anosmin. This mutation is responsible for 30–70% of Kallmann syndrome in patients.

The fibroblast GF receptor (FGFR1) on chromosome 8 can cause anosmic or hyposmic Kallmann syndrome.[40,60] Patients with Kallmann syndrome need to be counseled regarding transmission to the offspring.

Mitochondrial Deoxyribonucleic Acid Deletions

The mitochondrial DNA deletions can affect spermatogenesis and impair motility.

Monogenic Disorders

More than 50 disorders by Mendelian inheritance are associated with the male infertility.

Epigenetic Disorders

Spermatogenesis is a several-step process where a single error or an accumulation of errors can lead to the SNP at exon 13, which is a risk for an infertile phenotype if combined with other polymorphisms. Severe disorders in spermatogenesis result. Epigenetics refers to alteration of the genetic code changing the[61] transcription and gene expression without affecting the basic DNA sequence.

Sperms harvested from the testis before maturation may not have a fully functional *centrosome. If* the *protamines P1 and P2 are* translated too early, spermatogenesis is arrested at the spermatid stage and the nucleus condenses prematurely. Also, an unequal P1:P2 ratio has been observed in the infertile men.

An SNP of the gene *G197T*, which codes for P1 may be the reason for sperm DNA fragmentation and teratozoospermia. *Histones* are important players in the transmission of epigenetic information. Their role in male fertility is under investigation.

Imprinting Disorders

Imprinting is the methylation of DNA during the last phase of spermatogenesis and determines which genes from the paternal genomes are to be expressed in the embryo. New imprints in the germ cells are made possible by reset of parental imprints in every cycle and are achieved by the different processes. In the normal men, paternally differentially methylated regions (DMR) of the DNA should be methylated and the maternal DMRs should be unmethylated.[63]

A study by Kobayashi et al. showed that 14% of infertile patients had abnormalities in the DMR of the paternal imprint and 21% of the infertile patients had abnormalities in the maternal imprint. Most patients with abnormalities in both imprints were oligospermic. These men had low success rates with assisted reproductive technology (ART). It was also found that these men have a higher risk of transmitting the imprinting errors to their children.[64]

The use of immature sperms in ART, when the epigenetic code is not well established, may result in an offspring with an imprinting disorder. The abnormalities in the centrosome, and sperm nuclear protein may not permit activation of the oocyte by the immature sperm. Thus, control of methylation may be the key point in regulation of the first few steps of fertilization in ART.[65] However, many studies have shown conflicting results of the occurrence of imprinting disorders such as Angelman and Beckwith–Wiedemann syndrome in infertile men.[66]

Defects in messenger RNA transcripts (mRNA), telomere length, mitochondrial DNA degradation in infertile men, and their impact on fertility and transmission to offspring are under evaluation by the use of novel technologies of genomics, proteomics, metabolomics, and microarray techniques.[67]

The exact transmission of genetic and epigenetic information is essential for fertility. The consolidation of new molecular techniques when processed for clinical application will enable the clinician to make the right decisions in ART.

Genetics of Female Infertility

The genetic control of reproduction in the female is complex as the genital tract development, gametogenesis, and the endocrine control of reproduction all come under the genes. However, complete knowledge in this area is still under research. During sexual development, in utero genetic misdirections can lead to congenital malformations of the reproductive tract that manifest as anatomical abnormalities of the Müllerian ducts, uterus, endometrium, fallopian tubes, and ovaries resulting in subfertility. Another facet of the genetics includes a wide spectrum such as POF, polycystic ovary syndrome (PCOS), endometriosis, and leiomyoma. As in male subfertility, genetic syndromes that manifest in female infertility are fragile X syndrome, myotonic dystrophy, Noonan's syndrome, Fanconi anemia, sickle cell anemia, β-thalassemia, etc.[68]

Chromosomal Disorders in Female Infertility

Sex Chromosomal Aneuploidies

47,XXX syndrome: The *47,XXX syndrome*, also known as trisomy X, is one of the most common causes of premature ovarian insufficiency (POI); the incidence is 1:1,000 female births. The extra X chromosome is due to maternal nondisjunction at meiosis I and there is an association with increased maternal age. As the extra X chromosomes are inactivated only after embryonic development, abnormalities occur. A few women with trisomy X may have primary ovarian insufficiency or genitourinary tract malformations, but majority are normal.[69]

Clinical features include:

- Small for gestational age at birth
- Ovarian dysfunction—rare
- Fertility may not be affected
- Risk of transmission to offspring is increased
- Mild-to-moderate problems in central nervous system (CNS) function as in motor, speech, language, and learning.

The treatment is directed holistically to speech and occupational therapy if needed.

The *48,XXXX syndrome* presents with mild-to-moderate mental retardation, facial, skeletal dysplasia, impaired secondary sexual characteristics, and fertility impairment due to POF in most cases. However, chromosomally normal offspring can be born.

The *49,XXXXX syndrome* presents with more severe mental retardation and microcephaly, congenital heart, and renal anomalies. Pregnancies have been reported.

Turner syndrome: Turner syndrome, also known as monosomy X or 45,XO chromosome disorder in females, has an incidence of 1:2,000 births **(Figs. 13 and 14)**. During meiosis, chromosomal nondisjunction results in the loss of chromosome X. No parental age effect has been reported.[70]

Clinical features include:

- Spontaneous abortions
- Newborns show decreased birth weight, neck webbing, posteriorly rotated ears, and lymphedema of the hands
- Older children and adults have facial, skeletal, renal, and congenital heart defects and primary amenorrhea with lack of secondary streak gonads
- The short stature homeobox gene (*SHOX*) the located is on the Xp escapes inactivation and single functional copy for SHOX causes short stature and skeletal features.

Ovarian function also declines rapidly in milder phenotypes of Turner mosaic as in 45,X/47,XXX.

45,X0/46,XY mosaicism: Mixed gonadal dysgenesis (45,X/46,XY mosaicism) is a rare sex chromosome

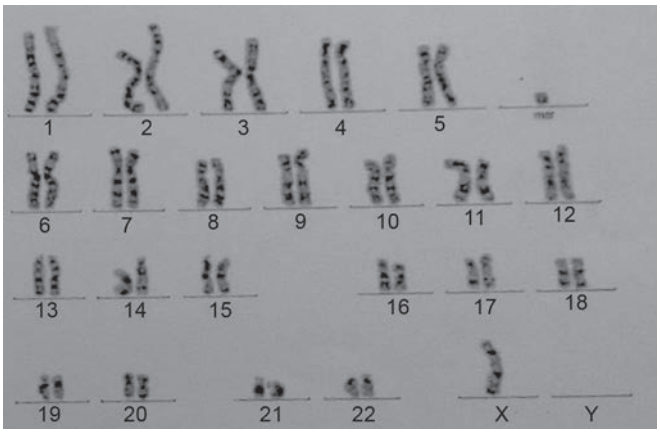

Fig. 13: Karyotype in Turner syndrome—the missing X.

Fig. 14: Clinical picture in Turner syndrome.

aneuploidy with a prevalence of approximately 1 in 15,000 newborns.[71] Here, two cell lines exist, of which one has 45,X karyotype (X monosomy) and the other has a normal male karyotype (46,XY). The two cell lines are differently distributed in individuals and is responsible for the varied phenotypes expressed by the affected individuals.[72] 45,X/46,XY mosaicism is most often caused by the loss of the Y chromosome through nondisjunction in some somatic cells after normal fertilization.[72,73] Both the 46,XY and 45,X cell lines divide nonstop, resulting in a baby with 45,X/46,XY. The 45,X/46,XY karyotype is also formed by the deletions, or translocations of Y chromosome segments.[72] This abnormality can repress the *SRY* genes, resulting in abnormal genitals (incomplete sexual differentiation) and testosterone levels.[71]

STRUCTURAL ANOMALIES OF CHROMOSOMES

The chromosomes can have structural rearrangements, either inherited or occurring de novo.

Balanced Translocations

Balanced translocations between X chromosome and autosomes mutate the genes, which when expressed results in variable phenotypes. A process of inactivation spreads from the translocated X segment to autosomal material and inactivates the genes causing mutations.

The features expressed may range from primary or secondary ovarian failure with often normal phenotypes. Learning problems and developmental delays can be seen. A phenotypically normal mother with an X autosome translocation can have a daughter with phenotypic abnormalities and mental retardation. De novo translocations are associated with significantly higher abnormal outcome. In a female with a balanced X autosome translocation, a 20–40% risk of a live-born child with a structural and/or functional aneuploidy is expected. Counseling X autosomal translocations becomes extremely difficult due to the variable phenotypes.[74]

Unbalanced translocation between the X chromosome and the autosome expresses a range of phenotypical abnormalities from mental retardation and multiple congenital anomalies to mild behavioral problems. This again makes counseling extremely difficult in a patient with prenatal detection of an unbalanced translocation.[74]

Deletions

Xp and Xq deletion in a female is associated with short stature and POF of varying degrees. Xp deletions often mimic Turner syndrome.

Duplications

Xp and Xq duplications have a spectrum of phenotypes ranging from normal to Turner syndrome features. Xq duplications can manifest as short stature, microcephaly, and gonadal dysgenesis.

Inversions

The X chromosome inversions can present in highly varied phenotypes ranging from normal intelligence quotient (IQ) to mental retardation and gonadal dysgenesis to mild menstrual irregularities. The phenotype depends on the site of inversion.

Ring Chromosome

A ring chromosome is a chromosome abnormality, where two ends of the chromosome break and the broken ends fuse to form a ring.[75] It often occurs spontaneously and is rarely inherited due to instability of ring chromosomes during cell division and so may be lost.[76] If transmitted, they form new rings and are transmitted to the offspring and coexist with normal karyotype and cause a mosaic karyotype in the maternal and fetal karyotypes. Ring chromosomes rarely impair female fertility. However, low ovarian reserve has been reported in women expressing ring chromosomes.[77]

Genomic Aberrations, Copy Number Variants

Newer techniques such as microarray have enabled studies of relationship of complex female subfertility factors such as endometriosis and primary ovarian failure to genomic loci paving the pathway for the whole genome analysis and findings of new genes related to the disease process. Multiple genes such as *PLCB1*, *RB1CC1*, *MAP4K4*, *RBBP8*, *IMMP2L*, *FER1L6*, and *MEIG1* are involved in meiosis. DNA repair or folliculogenesis was identified as possible candidate genes for POF and ovarian dysfunction. Following CGH studies identified new infertility-associated candidate genes and unveiled new details of the pathophysiology of female subfertility.[78]

Single-gene Disorders

Fragile X Syndrome

Fragile X syndrome is a disorder characterized mainly by mental retardation, long face, large ears, and prominent jaws. The syndrome was first reported in 1969 with constriction of the long arm on the X chromosome.[79] It has an incidence of 1:5.[80] The critical gene for fragile X is fragile X mental retardation gene (*FMR1*), located at Xq27.3. The pathology is caused by the expansion of the CGG repeat in the gene's 50 untranslated region to a premutation state of between 56 repeats and 199 repeats (a complete mutation has over 200 repeats). Generally, *FMR1* premutations are found in 16% of POF females with about 2% of the cases being sporadic and 14–21% familial.[81,82] Carrier screening of *FMR1* premutation is recommended for women of advanced maternal age or with a family history of fragile X.

Primary Ovarian Failure

Primary ovarian failure is defined as either complete or incomplete failure of the ovaries (also known as primary ovarian insufficiency). Recently, several genes have been discovered that show incomplete loss of function of the ovary, leading to the term "primary ovarian insufficiency." A number of genes have been associated with POF or POI. X-linked genes include *FMR1* and bone morphogenetic protein 15 (BMP15) located in the Xp11.2 region. Many autosomal mutations are often found in women with POF or POI such as *AR*, *CDKN1B*, *CYP19A1*, *GDF9*, *FIGLA*, *FOXL2*, *FOXO1a*, *FOXO3a*, *INHA*, *LHX8*, *NOBOX*, and *NANOS3*, located at the Xp11.2 region.[83]

Polygenic Complex Female Infertility

Endometriosis

Endometriosis is a complex disease characterized by the inflammation and colonization of functional endometrium in extra endometrial sites with multiple pathological effects. In the case of endometriosis, the five to eight times higher prevalence rate has a genetic basis authenticated by the identification of candidate genes, SNPs and CNVs. Follow-up studies are needed, however, to close down on critical regions. A significant linkage to *10q26* gene was identified although more clarity was needed to point to a single gene.[84] Among two genome-wide association studies (GWAS) conducted in 2010 and 2011,[85,86] only one common locust was found in the 1p36 region, which contains *WNT4*, a gene responsible for cell proliferation, which plays a key role in embryogenesis. Earlier studies have noted association of this gene locus in endometriosis.

Polycystic ovarian syndrome has a dominant inheritance; however, no specific gene has been identified. The gene for insulin resistance *INSR* has a direct correlation as shown by the GWAS study. Three additional loci (2p16.3, 2p21, 9q33.3) were also identified.[87] Some studies have identified the gene of interest *DENND1A*, a guanine nucleotide exchange factor. As yet, the cause of PCOS is unknown; both genetic and environmental factors must be taken into consideration.

Leiomyoma

Leiomyoma is commonly known as fibroids and interfere with female fertility depending on the size and location. Mutations in mediator complex subunit 12 (MED 12), cytogenetic anomalies, and aberrant DNA methylation or demethylation have been observed. A direct cause of genetics in genesis of fibroids has been observed. Mutations in fumarate hydrates (*FH*) gene can cause renal cell carcinoma and hereditary leiomyomatosis.[88,89]

Mutations in *HMG1C* and *HMG1Y* have been implicated in origin of leiomyomas.[90]

Müllerian Anomalies

Some of the uterine malformations may result from spontaneous mutations, while majority are due to environmental factors. The *EMX2* gene mutation has been implicated as the cause of uterus didelphys in some females.[91]

Gene Polymorphisms

Follicle-stimulating hormone receptor polymorphisms coded in chromosome 2 can present as a range of symptoms ranging from POF to varied response to FSH administration to ovarian hyperstimulation syndrome. Polymorphisms of the genes for FSH and LH are now being studied for use in clinical medicine for identifying poor response to controlled ovarian stimulation in ART. In a recent study, the link between LHCGR N312S polymorphism and the difference in dosage requirement in women homozygous and heterozygous for serine was noted. Subsequently, alteration in recombinant human luteinizing hormone (r-hLH) dose according to the polymorphism resulted in a significant increase in pregnancy rates.[92] Thus, algorithms for controlled ovarian stimulation based on genomic profiles could improve results in ART.

CONCLUSION

The genetics and the molecular basis of male and female infertility are the forefront of research in reproductive medicine where the future holds specific targeted treatments, which will yield better clinical outcome. On the other hand, the increased risk of transmission of the genome necessitates the importance of accurate diagnosis and appropriate counseling, especially in assisted reproduction. Cytogenetic screening is indicated in suspected situations and counseling is mandatory prior to ART. The role of cytogenetics in reproductive medicine is not only in the diagnosis of the cause, but also in enhancing fertility rates,

prevention of transmission of genetic aberrations, and future prenatal diagnosis. With the advances in infertility treatments, cytogenetics has parallelly developed into a highly sophisticated field with karyotyping, array technology, and preimplantation genetic testing.

KEY POINTS

- Newer applications of cytogenetics and molecular techniques have enabled diagnosis of genetic basis of many factors causing infertility.
- Subtle disturbances in mitosis and meiosis during gametogenesis and embryogenesis,can amplify these aberrations and cause infertility.
- Diagnosis of certain chromosomal and genomic factors are possible now and can guide the clinician in treatment and counselling in infertility.
- Knowledge and application of cytogenetics in infertility is also crucial to ascertain the risk of transmission of the abnormal factors across generation and hence is of epidemiological importance.

CHAPTER 19

Obesity and Infertility

Nupur Garg

"Take care of your body it is the only place that you have to live."
—Jim Rohn

INTRODUCTION

There has been a rising trend in obesity and overweight population in the past few years which has become an epidemic worldwide. According to the recent World Health Organization (WHO) global estimates, the worldwide prevalence of obesity has nearly tripled between 1975 and 2016.[1] In 2016, more than 1.9 billion adults aged 18 years and older were overweight. Of these, over 650 million adults were obese. Almost half of the children under 5 years of age who were overweight or obese in 2019 lived in Asia. Obesity has become a pandemic because of the changes in lifestyle resulting in a more obesogenic environment (inexpensive calorie-dense food, reduced physical activity, and inexpensive nonphysical entertainment). Genetics has also been implicated as a possible cofactor.[2,3] Women are affected most due to their small size and extra weight which is gained with each pregnancy.

Obesity has adverse effects on all systems, including reproductive health. It leads to increased health risks such as diabetes mellitus, hypertension, coronary heart disease, and osteoarthritis and is associated with various malignancies, particularly endometrium, breast, and colon cancers. Obesity also plays a significant role in reproductive disorders, particularly in women. It is associated with anovulation, menstrual disorders, infertility, difficulties in assisted reproduction, miscarriage, and adverse pregnancy outcomes.

OBESITY AND IMPAIRED REPRODUCTIVE POTENTIAL

Hippocrates recognized the adverse effect obesity has on fertility and wrote that "*People* of *such constitution cannot* be *prolific* … *fatness* and *flabbiness* are to *blame*. The *womb* is *unable* to *receive* the *semen* and *they menstruate infrequently* and *little*."[4]

Several studies have shown a lower fertility in overweight and obese women. A Dutch study prospectively evaluated the effect obesity has on fecundity and found that an increase in waist–hip ratio (WHR) by 0.1 unit led to a decrease in the probability of conception by 30% per cycle.[5] Similarly, a health study in nurses comparing 2,527 married nulliparous women with anovulatory subfertility with 46,718 married multiparous women determined the relative risk of infertility for each body mass index (BMI) category found that above a BMI of 23.9, there is a significantly high risk of subfertility.[6]

Obese women suffer from menstrual cycle disturbances and anovulation more often than nonobese women. Menstrual cycle disturbance was found to be 3.1 times more common in obese than in normal-weight women.[7] Negative effect of excess fat was reinforced by the fact that weight-loss programs led to the resumption of normal menstrual cyclicity, normal ovulation, and natural pregnancies.[8]

Obese women are also found to have increased chances of miscarriages following natural conception, ovulation induction, and assisted conception. A recent meta-analysis found an increased risk of miscarriage among women (BMI 30 kg/m^2) undergoing assisted conception [in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI)].[9] A further meta-analysis also found that patients with a BMI of 25 kg/m^2 were found to have a significantly elevated odds of miscarriage regardless of the mode of conception.[10]

FERTILITY RISKS IN OBESITY

Obesity is associated with greater risks for adverse health outcomes across the reproductive spectrum:[11-19]

- Higher rates of infertility[12]
- Subfertility (increased time to pregnancy)[13]

- Early pregnancy loss[10,14,15]
- Fetal deaths, stillbirths, and neonatal deaths[15]
- Congenital anomalies[16]
- Pregnancy complication[17]
- Greater risk of cesarean delivery and poor wound healing[18]
- Increased difficulty and shorter duration of breastfeeding.[19]

DIAGNOSIS AND CLASSIFICATION OF OBESITY

Obesity is defined as the condition of excess body fat that negatively impacts the health. As excess fat is the main variable that defines obesity, diagnosis of obesity requires measurement of body fat. There are several methods available to assess body fat.

Methods of Assessment of Body Fat

Body Mass Index

- The most widely accepted measure of obesity is the BMI [weight (kg)/height (m^2)] with cutoff points of 25 kg/m^2 (overweight) and 30 kg/m^2 (obese), as recommended by the National Heart, Lung, and Blood Institute's North American Association for the Study of Obesity expert committee.[20]
- BMI cutoff points are generated to predict health risks associated with increasing BMI.
- BMI is useful but a crude indicator of obesity. It does not distinguish dangerous adiposity (such as waistline intra-abdominal fat) from potentially less harmful fat in other areas of the body or healthy "nonfat" body mass such as muscle.
- In South Asians, body fat is more centralized with mean WHR being higher for a given level of BMI compared to Europeans.[21] Among Asians, morbidity and mortality were found to be occurring at lower BMI compared to Europeans[22,23] and hence BMI cutoffs have been redefined in Asian population with cutoff for overweight >23 kg/m^2 and obesity >25 kg/m^2 **(Table 1)**.

Distribution of Fat

- Fat deposition in abdominal or visceral region is important clinically as it plays the most significant role in the pathogenesis of metabolic syndrome.
- Visceral adipose tissue can be measured with the help of magnetic resonance imaging (MRI), computed tomography (CT) scan, and dual-energy X-ray absorptiometry (DEXA) performed at the level of L3/L4 and visceral fat area is calculated **(Fig. 1)**. An area >130 cm^2 has been associated with increased risk, whereas an area <110 cm^2 has been associated with low risk.

Waist Circumference Measurement

- Simple clinical measurement of visceral fat is waist circumference. WHO recommendations for the measurement of waist circumference involve the subject standing with feet 25–30 cm apart, weight evenly

TABLE 1: Comparison of body mass index (BMI) among European and Asian populations with respect to cardiovascular risk [World Health Organization (WHO), 2000].

Classification	*WHO BMI (kg/m^2)*	*Asian BMI (kg/m^2)*	*Cardiovascular risk*
Underweight	<18.5	<18.5	Low
Normal range	18.5–24.9	18.5–22.9	Average
Overweight	25–29.9	23–24.9	Increased
Obese I	30–34.9	25–29.9	Moderate
Obese II	35–39.9	= 30	Severe
Obese III	= 40		Very severe

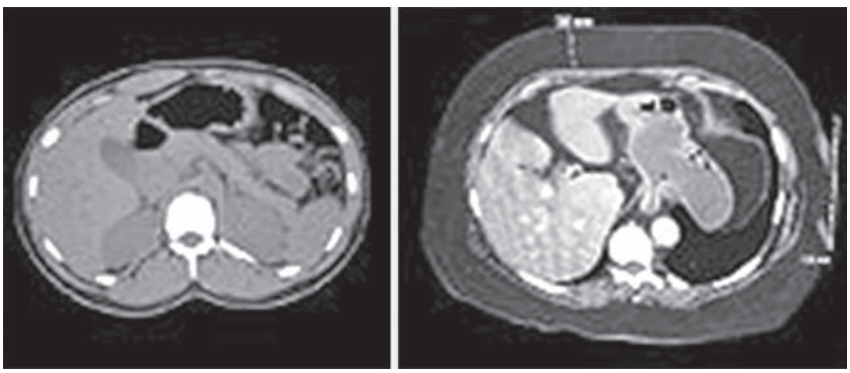

Fig. 1: Cross-sections of lumbar region of a normal-weight (left) and an obese person (right), taken by computed tomography (CT) scan. Note the increased thickness of subcutaneous fat of the obese person.

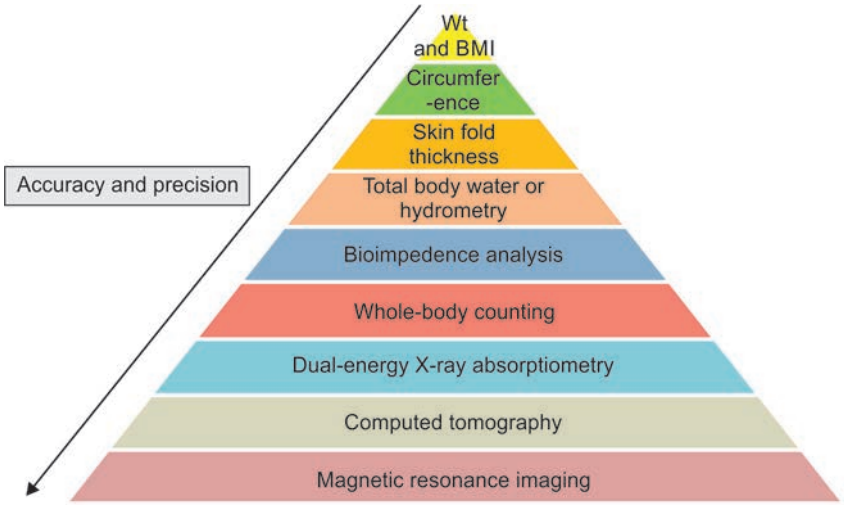

Fig. 2: Techniques in body composition.
(BMI: body mass index; Wt: weight)

distributed, and measurement taken midway between the inferior margin of the last rib and the crest of ilium in a horizontal plane. For hip circumference, measurement is taken around the pelvis at the level of maximum protrusion of the buttocks.[24]

- Waist circumference cutoff for increased risk of metabolic disease in Americans has been found to be ≥102 cm in men and ≥88 cm in women. The cutoff for waist circumference in Asians is ≥90 cm in men and ≥80 cm in women.[25]

Waist–hip Ratio

Waist–hip ratio is also used to measure abdominal obesity. In Caucasians, a WHR >1 for men and WHR >0.85 for women are used as a measurement of visceral adiposity.[26] However, waist circumference is preferred over WHR for measuring abdominal obesity.[27]

CONCEPT OF NORMAL-WEIGHT OBESITY

Excessive body fat despite normal body weight has been described as normal-weight obesity (NWO) syndrome.[28] NWO is a condition in which a person has an adequate BMI but an increased body fat percentage and a greater risk of developing noncommunicable chronic diseases. It is important to accurately diagnose individuals with excess body fat using more precise parameters other than BMI **(Fig. 2)**.

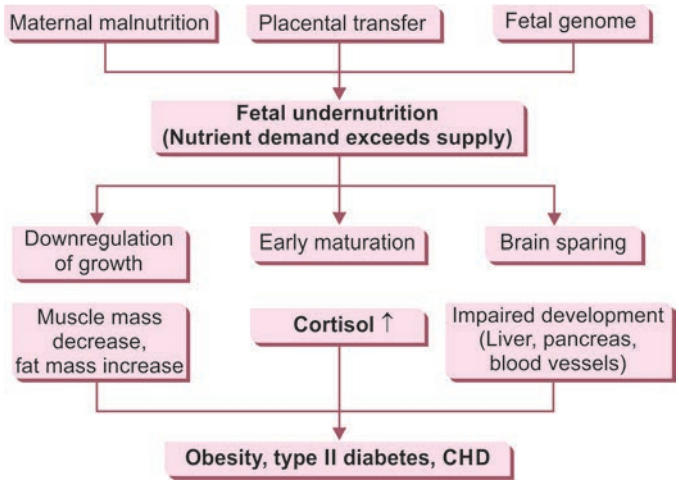
PATHOPHYSIOLOGY OF OBESITY

In Utero Programing

Barker's Hypothesis: Fetal Origin of Adult-onset Diseases

- Undernutrition and unfavorable intrauterine environment during early life can cause irreversible changes (in both structure and function) in developing systems of the fetus (i.e., programing).
- This may present as a disease over a period of time due to "dysadaptation" with changed environmental circumstances **(Flowchart 1)**.[29]
- Research has found that children born small for gestation tend to develop adiposity and hyperinsulinemia.[30] Precocious puberty (appearance of pubic hair before 8 years of age) has also been demonstrated as a part of this sequence, as well as anovulatory and hyperinsulinemic hyperandrogenism in late adolescence and adulthood.[31]

Flowchart 1: Fetal origin of obesity.



(CHD: congenital heart disease)

ROLE OF GUT MICROBIOME IN ORIGIN OF OBESITY

The gut microbiome is now recognized as a separate endocrine system and is involved in the body's homeostatic process. A diet loaded with excess fat increases gut permeability, resulting in increased levels of lipopolysaccharides

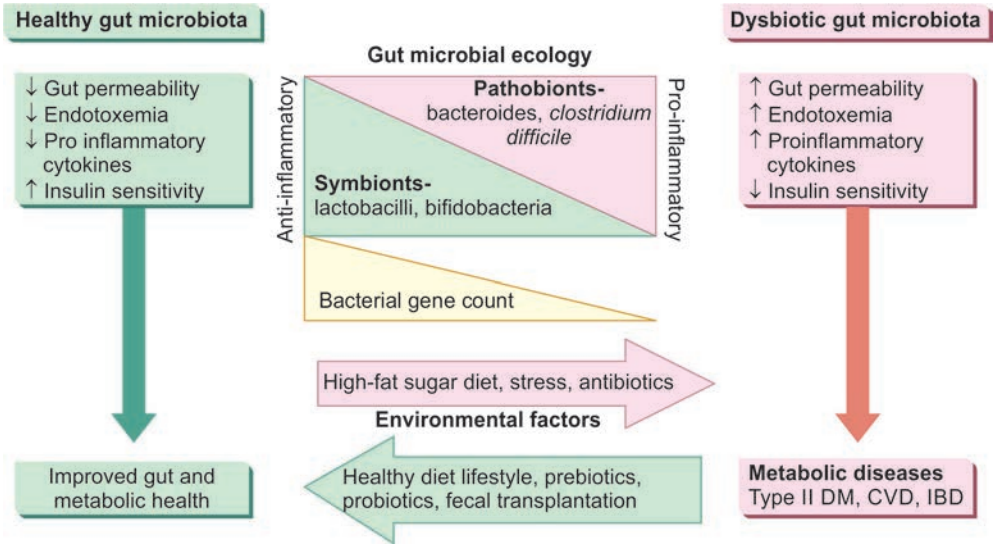


Fig. 3: Effects of a healthy gut microbiota and dysbiosis on the gut and metabolic health of the host. (CVD: cardiovascular diseases; DM: diabetes mellitus; IBD: inflammatory bowel disease)

in the body's systemic circulation. Lipopolysaccharides are endotoxins that are linked to inflammation-related processes such as obesity and insulin resistance.[32] Altered gut microbiome influences gut epithelium and motility, leading to the extraction of more calories from food, increased calorie absorption, and fat storage. Gut microbiota also affects many other regulatory processes in the body, such as mitochondrial fatty acid oxidation, ketogenesis, glucose uptake/insulin sensitivity, insulin secretion, increased lipogenesis, and cholesterol and triglyceride synthesis.[32] These processes all contribute to metabolic disease and obesity **(Fig. 3)**.

ENDOCRINE FUNCTION OF ADIPOSE TISSUE—THE ROLE OF ADIPOKINES

- Adipose tissue is a highly developed, endocrine and paracrine organ, which produces a variety of adipokines such as leptin, adiponectin, resistin, visfatin, omentin, ghrelin, and inflammatory cytokines such as tumor necrosis factor alpha (TNF-α), interleukin 6 (IL-6), and monocyte chemoattractant protein 1 (MCP-1). Adipokines are cytokines mainly secreted by adipocytes.
- Adipokines function as signaling molecules (hormones), and any abnormality in adipokines can cause inflammation and abnormal cell signaling which in turn can negatively affect cell metabolism and function **(Fig. 4)**.[33]
- The changes in body mass affect the levels of these adipokines. The direct effect of these adipokines on reproductive function during obesity has not been proven definitely, although they act indirectly by disturbing other regulatory systems. It has been seen that an excess or deficiency of adipose tissue results in sexual maturation disorders, pubertal disorders, and fertility disorder.[34]

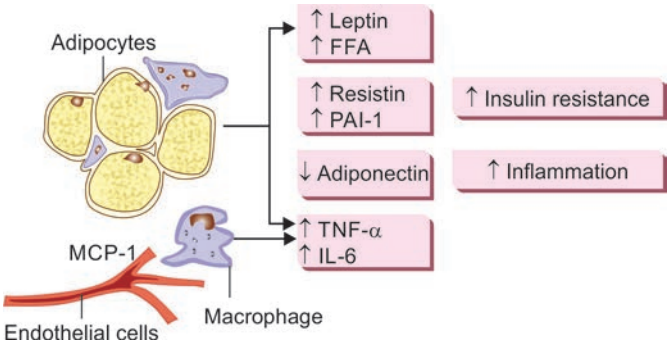

Fig. 4: In obesity, adipocytes release MCP-1, which attracts macrophages into the adipose tissue, which further increases the production of proinflammatory adipokine (TNF-α) and decreases adiponectin production, resulting in insulin resistance and inflammation.[35] (FFA: free fatty acid; IL-6: interleukin 6; MCP-1: monocyte chemoattractant protein 1; PAI-1: plasminogen activator inhibitor 1; TNF-α: tumor necrosis factor alpha)

Physiological Role of Adipokines

Leptin

- Adipokine that has been most studied and identified in more than 30 biochemical products secreted by adipocytes is leptin. Leptin is a peptide hormone with 167 amino acids and a molecular weight of 16 kDa and is synthesized from the "*ob*" gene in adipocytes. Its secretion is pulsatile, which increases with food intake and decreases during starvation. It thus reduces food intake and maintains energy homeostasis.
- It is a key signaling protein, relays the magnitude of the peripheral energy stores to the brain (hypothalamus), and also has metabolic and reproductive functions. Leptin has varied effects on reproduction and the target organs include hypothalamus, ovary, and endometrium.
- In the hypothalamic–pituitary axis, leptin has a stimulatory effect.[36] It has been hypothesized that an

elevated leptin level beyond a certain threshold is required for the activation of the hypothalamic–pituitary axis and the onset of puberty. The nutritional level of a person influences this central effect, with fasting causing a decrease in leptin levels resulting in the inactivation of gonadotropin-releasing hormone (GnRH) pulsatility. On the contrary, in well-fed state or energy-positive state also, no effect on GnRH secretion is seen due to the development of central leptin resistance leading to dysregulatory state in obesity.

- Leptin also influences steroidogenesis and folliculogenesis in ovarian cells. It modulates the stimulatory actions of gonadotropins and regulates perifollicular blood flow by promoting endothelial cell proliferation and angiogenesis.[37] Leptin also regulates the levels of reproductive hormones such as progesterone during the menstrual cycle and estradiol and human chorionic gonadotropin (hCG) during pregnancy.[38]
- Studies have shown that leptin may also affect oocyte maturation and early embryo development.[39] The endometrium and developing placenta express both leptin and its receptor[40] suggesting a possible role in the implantation of embryo and fetal growth.
- Leptin is produced in increased amounts with increasing adipose tissue. With high leptin levels as seen in obesity, a dysfunctional energetic state occurs suggesting a possible development of leptin resistance and altered leptin receptor sensitivity. This adversely affects leptin-mediated actions in the reproductive system and fertility.

Different adipokines and their effects on obesity are summarized in **Table 2**.

Pathophysiology of obesity and female fertility may be considered at the following levels:

- Central effects on the hypothalamus and pituitary
- Peripheral effects on the ovary and oocyte
- Direct effects on the embryo
- Effects on the endometrium
- Effects on pregnancy.

Effect of Obesity on Hypothalamus and Pituitary

- Obese women have higher circulating levels of free fatty acids, which stimulate increased insulin release and also lead to insulin resistance which together combined lead to hyperinsulinemia.[46]
- The ovary is a target organ for insulin action via both insulin receptor and insulin-like growth factor 1 (IGF-1) receptor. Hyperinsulinemia, as seen in obesity, stimulates androgen production from the ovary directly by activating ovarian theca cells or indirectly by suppressing the synthesis of sex hormone-binding globulin (SHBG) from liver which in turn leads to increased free androgen levels. It also decreases the synthesis of IGF-binding proteins 1 and 2 in liver leading to high free IGF-1 levels which in turn stimulates androgen synthesis from adrenals and ovarian theca cells.[47]
- Raised androgen is aromatized to estrogen at increasing rates in the periphery owing to excess adipose tissue. This leads to negative feedback on the hypothalamic–pituitary–ovarian (HPO) axis and affects gonadotropin production[48] **(Flowchart 2)**. This manifests as *menstrual abnormalities* and *ovulatory dysfunction*.

Furthermore, in obesity, there is altered hypothalamic leptin receptor expression.[49] An increased neuropeptide-Y level is seen in the hypothalamus, leading to reduced central leptin sensitivity and decreased GnRH pulsatility.

TABLE 2: Effects of the adipokines on reproduction.

Adipokines	*Serum levels in obesity*	*Effect in obesity*
Leptin[41]	Increase	• Dysregulation of GnRH secretion • Altered ovarian steroidogenesis • Dysregulation of folliculogenesis and perifollicular blood flow
Adiponectin[42]	Decrease	• Increased insulin resistance • Interference with folliculogenesis • Modulation of sex steroid secretion
IL-6[43]	Increase	• Increased insulin resistance • Impaired LH secretion • Impaired response to LH • Impaired estrogen secretion
PAI-1[44]	Increase	• Increased PAI-1 directly correlate with the development of metabolic syndrome • Increased miscarriage risk
TNF-α[45]	Increase	• Reduced insulin sensitivity • Inhibition of gonadotropin secretion • Impaired steroidogenesis • Induces corpus luteum regression • Impaired endometrial development

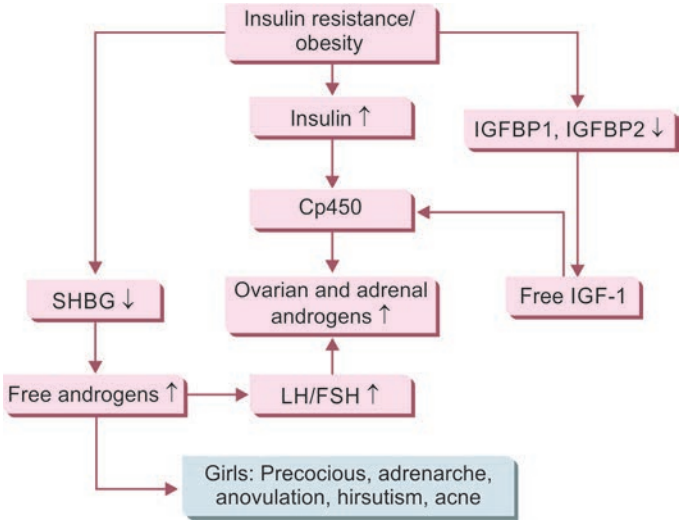
(GnRH: gonadotropin-releasing hormone; IL-6: interleukin 6; LH: luteinizing hormone; PAI-1: plasminogen activator inhibitor 1; TNF: tumor necrosis factor)

Effect of Obesity on Ovary and Oocyte Quality

Ovarian responsiveness to gonadotropins is impaired in obese women. Possible reasons suggested are as follows:

- Altered follicular environment with high levels of triglycerides, insulin, and inflammatory markers such as C-reactive protein (CRP)[50]
- Elevated follicular leptin levels have an inhibitory effect on follicle-stimulating hormone (FSH).[51]
- Insulin resistance has been associated with a relative gonadotropin resistance.[52]
- Altered pharmacodynamics of gonadotropins though suggested has not been found to be responsible for increased dose requirement in obese women.[53]

Flowchart 2: Obesity leading to dysregulation of hypothalamic–pituitary–ovarian axis.



(FSH: follicle-stimulating hormone; IGF: insulin-like growth factor; IGFBP1: insulin-like growth factor-binding protein 1; LH: luteinizing hormone; SHBG: sex hormone-binding globulin)

- Animal studies have shown that obesity affects oocyte quality resulting in more number of aneuploid oocytes, apoptotic follicles, and intracellular organelle damage.[54] The mechanism suggested has been lipotoxicity, which generates reactive oxygen species leading to disarrayed meiotic spindles, mitochondrial and endoplasmic reticulum stress, and apoptosis.[55,56]

Effect on Embryo

- Embryos may also be susceptible to lipotoxicity as previously discussed regarding the oocyte.
- There occurs an imbalance between omega 3 and omega 6 fatty acids required for the normal development of embryo resulting in poor blastocyst rates with fewer cells in the trophectoderm with poor glucose uptake and high levels of triglycerides resulting in poor pregnancy rate.[57,58]
- The metabolomic profile of spent culture media of day 3 embryos from obese women has shown significant reductions in the concentration of saturated fatty acids compared to normal-weight women.[59]
- In addition, hyperleptinemia exerts a direct negative effect on the developing embryo.[60]

Effect on Endometrium

The histopathological and molecular effect of obesity on the endometrium remains to be fully elucidated. Studies have shown poor implantation rates in obese women.

Possible mechanisms suggested for compromised endometrial receptivity and poor implantation rates are as follows:

- Low leukemia inhibitory factor (LIF) levels in endometrium[61]
- Relative hyperestrogenemia is found to be detrimental to endometrial receptivity.[62]
- Elevated insulin levels have been associated with a reduced glycodelin and insulin-like growth factor-binding protein 1 (IGFBP1).[63]
- Elevated levels of acute-phase proteins and proinflammatory cytokines [including IL-6, plasminogen activator inhibitor 1 (PAI-1) and TNF-α]; these inflammatory markers are thought to exert a negative effect upon implantation and early embryonic development.[63]
- Altered endometrial gene expression.[64]

Animal studies have shown:

- Poor endometrial decidualization in obese mice[65]
- Decreased implantation sites[65]
- Decreased response to hormonal stimulation in the endometrial stromal cells[65]
- Poor embryo-endometrial crosstalk, as embryo quality also suffers in obesity
- Dysregulation of leptin expression in endometrium.[66]

Pathophysiology of obesity and its effect on fertility has been summarized in **Flowchart 3**.

Effect on Pregnancy

Decidualization and implantation defects may negatively affect the placentation process. Many of the pregnancy complications seen in obese women are linked to placental dysfunction, including stillbirth and pregnancy-induced hypertension. All the causes listed above may result in poor implantation, placentation, and adverse pregnancy outcomes **(Flowchart 4)**. A recent meta-analysis has confirmed increased odds of maternal, fetal, and neonatal complications in pregnant obese mothers compared with standard BMI mothers.[67]

OBESITY AND POLYCYSTIC OVARY SYNDROME

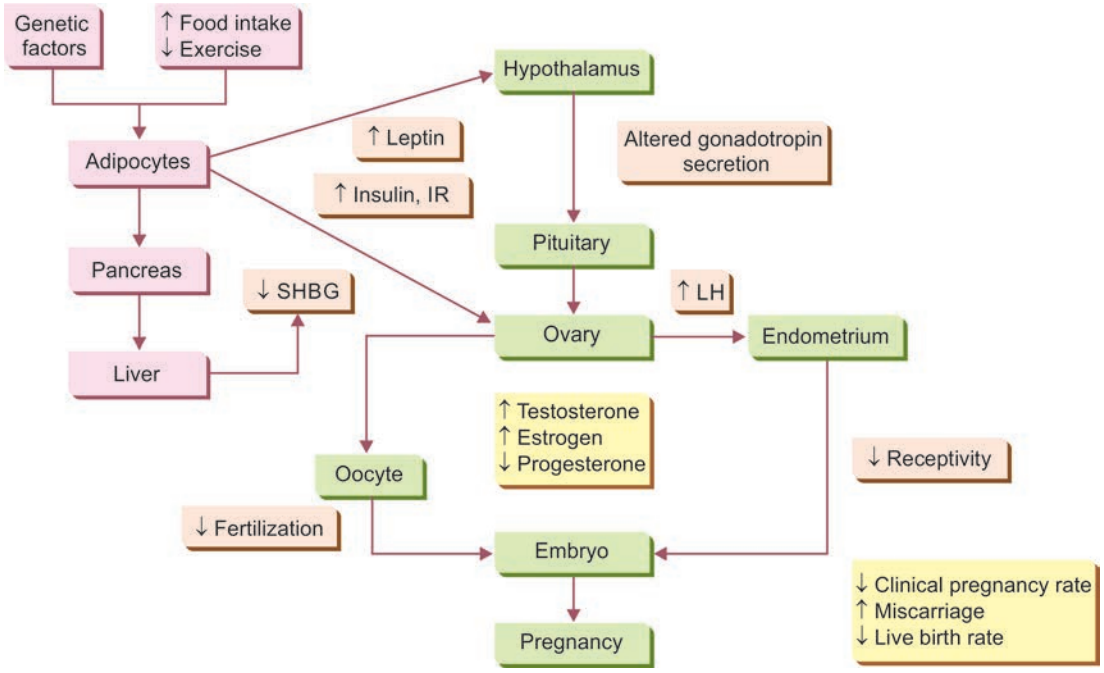
Obese women with polycystic ovary syndrome (PCOS) have a more severe phenotype and had a higher prevalence (78%) of:

- Disturbed menstrual cyclicity[68]
- Increased insulin resistance[69]
- Impaired response to gonadotropin during superovulation[70]
- Increased chance of cycle cancellation
- Reduced ovulation rates
- Reduced chance of treatment success following assisted reproductive technology (ART)[71]
- Increased risk of miscarriage.[71]

OBESITY AND ASSISTED CONCEPTION

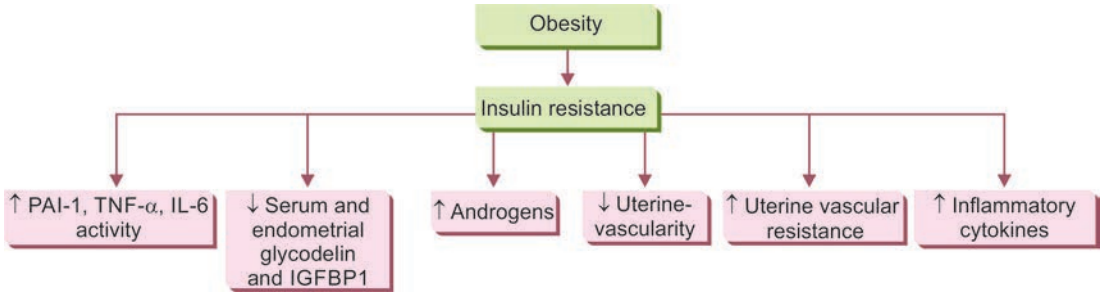
The majority of the studies suggest that obesity has a deleterious effect on ART. Obesity has been reported to affect ovarian stimulation in women undergoing treatment.

Flowchart 3: Pathophysiology of obesity and its effect on fertility.



(IR: insulin resistance; LH: luteinizing hormone; SHBG: sex hormone-binding globulin)

Flowchart 4: Possible causes of miscarriages in obese women.



(IGFBP1: insulin-like growth factor-binding protein 1; IL-6: interleukin 6; PAI-1: plasminogen activator inhibitor 1; TNF-α: tumor necrosis factor alpha)

RESPONSE TO GONADOTROPIN STIMULATION AND CYCLE CANCELLATION

- Obesity impairs ovarian responsiveness to gonadotropin stimulation, requiring higher dosages and longer stimulation, and fewer mature follicles are obtained.[72-74] Several studies have documented a higher risk of cycle cancellation with increasing maternal BMI, with adjusted odds ratios (ORs) for women with BMI > 40 kg/m^2 compared with normal-weight women ranging from 2.73 [95% confidence interval (CI) 1.49–5.00] to 3.46 (95% CI 1.85–6.49).[71]
- In a cohort study of women with PCOS undergoing ovulation induction with either clomiphene or gonadotropins, it was observed that elevated BMI negatively affected ovulation rates. In this study,[75] obese patients had significantly lower ovulation rates at 6 months of treatment: 79% in women with a BMI of 18–24 kg/m^2 compared with 15.3% with a BMI of 30–34 kg/m^2 and 12% if BMI is 35 kg/m^2. Some authors, however, have been unable to demonstrate any difference in ovarian response to stimulation in obese women.[76,77]

Fertilization Rates

Obesity alters oocyte morphology,[78] reduces fertilization in some[79] but not all[78,80] studies, and impairs embryo quality in women less than 35 years of age.[80]

Implantation and Pregnancy Rates (Embryo vs. Endometrium)

- A national study of ART in the United States reported reduced clinical pregnancy rates with increasing BMIs with the use of autologous but not donor oocytes and reduced live birth rates with increasing BMIs regardless of oocyte source and embryo status.[81] Even studies limited

to obese women using donor oocytes and eliminating the potential effect of older maternal age and lower quality of the embryos have reported significantly reduced implantation and pregnancy rates and higher abortion rates.[82] This suggests that oocyte quality is a primary, but not the only factor impairing IVF outcomes in obese women using autologous oocytes.

- Obesity also appears to alter endometrial receptivity during IVF since third-party surrogate women with a BMI >35 kg/m^2 have a lower live birth rate (25%) compared with those with a BMI <35 kg/m^2.[83]

Miscarriage Rate

- Obesity has been linked with increased pregnancy loss in many[84,85] except few studies.[86] A meta-analysis in 2008 of both spontaneous and assisted reproductive conception showed that women with a BMI >25 kg/m^2 had a significantly higher risk of miscarriage at <20 weeks of gestation, with an OR of 1.67.[87]
- A meta-analysis of 33 IVF studies including 47,967 cycles concluded that overweight or obese women have a higher rate of miscarriage compared with normal-weight women (BMI <25 kg/m^2).[84]
- In women with a history of recurrent pregnancy loss (RPL), obesity is a known risk factor for miscarriage in a subsequent pregnancy.[88]
- A chromosomal analysis of 117 miscarriage specimens from patients with RPL demonstrated that obese women had a much higher rate of euploid miscarriage, again suggesting a potential independent effect of obesity on the endometrium.[89]

Live Birth Rate

Obese women undergoing IVF/ICSI have lower live birth rates. It is thought that this is the cumulative effect of lower implantation and pregnancy rates, higher miscarriage rates, and increased obstetric complications.[90] Some authors have reported lower pregnancy and live birth rates in obese women undergoing assisted conception treatments.[91-93]

Others have been unable to demonstrate a reduction in success rates in obese women.[77,94]

Technical Difficulties During In Vitro Fertilization

Obese women are significantly more likely to encounter difficulty in observing the air bubble during ultrasound-guided embryo transfer and are more likely to have blood on or in the catheter after embryo transfer.[77] The effect of obesity in ART has been summarized in **Box 1**.

BOX 1: Summary of effects of obesity on assisted reproductive technology.

Effect of obesity on ART

- Impaired USS image quality due to adipose tissue[77]
- Increased duration of stimulation
- Increased total gonadotropin dose required[70]
- Increased follicular asynchrony[70]
- Increased cycle cancellation[70]
- Poor response to superovulation[75]
- Reduced follicular hCG concentration on the day of ovum pickup[95]
- Relative reduction in the number of cumulus–oocyte complex recovered at ovum pickup[9]
- Relative reduction in metaphase II oocytes recovered at ovum pickup[9]
- Relative number of surplus good quality embryos available for cryopreservation[80]
- Reduced pregnancy rates[9]
- Increased miscarriage rates[90]

(ART: assisted reproductive technology; hCG: human chorionic gonadotropin; USS: ultrasound scan)

OBESITY AND MALE INFERTILITY

- Obesity has a negative effect on male fertility. In 2006, Sallmen et al. illustrated a dose–response relationship between BMI and male infertility, with worsening male fertility for every three-point increase in BMI >25 kg/m^2, with an OR[96] of 1.12. These results were later confirmed in several other studies.[97,98]
- The mechanism suggested for the effect of obesity on male fertility includes thermal effects, hyperestrogenism, hypogonadotropic hypogonadism, diabetes mellitus, sexual dysfunction, and sperm epigenetic perturbations.

Sperm Parameters

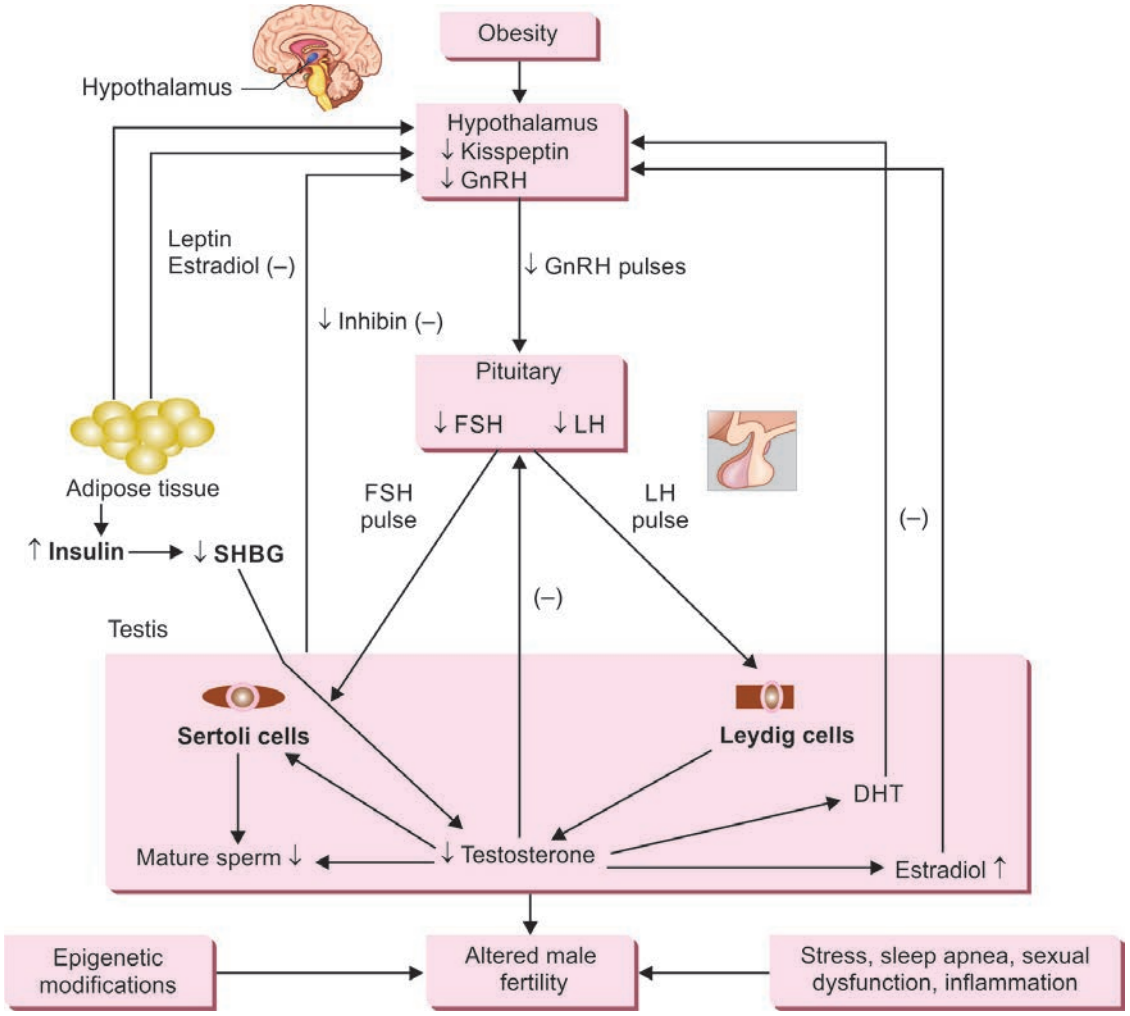
The impact of obesity on sperm parameters is complex and likely multifactorial. Obese men are at a higher risk of:

- Oligozoospermia[99,100]
- Decreased total progressive motility[100]
- Raised deoxyribonucleic acid (DNA) fragmentation index.[101]

The mechanisms suggested are as follows **(Flowchart 5)**:

- Obesity is associated with the risk of diabetes and insulin resistance. Hyperinsulinemia leads to a reduction of sex hormone-binding globulin levels. This allows greater free testosterone levels, which aromatizes to estrogen in the periphery.[102] This hyperestrogenemic state has a detrimental effect on the androgen axis affecting semen quality.
- Hyperestrogenemia downregulates the release of kisspeptin from kisspeptin neurons and decreases the activity of hypothalamic–pituitary–gonadal (HPG) axis by negative feedback and thus of FSH and luteinizing hormone (LH).[103]
- Leptin resistance seen in obese men with hyperleptinemia results in the failure of leptin to stimulate HPG axis.[104]
- Sleep apnea is commonly found in obese men. Nocturnal sleep disturbances affect nocturnal LH pulsatility

Flowchart 5: Hormonal pathway responsible for male infertility.



(DHT: dihydrotestosterone; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; LH: luteinizing hormone; SHBG: sex hormone-binding globulin)

reducing testosterone levels. Intermittent hypoxia associated with sleep apnea can affect gene expression, sperm motility, and fertility.[105]

- Many environmental toxins are fat-soluble favoring adipose tissue for their accumulation making obese men susceptible to perturbation of the male endocrine axis and spermatogenesis.[106]
- Increased lower abdominal and thigh fat leads to increased testicular temperature. This negatively impacts both testosterone synthesis and spermatogenesis.[107]
- Obese men often suffer from sexual dysfunction resulting from decreased testosterone levels and vascular endothelial dysfunction secondary to inflammation.[108]
- Obesity alters fertility by affecting the epigenetic patterns of sperm, that is, sperm micro-RNA content and DNA methylation variations. These important markers in sperm, when altered, are thought to be implicated in abnormal phenotypes in the offspring and perturbations in embryogenesis.[109]

Male Obesity and Advanced Reproductive Technology Outcome

- The impact of male obesity on ART outcome is conflicting. Some studies suggest that obese men undergoing ART have a statistically significant decrease in live birth rate compared with normal-weight men.[110] Another study has reported a lower pregnancy rate in males undergoing IVF, but no significant difference if ICSI was used for ART therapy. In contrast, Thomsen et al. have reported no decrease in semen quality or IVF outcome in obese men undergoing ART.[111] Further research is required to assess the exact impact of male obesity on ART outcome.
- Despite the associations between obesity and semen parameters, it is clear that men with high levels of body fat are, in general, still capable of siring offspring, which may be accounted by the fact that in some cases lower maternal age results in improved oocyte quality, which may independently improve outcomes but may also

provide an improved opportunity for correction of some defects, such as sperm epigenetic abnormalities, after fertilization.[112]

Management

Lifestyle Modification

Weight management can be achieved through a lifestyle modification program that combines dietary modification, physical activity, and behavioral interventions, including psychological, behavioral, and stress management strategies.[113] Current recommendations for lifestyle modification for obesity include a weight loss of 7% of body weight and increased physical activity to at least 150 minutes weekly of moderate activity such as walking.[114]

Diet and Weight Loss

Calorie restriction is the mainstay of successful weight loss.[115] Calorie restriction of up to 500–1,000 kcal/day from daily dietary intake leads to a weight loss of 0.5–1 kg weight loss per week. Dietary composition plays a less important role in weight loss. Though few authors have published about "fertility diets," characterized by low content of trans fats and animal protein and more of low-glycemic carbohydrates, high-fat dairy, and multivitamins.[116-119] Similarly few observational studies have suggested the potential benefits of the Mediterranean diet, and found a lower risk of infertility and increased chances of pregnancy on adhering to the diet.[120]

Exercise and Weight Loss

Physical activity alone is less effective in producing weight loss. The addition of physical activity on top of a diet modification enhances weight loss.[121]

Studies examining the effect of physical activity on obese infertile population independent of weight loss have shown improved fertility. A recent study reported more than threefold higher pregnancy and live birth rates in obese women who exercised regularly compared with obese women who were not physically active.[122] Because exercise reduces the oxidative stress characteristic of overweight and obesity, it may represent the best therapy currently available.

Exercise Programs

At present, there are no evidence-based guidelines on exercise training programs to improve fertility. The following is the recommended framework for prescribing aerobic exercises to people who are overweight and obese[123] **(Table 3)**.

Patients starting a program of moderate exercise (e.g., walking) do not require prescreening, whereas those starting vigorous-intensity programs should be screened for cardiovascular and respiratory adequacy.

Drugs for Weight Loss

Few medicines are available for the treatment of obesity. Examples of the Food and Drug Administration (FDA)-approved drugs that may be considered for the long-term treatment of obesity include orlistat, lorcaserin, the combinations of phentermine and extended-release topiramate, and the fixed-dose combination of bupropion and naltrexone **(Table 4)**. According to Endocrine Society Guidelines, pharmacotherapy for weight loss is indicated in patients with a BMI ≥30 kg/m^2 or ≥ 27 kg/m^2 along with associated comorbidities (e.g., diabetes, hypertension).[124] Drugs for weight loss are indicated in addition to caloric restriction and increased physical activity. The patient should be reassessed by week 12. If a patient fails to lose at least 5% of baseline body weight, drugs should be discontinued, as it is unlikely that the patient will achieve and sustain clinically meaningful weight loss with continued treatment.

Weight-loss medications target important neurotransmitters involved in feeding behavior.[125]

Neurotransmitters govern the body's response to starvation and dietary intake.

- *Norepinephrine and dopamine:* Released by sympathetic nervous system in response to food intake. Fasting and starvation lead to decreased levels of these neurotransmitters.

TABLE 3: Recommended exercise program for weight loss in obese.

	Recommendations
Frequency	≥5 days per week
Intensity	• Moderate to vigorous intensity • If body mass index (BMI) >35 kg/m^2, vigorous intensity is not appropriate • Gradual shift to vigorous intensity after an initial 4–12-week period of moderate-intensity activity
Time	The ultimate minimum goal should be to achieve 30–60 minutes of continuous aerobic exercise 5–7 times per week
Type	• *Aerobic isotonic exercise* is of the greatest value for persons who are obese • *Brisk walking*: Ideal for obese, sedentary individuals constitute moderate-intensity physical activity • *Cycling, swimming, water aerobics*: Ideal for BMI >35 kg/m^2 and joint problems constitute moderate-intensity physical activity • *Anaerobic isotonic exercises*, e.g., weight lifting and resistance training can be cautiously added as an adjunct after the aerobic goal described above is achieved • Not indicated for patients with hypertension and heart diseases

TABLE 4: Mechanism of action of Food and Drug Administration (FDA)-approved drugs for weight loss.[126]

Drug	*Mechanism of action*	*Dosage*	*Side effects*	*Comments*
Orlistat	Pancreatic lipase inhibitor	120 mg b.d.	Flatulence, fecal urgency, fecal incontinence, steatorrhea	• Reduce absorption of fat-soluble vitamins • Recommended for patients with cardiovascular disease
Bupropion–naltrexone	Dopamine-NE reuptake inhibitor/ opioid receptor antagonist	360 mg/32 mg	Constipation, headache, nausea, insomnia, tremors	Weight loss: 1-year: 5%
Lorcaserin	Selective serotonin 2c receptor agonist	10 mg b.d.	Dry mouth, constipation, headache, dizziness, nausea, fatigue	Weight loss: 1-year: 5–6%
Phentermine–topiramate	Norepinephrine-releasing/Na^+ GABA modulating agent	18.5–37.5 mg/96–192 mg	• Hypertension, palpitations, tachyarrhythmia • Insomnia, dry mouth, constipation, depression, anxiety	• CI: Hypertension, glaucoma • Hyperthyroid • Weight loss: 1-year: 5–11%
Liraglutide	GLP-1 receptor agonist	3 mg s.c. daily	Nausea, vomiting, risk of pancreatitis	Recommended for patients with cardiovascular disease

(CI: contraindicated; GABA: γ-aminobutyric acid; GLP-1: glucagon-like peptide 1; NE: norepinephrine)

- *Serotonin:* Low serotonin levels and high neuropeptide Y levels are associated with a craving for carbohydrate food.
- *Proopiomelanocortin* (POMC): Integrates multiple energy signals. Increased firing leads to the release of norepinephrine and dopamine and weight loss.
- β-*Endorphins:* Endogenous opioid peptide inhibits POMC firing, thus increasing appetite and cravings. Cravings for fatty and sugary foods among obese and bulimic patients involve the endorphin system.
- *Glucagon-like peptide 1* (GLP-1): It is a gut peptide. It amplifies glucose-dependent insulin release, inhibits glucagon release, suppresses appetite, and slows gastric emptying.

Metformin has been proposed as a weight-loss medication. It is a biguanide that inhibits hepatic glucose production and increases peripheral tissue sensitivity to insulin, resulting in reduced circulating insulin and androgen levels accompanied by decreased body weight and visceral fat.[127] Metformin alone is not associated with weight loss; however, when metformin is combined with a low-calorie diet, weight loss has been demonstrated. Drugs such as fenfluramine, dexfenfluramine, sibutramine, and rimonabant are no longer used due to adverse effects associated with them.

ROLE OF PRE- AND PROBIOTICS

A promising new treatment/preventive intervention for obesity has been proposed based on the principle of modulation of the intestinal microbial community in the form of probiotics and prebiotics in order to reduce the susceptibility to obesity.[128] Probiotics are defined as "live microorganisms, which exert health benefits to host by supplying a healthier and more diverse population of microorganisms." Animal studies on probiotic-fed animals have shown less weight gain, fat accumulation, and white adipose tissue compared to placebo-treated animals. Specific strains belonging to *Lactobacillus* (*L. casei*, *L. gasseri*, *L. rhamnosus*, and *L. plantarum*) and *Bifidobacterium* species have been widely used as probiotic treatment.

Prebiotics are "nondigestible food ingredients and supplements that enhance the effect of probiotics by selectively stimulating the growth and/or activity of one or a limited number of bacterial species already established in the colon, e.g., galacto-oligosaccharides (GOSs), fructo-oligosaccharides (FOSs), soybean oligosaccharides, inulin, gluco-oligosaccharides, xylo-oligosaccharides, lactulose, and lactosucrose." Pre- and probiotics exert their beneficial effect by changes in gut microbiota, correction of intestinal pH, lower inflammation, lower insulin resistance, and greater satiety.[128]

MATCHING WEIGHT-LOSS MEDICATION TO A PATIENT'S PROFILE[124]

- Nonsympathomimetic agents such as lorcaserin or orlistat should be considered for patients with a history of cardiovascular disease (CVD) or uncontrolled hypertension.
- GLP-1 agonist liraglutide should be considered as the first line in patients with diabetes; patients with both diabetes and CVD might also do well.
- For individuals with obesity and depression who are taking a selective serotonin reuptake inhibitor (SSRI) or serotonin and norepinephrine reuptake inhibitor (SNRI),

lorcaserin is not recommended due to the potential for serotonin syndrome. Phentermine/topiramate or phentermine alone should be considered.
- Orlistat is safe for all individuals.

BARIATRIC SURGERY

Bariatric surgery is generally considered for patients with BMI >40 kg/m^2 or patients with BMI >35 kg/m^2 and associated comorbidities or failure of other treatments for weight control.[129,130] It is associated with significant and rapid weight loss. But, it is an expensive procedure.

Salient features of bariatric surgery:
- Weight loss at 12 months, with gastric bypass averages close to 40% of the initial body weight
- Complete resolution or improvement of hyperlipidemia, hypertension, type II diabetes mellitus, and obstructive sleep apnea in >60% of patients
- Restores menstrual regularity, more ovulations owing to shorter follicular phase, reduces serum testosterone
- Improves sexual function in both males and females and increased chances of pregnancy
- Benefits maintained up to 10 years after surgery.

Bariatric surgery may not be so beneficial for male fertility. There are some case reports of worsening of semen parameters following bariatric surgery, perhaps from postoperative nutritional deficiencies, causing secondary infertility from spermatogenic arrest[131,132] and impaired IVF pregnancy outcome. In another case series, however, semen parameters of three obese men remained stable up to 1 year following bariatric surgery.[133] Without larger studies to confirm the impact of bariatric surgery on sperm quality, individualized management with cryopreservation of semen samples should be considered in selected circumstances.

Bariatric procedures are of three types **(Figs. 5A to C)**:
1. Restrictive
   a. Sleeve gastrectomy (SG)
   b. Laparoscopic adjustable gastric band (LAGB).

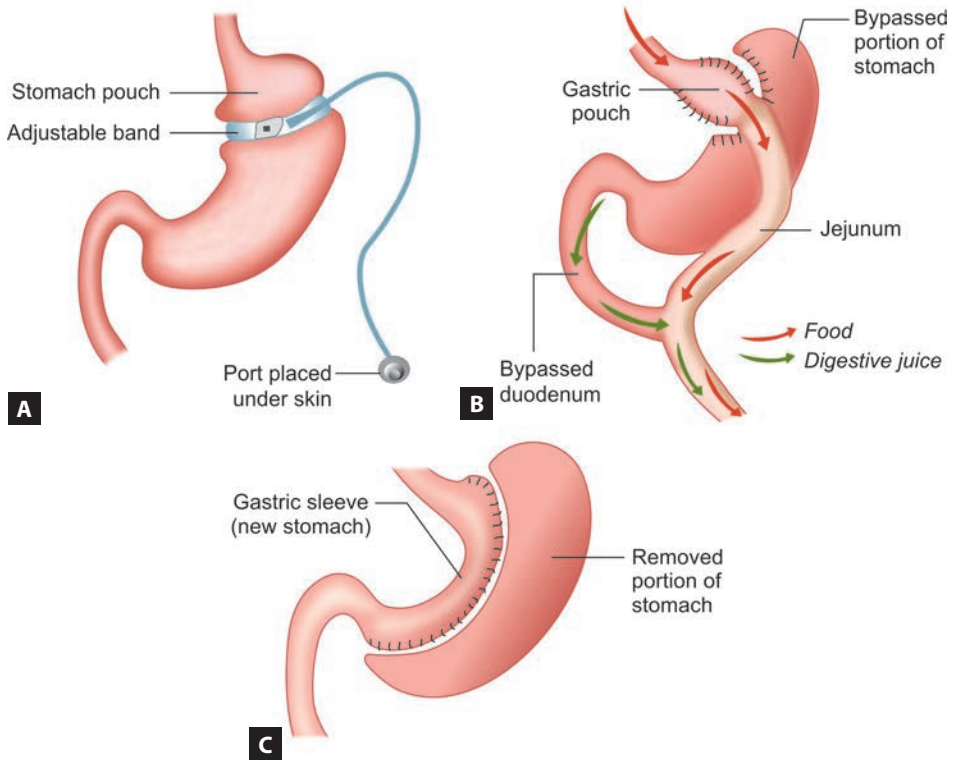
Restrictive procedures create a small gastric pouch with staples or a band that fills rapidly to induce early satiety.
2. Malabsorptive
   a. Biliopancreatic diversion.

Reduces absorption by anatomical modification
3. Combined restrictive and malabsorptive
   a. Roux-en-Y gastric bypass (RYGB).

The RYGB creates a small stomach pouch and attaches it to a loop of jejunum to shorten the length of the intestinal tract, restricting food intake and causing malabsorption.

In Vitro Fertilization and Pregnancy after Bariatric Surgery

There are limited studies on the effect of bariatric surgery on reproductive outcome. Available evidence suggests that IVF after bariatric surgery is safe. Surgically induced weight loss



Figs. 5A to C: Types of bariatric procedures. (A) Adjustable gastric band (Lap band); (B) roux-en-Y gastric bypass (RYGB); (C) vertical sleeve gastrectomy.

reduces pregnancy complications associated with obesity such as gestational diabetes, preeclampsia, hypertensive disorders, and macrosomia. Surgical complications such as bowel obstructions, internal hernia, gastric ulcer, band events, and staple-line stricture can occur in pregnancy, but are rare.[134,135] Some reports also suggest increased chances of preterm births and small-for-gestation age births in women undergoing bariatric surgery. Postsurgical nutritional deficiencies owing to rapid weight loss have been suggested as the possible cause and are most commonly seen in malabsorptive rather than restrictive procedures.

Therefore, it is recommended that pregnancy should be delayed for a period of 1–2 years after the surgery and patient be supplemented with essential micronutrients. Sexually active women should be prescribed nonoral hormonal contraceptives as oral contraceptives may exhibit decreased efficacy due to malabsorption.

Preconceptional Weight Loss: Is it Worth the Wait?

The benefits of postponing pregnancy in women to achieve preconceptional weight loss must be balanced against the risk of declining fertility with advancing age, although optimizing weight gain during pregnancy can lower the incidence of gestational diabetes.[136]

Benefits are as follows:

- Spontaneous ovulation. Improved chance of unassisted conception[9,136]
- Improved sperm count and morphology and increased testosterone levels[137]
- Higher percentage and number of metaphase II oocytes in IVF[138]
- Decreased anesthesia-related morbidity associated with oocyte retrieval[139]
- Decreased pregnancy complications related to obesity.[140]

Weight Loss and In Vitro Fertilization Outcome

The research on weight loss and IVF outcomes has shown mixed results. There is insufficient evidence to suggest that preconception weight loss improves clinical pregnancy rates and live birth rates in IVF.[141] In fact, the use of very-low-calorie diets has been shown to have a negative effect on IVF outcomes.[142] There are some studies that have shown improved conception rates and improved live birth rates following weight loss.[143,144] Though outcomes after weight loss have been conflicting, we should keep in mind the possible benefits of decreased pregnancy risks and complications associated with obesity.

OBESITY AND ETHICAL DILEMMAS

Many International Programs and National Health System recommend a BMI threshold for access to IVF to women with obesity above which fertility treatment is denied until the patient loses weight.[145] Assuming weight loss as an achievable goal, increased anesthetic, surgical, and obstetric risks with obesity and fertility treatment are the most common cited reasons. There are several oppositions to this thought as denying a patient solely on the basis of arbitrary BMI cutoff violates the ethical principles of patient autonomy, beneficence/nonmaleficence, and justice. Regarding safety concerns, a recent evidence suggests that retrievals can be performed safely in women with class 3 and above obesity managed in the appropriate clinical setting.[146] Individualized approach based on BMI should be practiced, patients with comorbidities should be evaluated before the day of surgery, and the anesthesia team should be consulted.

TRANSGENERATIONAL EFFECTS

Evidence suggests that maternal obesity may confer a risk of metabolic dysfunction through multiple generations. Children born to obese mothers are more likely to develop obesity, type II diabetes, and cardiovascular disease as adults.[147] This may be due to epigenetic modifications in utero. Some studies have suggested that metabolic syndrome may be passed down generations through aberrant oocytes with defective mitochondria.[148]

NUTRIGENOMICS

Nutrigenomics is a newer field of genomic science. It is the study of the effects of nutrients on the gene expression. Nutrigenomics aims to study the influence of one's genetic constitution on nutrient's metabolism with respect to its absorption, elimination, or biological effects using the technology of microarray and single nucleotide polymorphism (SNP). Due to genetic variability, every individual responds differently to a certain diet. Nutrigenomics aims to devise the means to optimize or personalize nutrition according to the patient's genotype and thus prevent obesity.[149] Still in the research process, nutrigenomics will revolutionize the treatment of obesity and other nutrition-based diseases by identifying the ideal diet or nutrition based on one's genetic composition which will prevent lifestyle diseases and ensure proper function of all pathways involved in the maintenance of genome.

CONCLUSION

Obesity is the gravest health problem that we face today. It has now become a global epidemic. It has vast effects on all the systems of the body including the reproductive system in both males and females. High BMI has a strong association with adverse fertility outcomes. Weight loss through diet and multidisciplinary approaches such as exercise and behavioral modification has been found to benefit greatly in terms of improved fertility, fecundity, and decreased risks

associated with pregnancy. Preconceptional counseling in an obese women should address the reproductive and maternal–fetal consequences of obesity and preconception weight loss should be encouraged. At the same time, pregnancy should not be delayed for weight loss due to declining ovarian reserve with increasing age. Obese women undergoing IVF should be carefully evaluated with a multidisciplinary team to determine the safety of oocyte retrieval under anesthesia. There is no available evidence to deny women IVF treatment based solely on BMI threshold. The obesity-associated reproductive morbidity is directly proportional to the duration of obesity. This makes obese children and young population, especially vulnerable in terms of their future reproductive potential. This population of obese adolescents should be the target of primary prevention such as lifestyle modification.

KEY POINTS

- Obesity is associated with decreased fertility and poor pregnancy outcomes.
- MRI is the most accurate and precise method for assessment of body fat.
- In utero programming and Gut microbiome may play an important role in onset of obesity.
- Preconception counseling and lifestyle modification are most important to improve the outcome in such patients.
- Pre-Pro Biotics and GLP-1 agonists are the promising new treatment in management of obesity.
- Obesity has deleterious effect on ART outcome.
- Although weight loss has not been shown to improve the IVF outcome it does decreases the pregnancy risks and complications associated with obesity.
- It is not recommended to delay IVF treatment to achieve ideal body weight, though lifestyle modification should continue.
- Multidisciplinary approach is recommended in obese women with multiple morbidities undergoing IVF.
- Nutrigenomics is the breakthrough science to deal with personalized nutrition based on ones genes.

CHAPTER 20

Unexplained Infertility

Abha Bhat

INTRODUCTION

Conception is by far one of the most elaborate and magnificent choreographies of nature, with each component working in complete harmony and synchrony with the other. The challenges in investigating and evaluating conception are twofold. Many steps in this complex set of events, though reasonably well understood, are not all easy to evaluate with currently available technologies with any degree of accuracy and ease, for example, the process of sperm capacitation and the ability of spermatozoa to bind to and penetrate zona pellucida (ZP), the quality of eggs, bidirectional tubal motility, etc. Certain steps have as yet eluded complete comprehension and understanding such as implantation and its determinants and are therefore impossible to diagnose. The unexplained therefore ranges from the not-so-easily diagnosed to the not-so-well understood. This chapter is an attempt to understand the "diagnosis" of unexplained infertility (UI) in current practice and the management thereof.

Average natural fecundity of human beings is only about 20% per month, and approximately 90% of couples achieve conception within a year of unprotected intercourse.[1,2] Those who are unable to conceive within this time frame are said to be subfertile and should be evaluated. Of these, 15–30% of couples will have no abnormality when subjected to standard fertility investigations, namely semen analysis, tubal patency tests, and ovulation studies. This group is classified as having UI. The fecundity rate in this group has been reported as 2–4% per menstrual cycle.[3] 50% of these couples will conceive in the subsequent year and another 12% in the year after.[4] It is in this group that management should be individualized based on patient characteristics as well as patient choice as many of the pregnancies that occur in this group following treatment may have occurred naturally without intervention. Several prediction models have been proposed to help clinicians in counseling patients.[5]

INCIDENCE

There is no universal consensus on the standard tests to be done for fertility evaluation. As such, the incidence of UI varies with the diagnostic criteria used. Many of the steps leading to conception cannot be routinely evaluated; hence, many reproductive disorders may not be amenable to detection. It may be speculated that the incidence of UI will decrease with advances in diagnostic modalities.[6,7]

CAUSES

The contributory causes may be in the male and/or the female partner.

UNEXPLAINED MALE INFERTILITY

Male partners who have a normal medical history, normal physical examination, a semen analysis reported as normal and, in whose partner, no female factors have been identified are classified as having unexplained male infertility (UMI). The average incidence of UMI is 15% (range: 6–37%). Possible factors leading to UMI may be the presence of antisperm antibodies (ASAs), sperm deoxyribonucleic acid (DNA) damage, elevated levels of reactive oxygen species (ROS), genetic defects, and sperm dysfunction. Coital factors (inappropriate timing of intercourse, erectile dysfunction, or anejaculation) may also contribute. A thorough initial assessment is therefore imperative in all couples and should include detailed sexual history and appropriate investigations **(Box 1)**.[8]

Sperm Deoxyribonucleic Acid Damage

Deoxyribonucleic acid damage may be present in the form of single or double DNA strand breaks, base deletion or modification, interstrand or intrastrand cross-linkage, or DNA-protein cross-linkage. The most common cause of DNA fragmentation is oxidative stress (OS). It may be associated with advanced paternal age, inadequate diet, drug abuse, tobacco use, environmental factors such as pesticide

BOX 1: Unexplained male infertility.

- Sperm DNA damage
- Immune infertility
- Oxidative stress
- Genetic defects
- Fertilization defects
- Coital factors:
  - Inappropriate timing of intercourse
  - Erectile dysfunction
  - Anejaculation

(DNA: deoxyribonucleic acid)

exposure or air pollution, varicocele, systemic diseases, and genital inflammation. DNA damage has been reported in 5–8% of normozoospermic men.[9] In a small controlled study on 28 normozoospermic individuals, sperm integrity defect as measured by sperm chromatin structure assay (SCSA) was reported to be 89.2%.[10]

Immune Infertility

Binding of autoantibodies to the antigens present in the male or female gametes may lead to immune infertility. Formation of ASA results from exposure of immune system to sperm antigens following a breach in blood–testis barrier. The breach may occur as a result of trauma, infection, or obstruction.[11]

There is evidence of ASA-induced functional deficit in the sperms. In the presence of ≤80% of sperms with sperm-bound ASA, a fertilization rate of 72% was seen, and if ≥80% of sperms contained sperm-bound ASA, the fertilization rate was 27%. There was no clear correlation between localization and fertilization capacity of spermatozoa. Complement in the female cervical mucus can bind to antibodies and cause lysis of sperm cell, reduce motility, and inhibit the ability of sperms to penetrate cervical mucus. ASA can also interfere with spontaneous and induced acrosome reaction (AR), spontaneous capacitation reaction, and recognition of sperm-binding sites on ZP. DNA fragmentation too has been found to be more frequent than fertile controls and ASA-negative patients.[8,11]

Presence of ASA correlates well with sperm agglutination, but this rarely affects a significant proportion of motile sperms even if all ejaculated sperms are coated with antibodies. Furthermore, several substances are present in semen that inhibit the seminal complement system activation.[8] This may be the reason for finding normal semen parameters in many men with immune fertility and the inconsistent correlation of ASA with infertility.

Oxidative Stress

Reactive oxygen species represent a broad category of molecules that are byproducts of oxidative metabolism. These may be either in the form of oxygen-free radicals (hydroxyl and superoxide ions), nonradical species (hydrogen peroxide and lipid peroxide), or reactive nitrogen species (nitrous oxide, nitroxyl ion, and peroxynitrite).[8] ROS in small amounts play a physiological role in capacitation, hyperactivation (HA), motility, AR, and fertilization.[12,13] ROS may also have a role in the regulation of nuclear maturation in spermatozoa.[14] The level of ROS is restricted by seminal antioxidants such as β-mercaptoethanol, protein, vitamin E, vitamin C, cysteamine, cysteine, taurine, and hypotaurine. However, elevated levels of ROS can overwhelm the body's natural antioxidant defense mechanisms and lead to damage of lipids, proteins, and DNA of spermatozoa, a condition called oxidative stress. Critical phases of spermiogenesis as well as sperms are vulnerable to ROS-induced damage. Sperm chromatin condensation is very vulnerable to damage by ROS as sperms do not have DNA repair mechanisms. The plasma membrane of sperm has high levels of polyunsaturated fatty acids and is especially susceptible to oxidative damage by ROS.[8] The antioxidant enzymes that are naturally present in the sperm cannot prevent tail and acrosome membranes from lipid peroxidation leading to reduced sperm motility and impaired sperm–oocyte interactions. Clinically, OS can be the underlying cause of reduced fertilization rates, failure of implantation, impaired embryonic development, recurrent pregnancy loss, and poor assisted reproductive technology (ART) outcomes.

Peroxides-positive leukocytes and morphologically abnormal spermatozoa (especially those with residual cytoplasm or cytoplasmic droplet) are the main sources of ROS. In spermatozoa, mitochondria and plasma membrane are the two major sites of ROS generation. Activated leukocytes in response to infection and inflammation can produce up to 100-fold higher levels of ROS compared to nonactivated leukocytes.[15] As such, even low-level leukocytospermia [$<1 \times 10^6$ white blood cells (WBCs)/mL of semen] has been associated with OS, and antibiotic therapy results in improvement in pregnancy rates.[16] Alcohol consumption, cigarette smoking, presence of varicocele, obesity, diabetes, too much physical exercise, psychological stress aging, environmental factors [such as nitric oxide (NO), lead, and electromagnetic waves from cell phones], and infections have also been etiologically associated with an induction of OS.[15]

Genetic Defects

Gene mutations and polymorphisms have been recognized in infertile men with normal spermiogram. Examples are *CatSper* gene 1 mutation and cytosine–adenine–guanine (CAG) repeat polymorphism in the gene coding for polymerase gamma, and sperm from these men have reduced oocyte penetration ability and fertilization rates.[17]

Fertilization Defects

The intricate and complex process of fertilization commences with capacitation which occurs in vivo during the travel of sperm through the female reproductive tract. In vitro, it can be induced by removal of seminal plasma and addition of culture media. This prepares the sperm cell to undergo HA and AR. "Hyperactivation motility" is characterized by lateral head displacement, high curvilinear velocity, and large amplitudinal flagellar waves and is essential for fertilization. The physiological mechanism is an increased intracellular calcium entry through sperm calcium channels called *CatSper1–4*.[8,18] Individuals with mutated *CatSper1* gene are infertile with poor HA response despite normal count, motility, and morphology.

Sperm binding to ZP is a crucial step in fertilization and a precursor to AR. Defects in ZP binding have been observed in 15% of infertile men with normal semen. Sperm-ZP binding triggers the release of hydrolyzing enzymes known as AR. AR is critical to enable sperm cell to penetrate the ZP and exposes the site of sperm that fuses with the plasma membrane of the oocyte. The processes should also occur in tandem for optimal fertilization potential. If AR occurs in a sperm before ZP binding, it would be unable to bind or penetrate the ZP.[8]

FEMALE INFERTILITY

Diagnosis of UI in the female partner is as ambiguous as in the male partner. Often the diagnosis of endometriosis, tubal infertility, premature ovarian aging, and immune infertility are missed **(Box 2)**.

Endometriosis

Endometriosis has been reported to be associated with infertility even in its mildest forms.[19,20] Severe endometriosis can be diagnosed on ultrasound. However, minimal to mild disease is not so easily picked up and has been reported as a dominant finding in women with UI.[21] The mechanism by which mild disease impacts infertility is less well understood. Peritubal adhesions that lead to altered tubal motility and function, toxic effect of peritoneal inflammation on the oocyte and sperms, and reduced endometrial receptivity may be the underlying factors contributing to infertility.

BOX 2: Causes of female unexplained infertility.

- Endometriosis
- Undiagnosed tubal factor
- Premature ovarian aging
- Immune infertility
- Poor oocyte quality
- Uterine cavity abnormalities:
  - Endometrial synechiae
  - Endometrial polyps
  - Chronic endometritis

Undiagnosed Tubal Factor

Fallopian tubes are crucial for sperm movement, oocyte capture and transport, and early embryo development. Through variations in tubal peristalsis or ciliary activity which may impact one or both fallopian tubes, subtle tubal abnormalities may cause defective transport of oocyte and impaired fertilization. Tubal diverticulitis, paratubal cysts, accessory fallopian tube, accessory ostium of fallopian tube, phimosis, agglutination, and sacculation have all been linked to infertility.[22]

Ovarian Aging

Ovarian reserve, generally defined as the number of oocytes remaining in the ovaries, may also influence the chances of conception. Being closely linked to age, the ovarian reserve decreases with age. Though this may impact the chances of conception, women with a low reserve continue to have regular ovulatory cycles.[23] Ovarian aging, which leads to poor ovarian response and poor follicular growth, may also contribute to unexplained female subfertility if found in chronologically young women well within the reproductive age bracket.[24]

Immune Infertility

In addition to the "self-tolerance," which is determined by the absence of autoantibodies, there exists a "natural tolerance" in the context of reproductive health. This tolerance extends to seminal fluid and its components (including sperm) as well as the semi-allogeneic embryo. The decidual cellular immune system comprises T helper cells, T follicular helper (Tfh) cells, and regulatory T cells. The humoral system consists of autoantibodies and pro- and anti-inflammatory cytokines. Alterations in any of the compartments of the immune system may interfere with the immune tolerance and lead to UI.

There may be an overall activation of the immune system or a production of autoantibodies specifically directed toward ovarian antigens. Majority of the antiovarian autoantibodies are directed against the β-subunit of follicle stimulating hormone (anti-FSH). Autoantibodies have been implicated in the causation of premature ovarian failure (POF), polycystic ovary syndrome, tubal infertility, endometriosis, and UI. Failure in differentiation of T cells into T-regulatory cells has been suggested as a mechanism of UI. Since the prevalence of antiovarian antibodies (AOAs) was similar in POF and UI, the latter may represent an early stage of autoimmune POF.[25]

The T helper 1 (Th1) cells inhibit while the T helper 2 (Th2) cells promote the trophoblastic invasion. The Th1/Th2 ratio has a crucial role in allowing the fetus to implant. For a successful pregnancy, the balance should therefore shift toward a Th2 response. The T helper 17 (Th17) cells play a fundamental role in the acceptance or rejection of the

fetus and some studies have suggested that high numbers of cells of Th17 subset may lead to UI and unexplained recurrent spontaneous miscarriages. Serum IL-17 has been shown to be an indicator of increased Th17 cells in the peripheral circulation. The different types of Tfh cells formed from the interaction of $CD4^+$ T cells and B cells may lead to the production of potential autoantibodies that trigger an inflammatory process during pregnancy and lead to infertility. $CD8^+$ $CD28^-$ Tregs, a subset of regulatory T cells (formerly called T suppressor cells) have a modulatory effect on the immune response that leads to the tolerance of the semi-allogeneic fetus, and a decreased number may therefore lead to infertility.[26]

Our understanding of the physiology, however, is insufficient and more studies are required to understand how autoimmunity can lead to infertility before manipulation of immunological milieu can be recommended to improve implantation or to cure infertility.[26]

Oocyte Quality

Good quality and maturity of oocytes are essential for fertilization and formation of good-quality embryos which progress to become blastocysts and then hatch before successful implantation. Quality of the oocytes may be affected by ovarian aging, endometriosis, and OS.[24,27,28] No biomarkers have been identified to date to evaluate the quality of the female gamete. Oocyte morphology can only be evaluated in the event of in vitro fertilization (IVF) process; hence, it can only be diagnosed retrospectively. Natural aging, which is strongly linked to decreased mitochondrial efficiency as well as increased OS, is the most common and obvious cause of decline in oocyte quality. In younger women, the quality may be compromised due to accelerated aging or due to genetic mutations that impact oocyte and embryo development. Since the quality of oocytes cannot be evaluated, many women may be wrongly classified as UI.[29]

Uterine Cavity Abnormalities

Congenital uterine anomalies are found in approximately 4.3% of fertile women, 3.5% of infertile women, and as many as 13% of women with recurrent miscarriages.[30] The most common anomaly is septate uterus accounting for approximately 35% of women followed by bicornuate uterus (25%) and arcuate uterus (20%). The general consensus is that malformations do not cause infertility but may be associated with reproductive loss, preterm delivery, malpresentations, and perinatal mortality. It is therefore prudent to offer hysteroscopic corrective surgery not only to symptomatic patients but also as a prophylactic procedure in asymptomatic patients.[31,32]

Acquired anomalies such as fibroids, synechiae, and polyps may be diagnosed on hysteroscopy. Fibroids may vary in size and may distort the uterine cavity. The evidence linking fibroids to infertility is not conclusive. The current evidence supports surgical correction of cavity-distorting myomas since it is correlated with improved pregnancy rates and lower risk of early pregnancy loss. The impact on live-birth rate (LBR) is however insufficient.[33] Non-cavity-distorting fibroids are unlikely to impact conception and LBR in women with UI.[34]

Uterine synechiae are commonly missed as the symptoms do not necessarily correlate with severity of adhesions, and mild cases of adhesions may be missed on the transvaginal ultrasound scan. They have been reported to be present in 1.5% of women undergoing hysterosalpingography (HSG)[35] and in 5–39% of women with recurrent miscarriages.[36] Patients with history of uterine instrumentation, miscarriage, endometritis, and tuberculosis should be evaluated and any suspicion should be confirmed by hysteroscopy.

Endometrial polyps have been reported in up to 24% of symptomatic patients and in >11% of subfertile women.[37,38] Hysteroscopic polypectomy should be offered to subfertile women as pregnancy rate as well as at term delivery rate increases, especially since it is a safe procedure with a low recurrence rate.[39] Interestingly, Stamatellos et al. reported no difference in the fertility rates and the total spontaneous abortion rate between patients who had a polyp ≤1 cm and those with polyp >1 cm or with multiple polyps.[40]

Chronic endometritis (CE) may exert a negative impact on the implantation potential of endometrium due to impaired decidual transformation. There is growing evidence of an association of CE with recurrent implantation failure (RIF) but a causal relationship with UI has not yet been established. In a study of 910 women, Cicinelli et al. found fluid hysteroscopy to be very reliable in the diagnosis of CE. The combination of focal or diffuse hyperemia, stromal edema, and polypoidal endometrium had a diagnostic accuracy of 93.4%. The incidence of CE in women with UI in this study was 40.7%.[41] In a further study by the same group, women with UI referred for hysteroscopy over the period of 1 year underwent endometrial sampling for histology and culture. The prevalence of CE in this group was 56.8%.

Women diagnosed with CE who have a successful resolution of inflammation following antibiotics have a higher rate of spontaneous pregnancy as well as live birth.[42,43] However, evaluation of infertile couples for CE cannot be recommended routinely, at least till a consensus is reached on the diagnostic criteria and specific treatment of this condition.[44]

Evaluation of Unexplained Infertility

At present, there is no consensus on the standard set of investigations to be done for a couple presenting with delay in conception. Significant differences exist in the tests that

are carried out with respect to criteria for normality and for their prognostic utility. The general agreement is that abnormal tests should only be correlated with infertility if the treatment of cause improves fecundity when compared to no treatment. It may therefore be better to perform a limited number of specific tests instead of a broad range of tests of dubious value.

INVESTIGATIONS OF THE MALE PARTNER

Semen Analysis

Semen analysis reports from different andrology laboratories suffer from a lack of uniformity. The highest variability is found for morphology, followed by count and motility.[39] The significant overlap in semen parameters between fertile and subfertile men makes semen analysis a suboptimal tool for assessment of male fertility potential.

The World Health Organization (WHO) guideline published in 2010 has revised the lower reference values of count to 15×10^6/mL, progressive motility to 32%, vitality to 58%, and normal morphology to 4%. With the change in the reference values, the previous estimation of prevalence of UI is likely to increase. Lack of standardization and training of staff in the andrology laboratories as well as wide biological variation in the semen parameters in ejaculates (of different men as well as in different ejaculates of the same man) limit the prognostic usefulness of semen analysis test.[45] A single analysis will falsely identify 10% of men as abnormal. Repeating the test when the first test is abnormal reduces the false-positive rate to 2%.[46] The lower limit of the reference range is taken as the 5th centile. The assessment of the fertilization potential may be more thorough if the 50th centile is also taken into account as this may give a more realistic understanding of the patient's seminal profile.[8] Computer-assisted semen analysis varies in its ability to predict fertilization and, therefore, is of limited use in practice.[46] In the absence of robust and cost-effective sperm function tests that reliably assess fertilization potential, it is not possible to diagnose or rule out male factor infertility, and men with suboptimal spermatozoa may be classified as normal and vice versa.

Antisperm Antibodies

Antisperm antibodies have been reported in 42% of men with IU, 10.7% of men undergoing fertility evaluation, and 10% of couples undergoing IVF treatment but only 2% of fertile men.[8] The role of ASA in causing male infertility, however, remains ambiguous at best.

Tests for Reactive Oxygen Species

Tests to assess OS are expensive, complex, and require extensive technical training and can quantify either the ROS or the antioxidants. Currently, available tests include chemiluminescence for ROS, total antioxidant capacity (TAC) for antioxidants, and malondialdehyde (MDA) assay for post-hoc damage from lipid peroxidation.[47] Recently, Agarwal et al. have suggested the use of MiOXSYS system to detect OS by measuring oxidation–reduction potential (ORP). This enables a direct evaluation of the redox balance between the ROS and the antioxidants. The authors claim that this simplified laboratory test can be a valuable tool in the male infertility workup and guide treatment of OS-induced male infertility.[47]

Sperm Deoxyribonucleic Acid Damage Assays

Sperm DNA integrity may be accepted as a specific marker of male infertility, but its utility is undermined by the lack of general consensus on a standardized objective assessment of DNA damage. Tests described for sperm DNA fragmentation are single cell gel electrophoresis (COMET) assay, SCSA, acridine orange test (AOT), terminal deoxynucleotidyl transferase (TdT)-mediated deoxyuridine triphosphate (dUTP) nick-end labeling (TUNEL) assay, and sperm chromatin dispersion (SCD) test.

Need for Better Tests for Male

Newer technologies need to be developed to fix the shortcomings of routine semen analysis. This may be through cost-effective and reliable techniques to assess OS, DNA fragmentation, and other subcellular defects that seem to be clinically relevant. The techniques of genomics, transcriptomics, proteomics, and metabolomics, which are presently very expensive and relatively inaccessible, may enable precise and comprehensive investigation of male UI in future.[8] Defects in sperm–oocyte interaction and fertilization may be diagnosed during an IVF cycle for the very first time, thereby placing the couple erroneously in the "unexplained" cases. With tests that can test the functions of spermatozoa, it may be possible to diagnose these defects earlier, thus enabling an optimal management plan with a shorter time to pregnancy.

INVESTIGATIONS OF THE FEMALE PARTNER

Hormonal Assays

Hormonal assays are routinely done assessment of ovarian reserve during the early follicular phase. This includes basal FSH, luteinizing hormone, and anti-Müllerian hormone (AMH). These tests are useful in predicting the outcomes of IVF including the number of oocytes, number of embryos, and number of clinical pregnancy. Use of age in conjunction with AMH, antral follicle count (AFC), and basal FSH also helps in prediction of poor ovarian response in an IVF cycle.[48,49] In addition, prolactin and thyroid hormones are also routinely assessed as these have an impact on the ovarian function directly and indirectly.

Ovulation Studies

Serum progesterone measurement that is timed approximately 1 week before the expected onset of menses is a cost-effective method of confirmation of ovulation, although this may need to be repeated weekly in women with irregular cycles.[50] There is however no consensus on reference values of serum progesterone for the purpose of confirmation of an ovulatory cycle. Values >18 nmol/L are considered by WHO as indicative of ovulation, while Hull et al. suggested a level >30 nmol/L.[51] The secretion of progesterone by the corpus luteum is pulsatile and fluctuates widely in the mid and late luteal phase raising the question of reliability of a single progesterone test for the assessment of ovulation and adequacy of luteal phase.[52] Ovulation studies, however, do not provide any information on the quality of oocyte released and hence have limited value in the diagnosis of UI.

Tubal Patency and Peritoneal Factors

Available tests to assess fallopian tubes are all directed to testing the structural patency of the tubes. However, it is known that tubal peristalsis and the internal milieu of the fallopian tubes are critical for fertilization of oocyte and normal implantation of the embryo. Presently, there are no tests that can assess the functional integrity of fallopian tubes.

Hysterosalpingogram is a less invasive, less expensive, and well-tolerated outpatient procedure and is generally the first-line investigation for evaluating tubal patency. Hysterosalpingo-contrast sonography is an alternative test with comparable accuracy.[53,54] HSG, however, may fail to detect tubal abnormalities, at least some of which are secondary to undiagnosed endometriosis.[55]

Laparoscopy is considered a gold standard in the diagnosis of endometriosis and should be offered to couples with UI prior to embarking on assisted reproductive techniques. Women diagnosed with mild endometriosis may be offered surgical removal of the endometriosis and this approach has been reported to improve postoperative pregnancies.[56] Women with hitherto undiagnosed endometriosis having severe tubal disease will benefit from assisted reproductive techniques without a period of expectant management.

De Cicco et al. compared 170 women with UI who underwent combined hysteroscopy and laparoscopy surgery with 100 women who refused surgery and ART treatment. 49.4% of patients who underwent combined surgery had pelvic pathologies. Of the 86 women who had no abnormalities, 28 achieved a spontaneous pregnancy and 23 conceived after ART. The authors concluded that combined laparoscopy and hysteroscopy should be done in women with UI as this may reveal the underlying pathology and indicate patients who would benefit from ART. They also concluded that those without an abnormal surgical finding would be unlikely to benefit from ART.[57]

In a large case–control study, Mahran et al. studied 600 infertile women who were subjected to laparoscopy or combined laparoscopy and hysteroscopy over a 3-year period. Of these, 38.2% of women had UI. Following surgery, women were treated with different options—expectant management (15.3%), ovulation induction with antiestrogens or gonadotropins (62%), intrauterine insemination (IUI) (10.7%), and IVF/intracytoplasmic sperm injection (ICSI) in (10.7%). 180 patients (30%) achieved pregnancy within a year of laparoscopy. The most favorable outcome was in women with UI (36.7%) while the worst was in women with endometriosis.[58] It may be inferred that women with UI may be offered laparoscopy to complete the evaluation. Following surgery, those with an underlying pathology may be offered ART while those without a pathology may be given the option of expectant management.

Laparoscopy is, however, not recommended by all. In a large prospective randomized clinical trial, Badawy et al. evaluated the role of laparoscopy in 512 patients with UI. The 255 women in the study group had laparoscopy followed by ovarian stimulation and timed intercourse for six cycles, while the 257 women in the control group had six cycles of ovarian stimulation with timed intercourse. The clinical pregnancy rates (CPRs) as well as miscarriage rates were not statistically significant in the two groups. The authors concluded that in patients with UI, laparoscopy may be done after ovarian stimulation with timed intercourse was found to be unsuccessful.[59]

Evaluation of Uterine Cavity

Transvaginal ultrasound is the preferred and almost universally used screening tool for the assessment of uterine cavity. Saline hysterosonography can be performed to enhance the diagnostic ability of ultrasonogram (USG) in select cases. Alternatively, 3D ultrasound can be done to evaluate both uterine structural anomalies and fibroids and intracavitary abnormalities.

Hysteroscopy is another tool available to diagnose uterine cavity abnormalities. It is both more expensive and invasive. Office hysteroscopy has made this test a lot less invasive than in the past; however, more randomized controlled trials are required before routine use of hysteroscopy in subfertile women can be recommended.

The alterations of endometrial microenvironment observed in CE may hamper endometrial receptivity, potentially causing female infertility.[4,5] Nevertheless, different studies have previously showed that CE is highly prevalent in patients affected by infertility, especially in case of repeated IVF failures,[10,11] with a prevalence of up to 57.55%.[12] Intriguingly, different studies demonstrated that antibiotic therapy is able to restore normal endometrial histology as well as to improve the implantation rate in such

patients,[10-12] suggesting a causal relationship between CE and defective endometrial receptivity. Although the correlations between CE and RIF have been largely evaluated, no study has still investigated the impact of CE on "unexplained infertility." UI is diagnosed in about 15% of couples seeking medical advice when standard investigations fail to identify any abnormality.[13] Due to a poor spontaneous pregnancy rate (between 2 and 4% per menstrual cycle)[14-16] and the lack of clear targets for therapy, such patients are often submitted to ARTs with limited results.[17]

"Diagnosis" of female UI is thus a diagnosis of exclusion. Many investigations available may shed light on the probable cause, but it is the clinician's responsibility to do investigations not to satisfy curiosity but to enable a prognostic evaluation and plan management. It may not be wise to do investigations that are not cost-effective and do not help in tailoring the treatment strategy. Laparoscopy may be advised to diagnose and treat endometriosis and to evaluate tubal patency. However, there is a knowledge gap regarding evaluation of oocyte quality, immune infertility, and implantation failure. Research in these areas may help decipher the enigma of "unexplained infertility" better.

MANAGEMENT

The couples diagnosed to have UI by definition have no underlying reason for infertility. This is thus a heterogeneous group with undiagnosed but varied subtle or molecular defects. The prognosis, where the duration of infertility is 3 years or more, is worse.[60] Age-related infertility is associated with poor oocyte quality that is independent of a lower ovarian reserve.[61] Counseling the patient on the reason for infertility and on prognosis is therefore difficult.

Many patients with UI conceive while awaiting treatment. It has not been possible so far to identify patients who would benefit from an expectant management in order to prevent unnecessary medical interventions. The latest Cochrane systematic review of the interventions for UI showed insufficient evidence of difference between expectant management and the four interventions—ovarian stimulation, IUI, ovarian stimulation with intrauterine insemination (OS-IUI), and IVF/ICSI. The odds of multiple pregnancy rate (MPR) may be expected to increase in OS and OS-IUI but not with IVF/ICSI when compared with expectant management.[62]

Fertility treatments have cost implications, at the same time, the "cost" of waiting, of the stress of undergoing repeated cycles of treatment in any form, of the disappointment with every failure, and cost of managing complications arising from multiple pregnancies cannot be minimized. Individualized management must therefore be planned for each patient taking into account their clinical circumstances, beliefs, and expectations of time to pregnancy.

Expectant Management

Management of patients with UI is at best empiric. Many studies have observed high spontaneous pregnancy rates in couples with UI. The cumulative pregnancy rates at the end of 12 months have been reported to vary from 14.3 to 27.4%.[63] Guzick et al. published a retrospective review of 45 studies in which average fecundity was 1.3–4.1% in the untreated group; this was lower than most other treatment groups.[64]

A large observational study was conducted in the Netherlands of 5,962 patients (of which 1,236 patients were diagnosed with UI) who were on the national waiting list for IVF or ICSI. Of these, 80 patients conceived spontaneously. The cumulative ongoing pregnancy rate was calculated to be approximately 13%. Patients of this group had 2 years or more duration of infertility and may have had a poorer prognosis.[65]

Younger women <30 years of age with shorter durations of infertility are more likely to conceive and a period of 6–12 months may be offered expectant management. This option has the lowest cost. It may be offered where limited resources are a concern, especially when the female partner is young and ovarian reserve is ample. This approach does not seem to compromise ongoing birth rates and is as effective as offering assisted reproduction immediately.

The National Institute for Health and Care Excellence (NICE) guidelines and the Royal College of Obstetricians and Gynaecologists (RCOG) guidelines advise a period of 2 years expectant management prior to offering IVF.[66] The American College of Obstetricians and Gynecologists (ACOG) guidelines advise a period of up to 6 months for a woman with UI who is 35–40 years old. However, this approach is likely to increase the time to pregnancy and may not be acceptable to patient.[67]

Superovulation and/or Intrauterine Insemination

Women who fail to conceive after a period of expectant treatment may be offered superovulation either alone or in conjunction with IUI. The thought behind this strategy is a combination of multiple ovulations and a higher density of motile sperm in the vicinity of the oocytes, which would positively impact the likelihood of fertilization and conception. This would also benefit women with cervical factors and subtle ovulation disorders. The understandable repercussion of this would be the risk of multiple pregnancies resulting from multiple ovulations. Unlike in the anovulatory patient where monofollicular ovulation is the desired goal, multiple ovulations are desirable in patients with UI. Multiple ovulations may be achieved with clomiphene citrate (CC), letrozole, or gonadotropins.

Clomiphene citrate is a commonly used ovulation induction agent that has been used in the treatment of UI. Studies comparing CC with placebo or no treatment have failed to show a clear benefit. The Cochrane collaborative

systematic review compared CC with no treatment in 1,159 patients with UI (data obtained from seven trials). There was no evidence of superiority of CC over expectant management (either with or without IUI) in achieving a clinical pregnancy.[68] These studies employed a standard protocol of treatment employing fixed doses of drugs without reporting multiple follicular developments or escalating the dose of drugs if the monofollicular response was seen. The objective of multiple ovulations was not always achieved and the confounding role of endometrial quality (which can be expected in CC therapy) was also not studied. This may be the reason for the lack of benefit seen with CC therapy.

Aromatase inhibitor induces ovulation without the disadvantage of antiestrogenic effect of CC. In a study of 214 patients, Fouda et al. demonstrated an improved ongoing pregnancy rate with letrozole plus IUI (33%) when compared with CC plus IUI (19%). On the other hand, DIAMOND trial studied 900 patients randomized to three arms: Letrozole (5 mg on cycle days 3–7), CC (100 mg on cycle days 3–7), and FSH (150 UI from cycle day 3 onwards). LBR was 23.3% in the CC group, 18.7% in the letrozole group, and 32.2% in the FSH group. While the difference in LBR in CC in comparison to the letrozole group was not significant, the LBR was significantly higher in the FSH group.[63]

Gonadotropins can also be used to achieve multiple ovulations. A review of a Cochrane database published in 2009 found insufficient evidence of a difference in LBR between oral and injectable ovulation-inducing agents. When data from three studies that had CPR as the outcome was combined, a significantly higher CPR was seen in the group treated with human menopausal gonadotropins.[68] The cost of treatment and patient's convenience should be taken into account before choosing the method of treatment. Patients should also be counseled regarding the risk of multiple gestations and ovarian hyperstimulation syndrome (OHSS).

In Vitro Fertilization

In vitro fertilization has been recommended by NICE for all patients who fail to conceive after expectant treatment for a period of 2 years. It is considered to be the most effective method of treatment as it helps with ovarian dysfunction, cervical factors, abnormal sperm–oocyte interaction, and tubal dysfunction. It is also expensive and invasive and has the additional risk of high multiple pregnancy and OHSS. Cochrane review on the role of IVF in UI showed higher CPR and LBR than expectant management.[68] Goverde et al. examined the efficacy of gonadotropins with IUI against IVF. No statistically significant difference was found. They also found IUI cycles more cost-effective than IVF.[63] On comparing IVF and natural cycle IUI, they found no significant difference in LBR (39% vs. 24%). ICSI was not found to be superior to IVF in terms of fertilization rate, CPR, and LBR.[63]

The FASTT (Fast Track and Standard Treatment) trial studied two arms with time to pregnancy as an endpoint. Reindollar et al. randomized patients to one of two arms: (1) A conventional arm with three cycles of CC (100 mg on days 3–7) and IUI followed by three cycles of gonadotropins (at a starting dose of 150 IU) and IUI and then up to six cycles of IVF or (2) an accelerated arm with three cycles of CC with IUI followed by up to six cycles of IVF. This study also reviewed per-cycle pregnancy rates and found no benefit to gonadotropin treatment after failed oral superovulation. The accelerated arm had a shorter time to pregnancy.[63]

To conclude, IVF may be offered to those couples who fail to conceive after 2 years of expectant management.[66] However, ovulation induction with oral or injectable agents may be offered in conjunction with IUI in an attempt to limit over-medicalization. IVF is probably the most effective management strategy once the 3–6 cycles of Ovulation Induction + IUI fail. It also provides an opportunity to rule out poor oocyte quality and abnormal sperm–oocyte interaction which would otherwise remain undiagnosed with currently available tests.

CONCLUSION

Unexplained infertility continues to confound and challenge fertility specialists the world over. Clinical experience and research have over the years implicated many factors as the possible cause of subfertility in these cases; however, most have not shown any direct correlation with fecundity. The causality remains ambivalent and tentative at best. This makes the management of UI much more difficult. The prognosis swings widely between those who conceive spontaneously or with treatment, who fortunately form the bigger group to those who are refractory to all treatments. It is this group of recalcitrant that are difficult to explain and understand and they continue to remain unexplained until age or a decreasing reserve becomes a definite factor needing correction. The way forward continues to remain an individualized tailor-made approach for each patient depending upon their clinical features, age and other logistical considerations, and the clinician's experience and judgment. More will hopefully be known to us in the future and the management will subsequently be a lot more assured and unequivocal.

KEY POINTS

- Causes of UI range from not so easily diagnosed to not so well understood.
- There is no standard prescribed list of investigations for evaluation. Most clinicians rely on their own experience as well as availability and cost of tests to guide them.
- The significant overlap in semen parameters between fertile and subfertile men makes semen analysis a suboptimal tool for assessment of male fertility.

- The correlation of ASA is inconsistent with infertility. Many men with immune infertility may have normal semen parameters.
- OS may affect fertility potential in both men and women, but it is difficult to diagnose.
- Sperm DNA integrity may be accepted as a specific marker of male infertility, but its utility is undermined by the lack of general consensus on a standardized objective assessment of DNA damage.
- Tubal peristalsis and the internal milieu of the fallopian tubes are critical for fertilization of oocyte and normal implantation of the embryo. Presently, there are no tests for the functional integrity of the tubes.
- It is known that the immune system has an important role in implantation, but our understanding of the physiology is insufficient to recommend manipulation of the immunological milieu to improve implantation.
- Hysteroscopy and laparoscopy may assist in the diagnosis and management of patients with endometriosis and uterine cavity abnormalities.
- The prognosis where the duration of infertility is 3 years or more is worse.
- Age-related infertility is associated with poor oocyte quality that is independent of a lower ovarian reserve.
- Management of patients with UI is at best empiric.
- High spontaneous pregnancy rates have been observed in couples with UI with expectant management.
- Cost of fertility treatments should also take into account the "cost" of waiting, of the stress of undergoing repeated cycles of treatment in any form, of the disappointment with every failure, and the cost of managing complications arising from multiple pregnancies cannot be minimized.
- Individualized management must therefore be planned for each patient taking into account their clinical circumstances, beliefs, and expectations of time to pregnancy.

CHAPTER 21

Fertility Preservation

Sonia Malik, Aneesha Grover

INTRODUCTION

Fertility preservation can be defined as a means for preserving an individual's ability to reproduce at will or at a chosen time.[1] Fertility preservation has given a new dimension to assisted reproductive technology (ART) services. With a post-thaw embryo/gamete survival rate of around 90% and around 50% implantation rate, the infertility specialists confidently offer cryopreservation to all who want to delay childbearing or whose fertility is at risk.[2] Both men and women have been benefited by it.

Concomitantly, there is a marked increase in the incidence of cancer worldwide in all age groups.[3] Childhood cancers are increasing and so are the young cancer survivors.[4] Moreover, with men and women delaying childbearing, there is a growing pool of cancer patients who require to save their fertility.

There are other noncancer patients as well whose fertility is at risk and will be benefited by this, for example, autoimmune disorders, and delayed marriages.

Many options are available to these patients; some are well established while some are emerging. Embryo/oocyte and semen cryopreservation are well-accepted methods of fertility preservation in postpubertal patients.[5-7] New techniques for mitigating the negative effect of cancer treatments, protecting ovarian function and preserving fertility are constantly being developed. Both existing and emerging techniques in fertility preservation will be dealt with in detail in this chapter.

INDICATIONS OF FERTILITY PRESERVATION

Both oncologic and nononcologic diseases can affect the fertility potential of an individual, either directly by the disease process itself or due to their fertility-threatening therapy. The main objective of fertility preservation intervention is to minimize or eliminate the disease burden and also preserve the individual's chance of achieving pregnancy.

Fertility preservation may be sought by both men and women for either cancer or noncancer indications.

FERTILITY PRESERVATION IN WOMEN

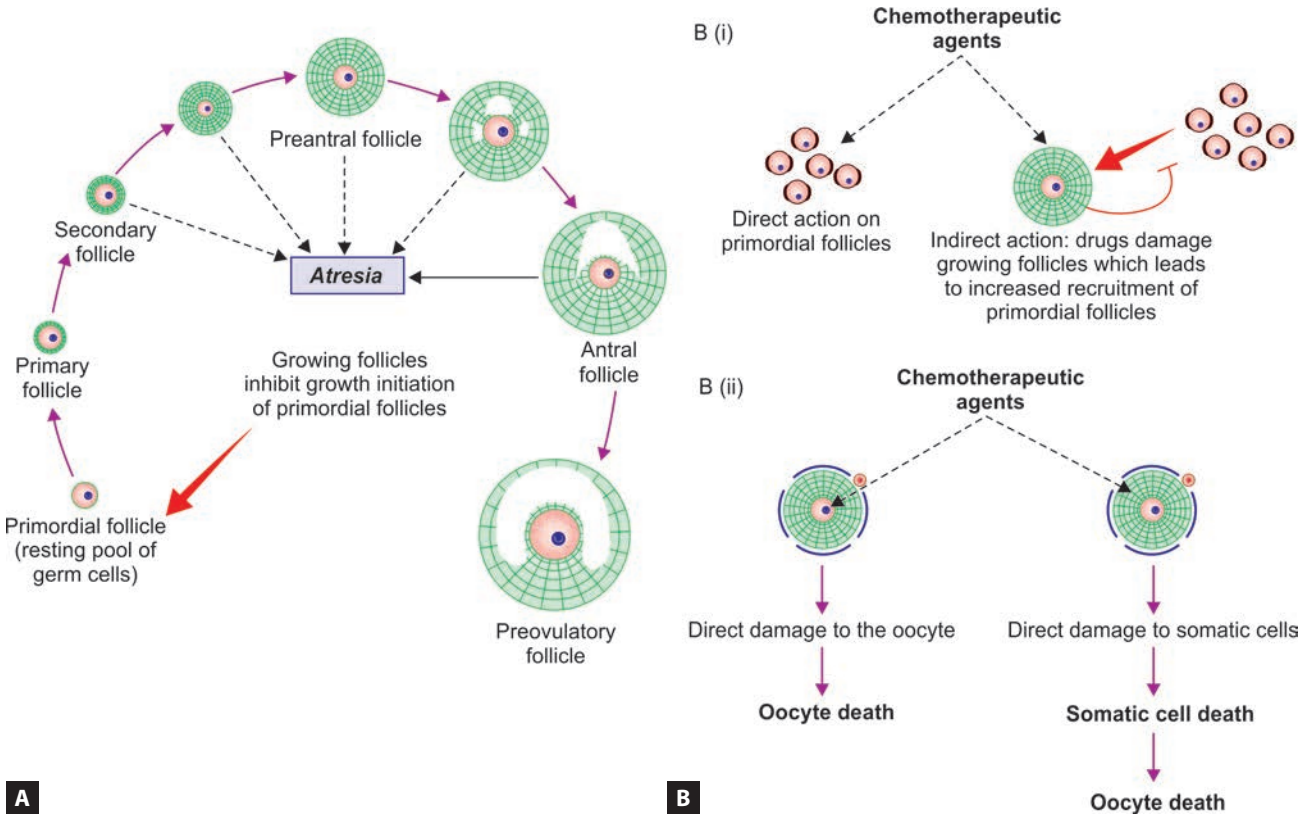
The European Society of Human Reproduction and Embryology (ESHRE) guidelines on fertility preservation, 2020, divided the subpopulation of women requiring fertility preservation into four subgroups,[8] namely:

1. Postpubertal women diagnosed with cancer undergoing gonadotoxic treatments
2. Postpubertal women with benign diseases undergoing gonadotoxic treatments or with genetic conditions predisposing to premature ovarian insufficiency (POI), for example, Turner syndrome
3. Transgender men (assigned female at birth)
4. Women considering oocyte cryopreservation for age-related fertility loss.

Cancer therapy in the form of chemotherapy or radiotherapy leads to POI. The degree of ovarian damage is related to the type and dose of chemotherapy and the dose and field of radiation.[9] The age of the patient and the ovarian reserve at the time of initiation of therapy are other prognostic factors for fertility decline after therapy. Decanter et al. found that the anti-Müllerian hormone (AMH) levels declined substantially after the initiation of chemotherapy.[10] Among the chemotherapeutic agents, it is the alkylating agents such as cyclophosphamide, chlorambucil, busulfan, and mechlorethamine, which have the maximum negative impact on the fertility potential of the woman. These agents cause single- and double-strand deoxyribonucleic acid (DNA) breaks in ovarian cells. They are also seen to cause cortical fibrosis and blood vessel damage in the ovarian tissue. These agents are thus associated with acute ovarian insufficiency, premature menopause, and poor reproductive outcomes.[9]

Figures 1A and B describe the follicle development in the ovary and the mechanism of chemotherapeutic damage of the ovary.[11]

Radiotherapy not only damages the ovaries but also reduces uterine vascularity and causes myometrial fibrosis, endometrial damage, and reduction in uterine volume.[9] It



Figs. 1A and B: Mechanism of cellular damage in ovary after cytotoxic therapy.
Source: Adapted from Morgan et al. 2012;18(5):525-35.

had been seen that an irradiation dose of as less as 2 Gy can destroy 50% of the primordial follicles in the ovary. It has also been seen that an abdominal irradiation dose of 20–30 Gy in childhood resulted in 97% of women to suffer from ovarian failure and 67% of women who received irradiation in prepuberty to suffer from ovarian failure.[9] Also, cancer debulking surgeries involving removal or damage to the reproductive organs can also result in loss of fertility.

Chemotherapy and radiotherapy may be advised before hematopoietic stem cell transplantation or bone marrow transplantation for nononcologic conditions such as thalassemia major, aplastic anemia, sickle cell anemia, and other myeloproliferative and myelodysplastic diseases. Alkylating agents may also be used in the treatment of autoimmune diseases such as systemic lupus erythematosus (SLE), Behçet's syndrome, Sjögren's syndrome, steroid-resistant glomerulonephritis, inflammatory bowel disease, and scleroderma, thereby putting the fertility potential of these individuals at risk.[9]

Some genetic disorders such as Turner syndrome, fragile X syndrome, and galactosemia (autosomal recessive disorder of galactose metabolism) predispose an individual to POI.

Some gynecologic diseases such as endometriosis are associated with declining fertility, not only due to the disease process but also because of the corrective surgeries done as treatment. The local inflammation caused by the endometrioma increases the follicular burnout and the cystectomy surgery for removal of the endometrioma has a negative impact on the ovarian reserve due to loss of germinal vesicles (GV) attached to the cyst. Fertility preservation should be offered in endometriosis if:[9]

- There is quantitative alteration in ovarian reserve due to repetitive surgeries
- Recurrent endometriosis
- Bilateral endometrioma
- A large (>5 cm) unilateral endometrioma.

Female fertility starts declining after the age of 32 years and this decline accelerates after the age of 37 years. Women who delay childbearing should therefore consider oocyte freezing in order to preserve their fertility.[12]

Sex affirmation procedures in transgender men who have been assigned female at birth involve surgical removal of ovaries and cross-sex hormone therapy. This has a deleterious effect on the fertility of these individuals. Therefore, fertility preservation may be offered to them before they undergo any of the sex-changing treatments.

FERTILITY PRESERVATION IN MALES

Men requiring fertility preservation can be subgrouped as per their indications:[13]

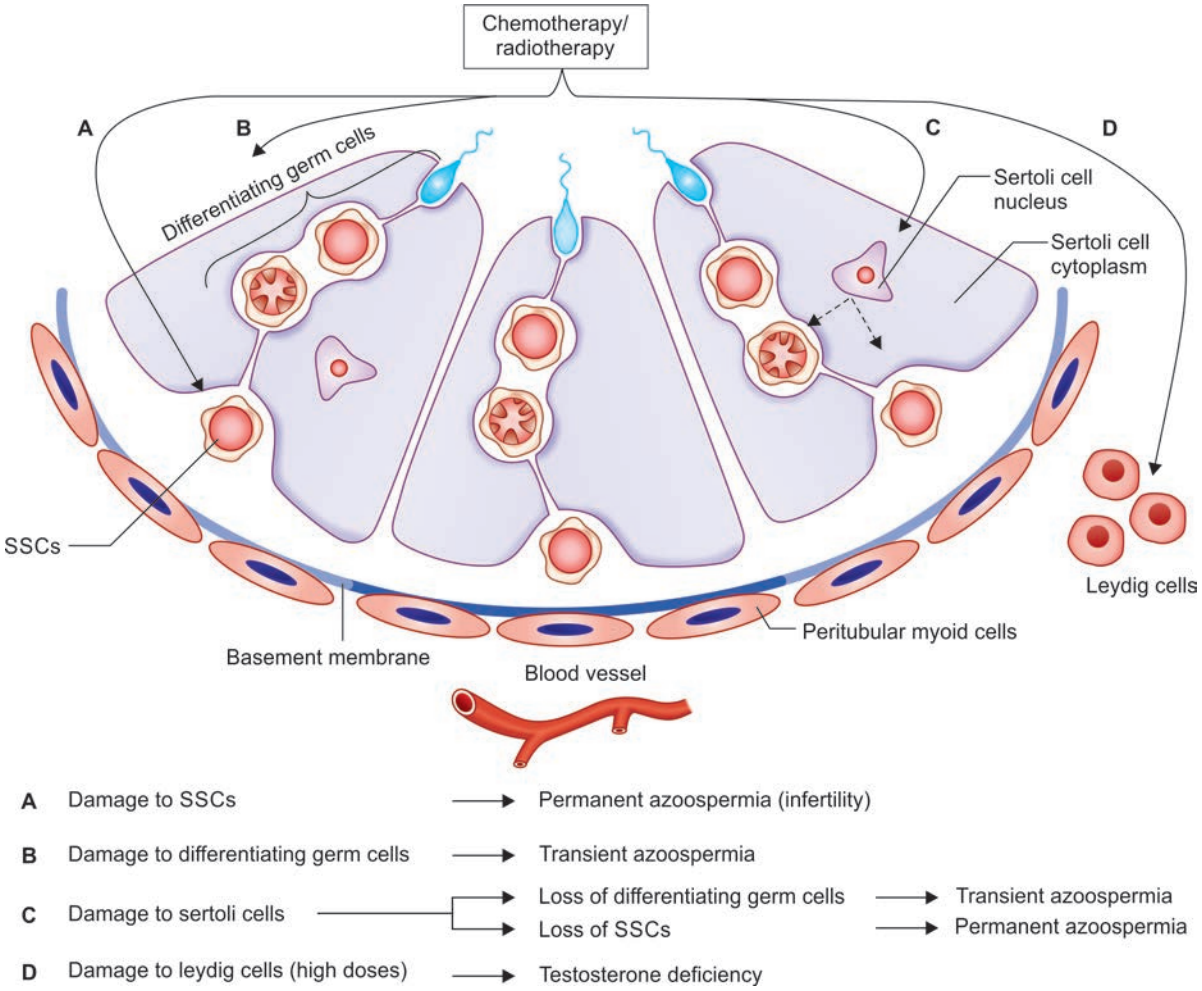


Fig. 2: Mechanism of cellular damage in testis after cytotoxic therapy.
(SSC: spermatogonial stem cell)
Source: Adapted from Anderson et al. 2015.

- *For medical indications*
  - Oncologic treatment: Adults/adolescents/prepubertal boys planned for gonadotoxic treatment in view of cancer
  - Human immunodeficiency virus (HIV) infection
  - Prevasectomy
  - Posthumous sperm retrieval
  - Men undergoing gender reassignment
- *Nonmedical conditions*
  - Social.

Cancer is one of the primary indications for fertility preservation in men. Radiotherapy and chemotherapeutic drugs, especially alkylating agents, adversely affect the spermatogonial stem cells and result in fertility problems.

Figure 2 describes the mechanism of cellular damage in the testis after cytotoxic therapy.[14]

It has been seen that the sperm quality is impaired even when the initial diagnosis of cancer is made, even before the initiation of any form of treatment.[9] Also if there is an adequate number of spermatogonial stem cells at the time of initiation of the cancer treatment, it has been observed that adverse effect of the treatment on fertility may be reversible.[15]

Surgical interventions can affect spermatogenesis both directly and indirectly. Direct damage to spermatogenesis occurs in procedures such as orchidectomy, while indirect impairment can occur due to damage to the sympathetic and parasympathetic nervous systems resulting in ejaculatory and erectile dysfunction.[16]

There are some nononcologic medical conditions which result in impaired fertility, either due to the disease process itself or due to the gonadotoxic nature of its treatment. Autoimmune diseases such as SLE, multiple sclerosis, and Crohn's disease are associated with abnormal sperm parameters and erectile and ejaculatory dysfunction.[17] Hematopoietic stem cell transplantation may be required in the treatment of these diseases. This in turn requires chemotherapy and radiotherapy to damage the diseased blood-forming cells and marrow, which also damage the spermatogonia.[18] The other nononcologic conditions associated with infertility include spinal cord injuries and

nerve injuries during abdominopelvic surgeries resulting in ejaculatory and erectile dysfunction.

Human immunodeficiency virus infection has a direct impact on fertility. It is associated with reduced seminal fluid volume, sperm concentration, vitality, motility, morphology, and fertilizing capacity of the sperms. The degree of impact is related to the duration of infection, age of the patient, and the presence of concomitant sexually transmitted disease (STD) infection. A low $CD4^+$ count has been directly correlated with reduced semen quality.[19,20]

Vasectomy is a permanent method for contraception. Only those men who are certain that they do not want to biologically father children in the future are offered this procedure. However, it has been observed that up to 6% of men who have undergone vasectomy request a reversal of the procedure due to a change in their life circumstances.[21] Hence, the option of fertility preservation before vasectomy may be discussed.

Posthumous sperm retrieval raises many ethical, moral, and legal issues for the patients, their families, and the clinicians. This is dealt with in greater detail later in the chapter. Perimortem sperm retrieval can be done either with the help of electroejaculation or through surgical sperm retrieval techniques. Postmortem sperm retrieval is done surgically through partial/complete orchiectomy, epididymectomy, or testicular aspiration and should be done within 36 hours of death in order to obtain viable spermatozoa.[9]

Gender reassignment procedure involves hormonal and surgical interventions. Hormone therapy causes decreased spermatogenesis and surgical intervention involves orchiectomy. Thus, cryopreservation of the spermatozoa should be contemplated if the patient wishes to father a genetic offspring in the future with the help of ART.[9]

One of the most upcoming indications for fertility preservation is for social reasons. There is now increasing evidence that advancing age of males is associated with increased risk of heritable disease-causing mutations in the offspring. Paternal age of >40 years is associated with declining sperm quality, increased risk of pregnancy complications, birth defects, childhood cancers, autism, and some psychiatric disorders.[9]

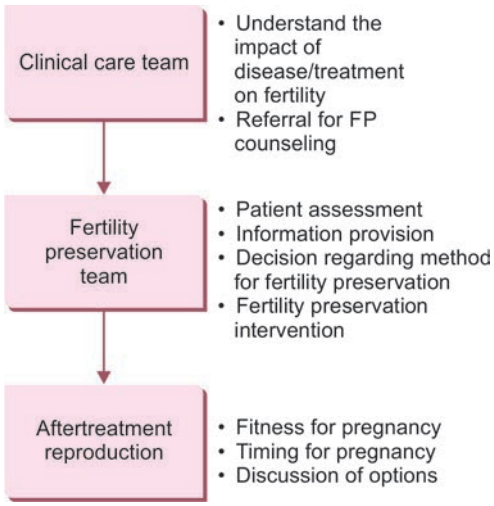
Table 1 describes the risk of developing infertility after anticancer treatment.[5]

TABLE 1: Risk of developing infertility after anticancer treatment.

Degree of risk	*Type of anticancer treatment in women*	*Type of anticancer treatment in men*
High risk (>80% risk of permanent amenorrhea in women; prolonged azoospermia in men)	• HSC transplantation with cyclophosphamide/TBI or cyclophosphamide/busulfan • External beam radiation to a field that includes the ovaries • CMF, CEF, CAF, TAC × 6 cycles in women ≥40 years	• Radiation >2.5 Gy to testis • Chlorambucil (1.4 g/m^2) • Cyclophosphamide (19 g/m^2) • Procarbazine (4 g/m^2) • Melphalan (140 mg/m^2) • Cisplatin (500 mg/m^2) • BCNU (1 g/m^2) and CCNU (500 mg/m^2)
Intermediate risk (40–60% risk of permanent amenorrhea in women; likelihood of azoospermia in men, especially when given with other sterilizing agents)	• BEACOPP • CMF, CEF, CAF, TAC × 6 cycles in women aged 30–39 years • AC × 4 cycles in women ≥40 years • AC or EC × 4 → taxanes	• Busulfan (600 mg/kg) • Ifosfamide (42 g/m^2) • BCNU (300 mg/m^2) • Nitrogen mustard • Actinomycin D
Low risk (<20% risk of permanent amenorrhea in women; only temporary reductions in sperm counts in men, especially when not given with other sterilizing agents)	• ABVD in women ≥32 years • CHOP × 4–6 cycles • CVP • AML therapy (anthracycline/cytarabine) • ALL therapy (multi-agent) • CMF, CEF, CAF, TAC × 6 cycles in women ≤30 years • AC × 4 cycles in women ≤40 years	• Carboplatin (2 g/m^2) • Doxorubicin (770 mg/m^2) • Thiotepa (400 mg/m^2) • Cytosine arabinoside (1 g/m^2) • Vinblastine (50 g/m^2) • Vincristine (8 g/m^2)
Unknown risk (risk of permanent amenorrhea in women; effect on sperm production in men)	• Monoclonal antibodies (trastuzumab, bevacizumab, cetuximab) • Tyrosine kinase inhibitors (erlotinib, imatinib)	• Oxaliplatin • Irinotecan • Monoclonal antibodies (trastuzumab, bevacizumab, cetuximab) • Tyrosine kinase inhibitors (erlotinib, imatinib) • Taxanes

(ABVD: adriamycin, bleomycin sulfate, vinblastine sulfate, and dacarbazine; AC: doxorubicin, cyclophosphamide; ALL: acute lymphocytic leukemia; AML: acute myeloid leukemia; BCNU: carmustine; BEACOPP: bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone; CAF: cyclophosphamide, adriamycin, fluorouracil; CCNU: lomustine; CEF: cyclophosphamide, epirubicin, fluorouracil; CHOP: cyclophosphamide, hydroxydaunorubicin, oncovin, prednisone; CMF: cyclophosphamide, methotrexate, fluorouracil; CVP: cyclophosphamide, vincristine, prednisone; EC: epirubicin, cyclophosphamide; HSC: hematopoietic stem cell; TAC: taxotere, adriamycin, and cyclophosphamide; TBI: total body irradiation)

Flowchart 1: Model of care for patients seeking fertility preservation.



(FP: family planning)

MODEL OF CARE FOR PATIENTS SEEKING FERTILITY PRESERVATION[8]

The model of care for patients seeking fertility preservation is shown in **Flowchart 1**.

CRITERIA FOR SELECTION OF PATIENTS WHO CAN BE OFFERED FERTILITY PRESERVATION

Fertility preservation should be offered only after careful individual assessment in terms of indication and risk assessment. A checklist for patient assessment and selection for fertility preservation is given below:[8,22]

- *Intrinsic factors:*
  - Assessment of health status of the patient
    - Surgical/anesthetic risk including thrombosis and infection
    - Malignant contamination of the gonad
  - The need to obtain fully informed consent (patient/parent)
  - Age of the patient (upper and lower limits for safety and efficacy)
  - Assessment of ovarian reserve in girls/young women
  - Assessment of pubertal stage in boys/young men (including testicular volume)
- *Extrinsic factors:*
  - Nature of predicted treatment (high/medium/low/uncertain risk)
  - Time available
  - Expertise available.

At the time of counseling, it is important to discuss with the patient about her risk of developing ovarian insufficiency after the oncologic treatment and also decide the method of fertility preservation that can be offered to her. Also, it is imperative to know the baseline ovarian reserve before any treatment modality can be offered. The parameters used to determine this are the age of the patient, the AMH levels, and the antral follicle count (AFC) in the ovaries.

The American Society of Clinical Oncology (ASCO) in 2006 proposed to stratify the patients into three categories (low, intermediate, and high) based on their risk of developing ovarian insufficiency.[23]

It is not recommended to offer fertility preservation to women with overt POI.[8]

INTERVENTIONS FOR FERTILITY PRESERVATION

All patients who are at substantial risk of posttreatment fertility loss should receive information about the fertility preservation options in a timely manner.[6,7] Because of the ever-expanding number of options for treating cancer and preserving fertility, there is now an opportunity to take a precision medicine approach by informing patients about the fertility risks associated with their cancer treatment and the options of fertility preservation available to them. It is then entirely their prerogative whether they wish to opt for it or not. Currently, sperm, egg, and embryo cryopreservation are standards of care for preserving fertility in reproductive-age cancer patients; ovarian tissue cryopreservation (OTC) is still considered experimental.[23] Adoption and surrogacy may also need to be considered in a few cases.

Flowchart 2 and Figures 3 and 4 graphically represent the fertility-preserving interventions available at present.[14]

Techniques of Fertility Preservation in Males

Sperm cryopreservation is a standard and well-accepted method of fertility preservation in postpubertal men. It should be offered prior to the start of cancer therapy as per the American Society for Reproductive Medicine (ASRM) and ASCO recommendations. There is not much to offer in fertility preservation for prepubertal boys as testicular tissue cryopreservation is still in the experimental stage and the utility of fertiprotectant agents such as gonadotropin-releasing hormone (GnRH) analogs is still not proven.

Sperm Cryopreservation

Sperm cryopreservation is the most common technique utilized for fertility preservation in pubertal and postpubertal males. Sperm banking may provide both a sense of security and reassurance of the future as both young cancer patients and their parents wish to be offered fertility preservation options.[24-26] Most often, sperm samples are collected by masturbation and cryopreserved after a period of abstinence of 2–3 days. Ideally, samples should be collected prior to initiation of cancer treatment to ensure sperm quality. Sperm collection can be challenging in adolescents and in those with ejaculatory dysfunctions. In case of azoospermia,

Flowchart 2: Summary of the available fertility preservation interventions.

sperm can be obtained by testicular sperm aspiration (TESA) or microdissection testicular sperm extraction (micro-TESE) in special cases. These sperms are cryopreserved for future use. Pregnancy rate of 33–56% has been reported in these patients. Although the exact length of time that cryopreserved sperm remains viable is unknown, successful paternity has been demonstrated with sperm stored up to 28 years.[27-29]

Testicular Tissue Cryopreservation

It is an option for prepubertal patients who have not initiated spermatogenesis, though it is still in experimental stage. Testicular tissue cell suspensions or direct testicular tissue preservation are achieved through mechanical and/or enzymatic digestion of testicular tissue followed by preservation in media, including agents such as ethylene glycerol, dimethyl sulfoxide (DMSO), and propanediol.[30-34] Again, tissue processing and cryopreservation result in decreased cell survival, with a post-thaw viability of 60%.[35,36] Till date, no study has demonstrated a technique to transform the immature, cryopreserved testicular tissue into functional gametes either in vivo or in vitro. Further, there is always a concern regarding the potential for reseeding the cancer when the cryopreserved tissue is reintroduced into the native host.[37]

Gonadal Shielding

Radiation treatment can damage the spermatogenic stem cells in the testes and cause infertility. This is unavoidable if both testes need to be radiated directly. However, when the radiation is directed at other structures in the pelvis, the testicular injury can be prevented by covering the testicles with a lead shield.

Gonadal Suppression

Infertility after exposure to radio- or chemotherapy results due to the inability of the spermatogonia to differentiate after exposure to the toxic therapy. Suppression of testosterone secretion with GnRH agonists or antagonists before or after the cytotoxic insult may help in recovery of spermatogenesis.[38]

Techniques of Fertility Preservation in Females

The choice of the optimal method for fertility preservation depends on the time available to start cancer treatment, cancer type and its treatment, age of the patient, and presence or absence of a partner. Embryo or mature oocytes cryopreservation has been accepted as established modes of fertility preservation in postpubertal women with cancer. OTC is still in experimental stage.[7,39] These options should be discussed as early as possible with the patient, ideally before starting treatment (ASRM and ASCO guidelines).[6,7]

Embryo Cryopreservation

Embryo vitrification is an established technique in ART.[6,7] It is routinely used to preserve the surplus embryos produced during an ART cycle. Unlike oocytes, the embryos are sturdy and can safely withstand the process of vitrification and thawing. They have over 90% survival rate post-thawing and 40% of them implant in the first attempt.[40] Cumulative pregnancy rate with frozen embryos is above 65% in infertility patients.[41] It requires 2 weeks for ovarian stimulation, followed by egg retrieval and cryopreservation. This can be a limitation for women with highly malignant tumors requiring immediate initiation of treatment and in prepubertal girls.

Oocytes Cryopreservation

Since 2013, oocyte cryopreservation is no longer considered an experimental procedure.[42-44] It is an ideal method for women without partners. Limitations of oocyte cryopreservation are similar to embryo cryopreservation. Additionally, being single-celled, they are more likely to be damaged during the process of vitrification and thawing. Mature [metaphase II (MII)] oocytes cryopreservation is preferred; however, even immature ones [GV/metaphase I (MI)] can be grown in lab through the process of in vitro maturation (IVM) and then frozen the next day.

- *Mature oocyte cryopreservation:* With advanced vitrification technology, pregnancy rates with mature oocytes have improved dramatically. A post-thawing survival rate of >90% and pregnancy rate of 45–50% have been reported with mature cryopreserved oocytes. Frozen oocytes yield similar pregnancy rates compared to fresh oocytes without increasing the risk of chromosomal abnormalities. So far, more than 900 children are born out of frozen oocytes with no apparent increase in congenital abnormalities.[38,45,46] It is the preferred method in postpubertal girls and in women without partners, provided enough time is available for the whole procedure of oocytes collection prior to starting cancer treatment, which takes about 2 weeks.
- *Immature oocyte cryopreservation and IVM:* IVM is a technique where immature oocytes are retrieved transvaginally from either unstimulated or minimally stimulated ovary. It takes 24–48 hours for the immature oocytes to mature in vitro once kept in a specially formulated medium.[47] Results are better if priming with human chorionic gonadotropin (hCG) is done prior to retrieval. Mature oocytes are then cryopreserved and if partner sperms are available, then embryos are first formed and then cryopreserved. This technique is important for a woman who needs to start anticancer treatment immediately or who has a hormone-sensitive tumor. So far, over 2,000 healthy infants have been born with this technique.[6,48,49]

The ovarian stimulation protocols which can be used for embryo/oocytes cryopreservation are:

- *Random-start controlled ovarian stimulation (COS)*: Random-start COS protocols have been specially developed for patients who are keen on fertility preservation. In this protocol, ovarian stimulation can be started irrespective of the phase of the cycle.[50-53] It is based on the concept that there are multiple waves of follicle recruitment within a single menstrual cycle.[54,55] Also, one need not bother about the synchronization of ovarian stimulation with endometrial development as no transfer will take place.
- *Role of tamoxifen aromatase inhibitors in patients with hormone-sensitive cancer/nonmalignant disease:* COS involves use of drugs which increase the serum estrogen levels. There is thus an apprehension that these drugs may activate hormone-sensitive diseases. It is thus suggested to use aromatase inhibitors such as letrozole, which causes multiple egg formation without much increase in serum estradiol (E2) levels.[56] For women who have hormone-sensitive cancers such as breast cancer, 5 mg of letrozole has been suggested from the second to third day of the cycle, followed by initiation of gonadotropins.[57] To start ovarian stimulation, initially GnRH antagonist is started at any point in the cycle

and once plasma E2 is below 50 pg/mL, oral letrozole administration at a dose of 5 mg/day is started from the second or third day of the cycle and then continued until the day of hCG administration. After 2 days of letrozole administration, 150 U of gonadotropins are added. A GnRH antagonist is administered when a follicle reaches 14–15 mm or the E2 level exceeds 250 pg/mL and hCG trigger is given when the lead follicles are 20 mm. Letrozole administration is however continued until the appearance of menses. Various studies have suggested no increase in risk of birth defects in babies post-letrozole intake in mothers.[58] Also, prospective data regarding the risk of breast cancer recurrence in patients undergoing COS with the letrozole protocol are reassuring when compared to the risk of recurrence in women with breast cancer who did not undergo COS.[59]

Figures 5A to E diagrammatically describe the stimulation protocols which can be used in women undergoing ovarian stimulation for fertility preservation.[60]

Ovarian Tissue Cryopreservation

It is a suggested method for patients where ovarian stimulation cannot be performed, mostly in prepubertal girls and in cases where anticancer treatment cannot be delayed. However, this procedure is invasive and requires general anesthesia and surgical removal of ovarian tissue. In addition, it needs medical expertise, which may not be available easily. As ovarian reserve declines with age, it should not be offered to women above 39 years of age (Oncofertility Consortium).[61,62] As per the ESHRE Guidelines on Female Fertility Preservation (2020), OTC can be offered under the following conditions:[8]

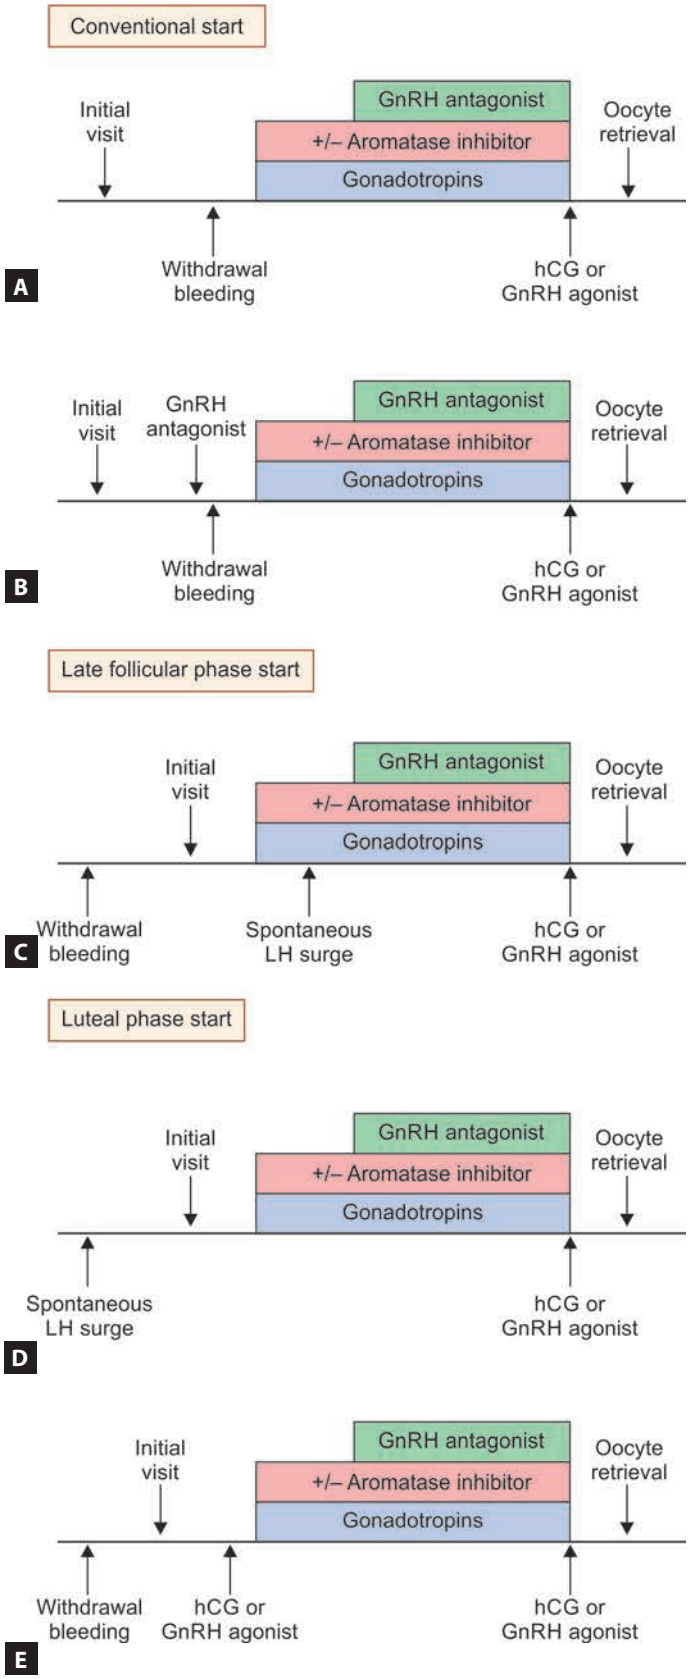
- In patients undergoing gonadotoxic treatment where oocyte/embryo cryopreservation is not feasible or if the patient so prefers.
- In patients with POI-associated genetic and chromosomal disorders

Ovarian tissue cryopreservation may also be considered in prepubertal girls.

However, OTC should not be offered to patients with low ovarian reserve (AMH <0.5 ng/mL and AFC <5) or advanced age (>36 years).[8]

Ovary can be cryopreserved as a whole or just the cortical tissue which contains follicles. The method of choice for OTC is slow freezing and not vitrification. Cryopreserved ovarian tissue can be used in two ways: (1) Thawed ovarian tissue can be transplanted back into the cancer survivor or (2) IVM can be performed on the follicles obtained from thawed ovarian tissue.

The replacement of the cryopreserved ovarian tissue is called ovarian tissue transplantation (OTT), which can be either at orthotopic (site of ovarian fossa) or at heterotopic (site other than ovarian fossa). Of the two, OTT at the orthotopic site is recommended to restore fertility.



Figs. 5A to E: Controlled ovarian stimulation (COS) protocols for women undergoing fertility preservation.[9] (GnRH: gonadotropin-releasing hormone; hCG: human chorionic gonadotropin; LH: luteinizing hormone)

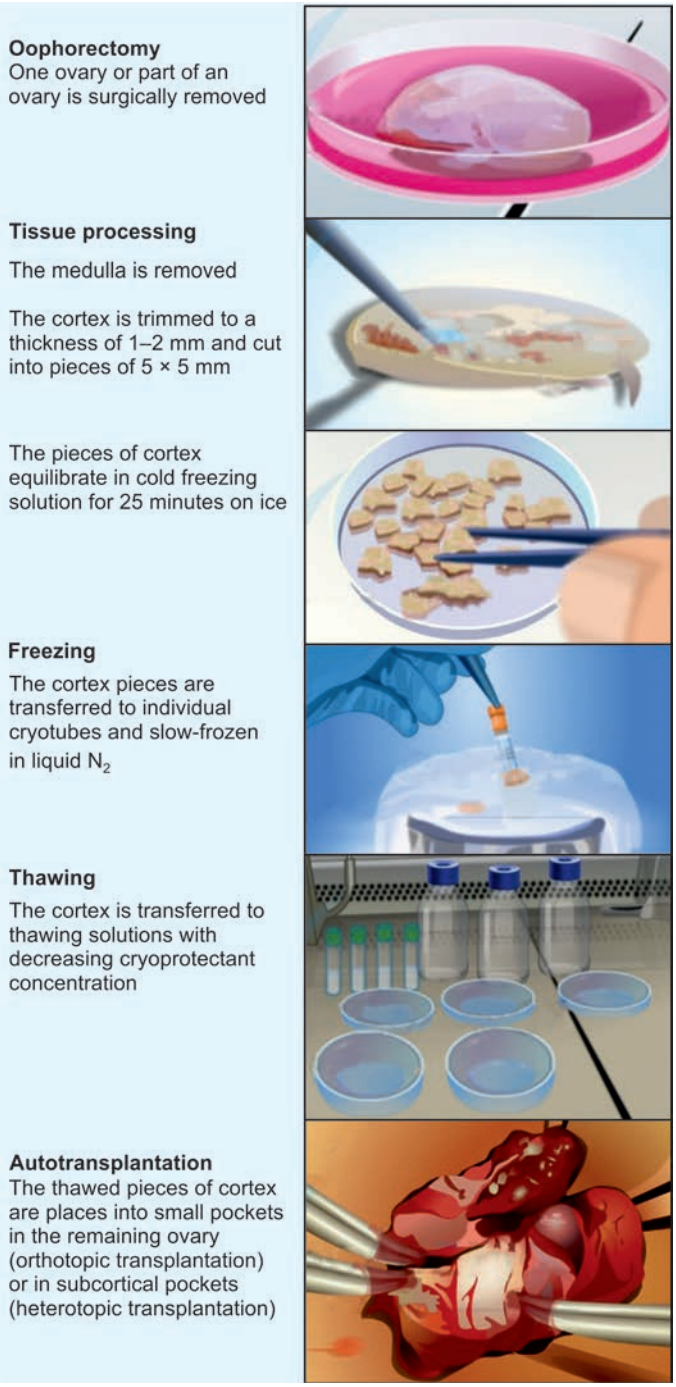


Fig. 6: Process of ovarian tissue cryopreservation.

Figure 6 describes the process of OTC.[63]

Most of the time, >50% of follicles are lost due to cryo-induced injury and ischemic damage.[64] Till date, 60 live births have been reported from either natural conception or with in vitro fertilization (IVF) after reimplantation of cryopreserved ovarian tissue.[65] It takes 4–6 months for this tissue to become functional.[66] Following transplantation, ovarian function continues for approximately 5 years.[65,67] It is imperative that before cryopreservation and transplantation of ovarian tissue, it should be checked for malignancy. Whole ovary cryopreservation with its blood vessels and stromal structure is still in experimental stage and needs further studies before it is applied in clinical practice.

Hormonal Suppression

Anticancer treatment kills fast dividing cells of the body, including germ cells. Based on this concept, GnRH agonists have been used during chemotherapy as a way to reduce the toxic effects of cancer treatment on growing ovarian follicles and their enclosed oocytes. It reduces ovarian activity by blocking the hypothalamic–pituitary–gonadal axis. It takes at least 10 days for its effect to come and should be continued 2 weeks post-chemotherapy.[68] Nevertheless, recent studies have demonstrated protective effects of GnRH agonists with a highly significant reduction in amenorrhea and ovarian insufficiency.[69,70]

This can be offered to premenopausal women with breast cancer who are receiving chemotherapy. However, there is not much evidence available regarding its protective effect on the ovarian reserve.[8]

It may also be offered in premenopausal women with autoimmune diseases receiving cyclophosphamide. However, limited evidence is available regarding usefulness of this approach.[8]

Transposition of Ovaries

In this technique, ovaries are moved out of the field of pelvic irradiation, also known as oophoropexy.[71] However, although the ovaries are out of direct irradiation field, the scatter dose may cause significant ovarian damage.[72] Ovarian transposition may be offered to women who are going to undergo radiotherapy without chemotherapy. However, it should not be offered to women who are at risk of having ovarian metastasis or have a low ovarian reserve.[8]

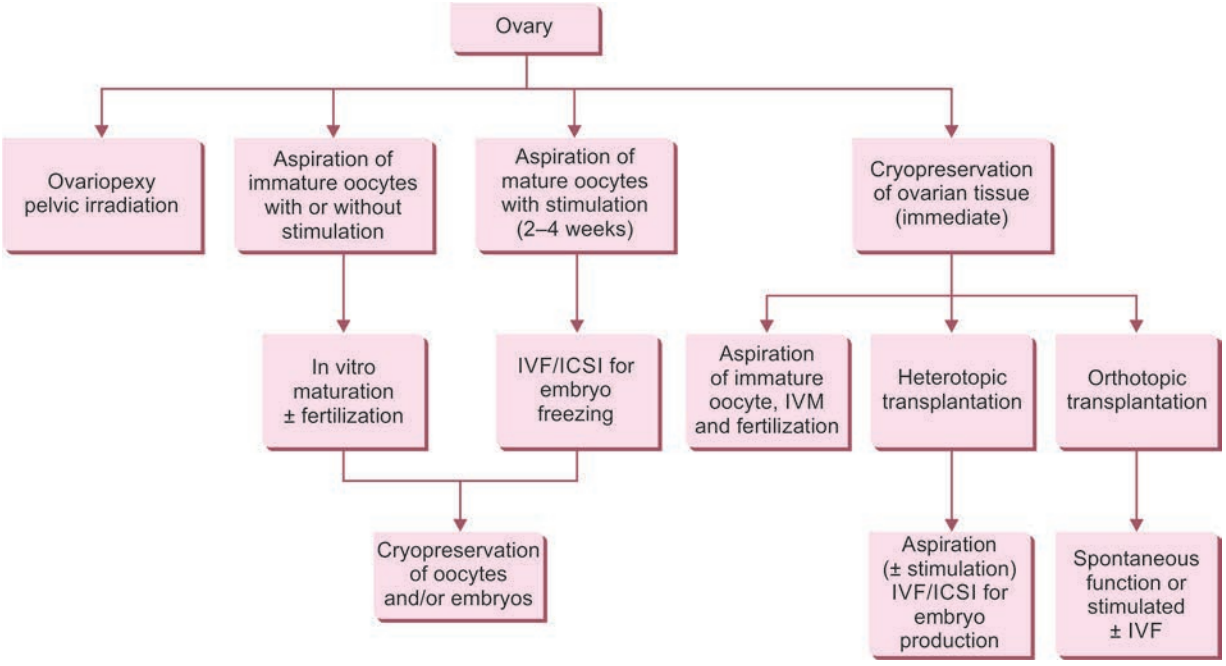
Flowchart 3 summarizes the various options available for fertility preservation in women.[63]

EMERGING TECHNOLOGIES

Ovarian Follicle Culture In Vitro

In patients with highly malignant cancer such as acute lymphoblastic leukemia or acute myeloblastic leukemia (AML), where treatment cannot be delayed, in them, OTC appears to be the only option for fertility preservation. However, this ovarian tissue might contain malignant tumor cells,[73] which could be reintroduced into patients when the tissue is transplanted.[74,75] Cancer recurrence after transplantation of cryopreserved ovarian tissue has been reported in some studies.[76] To mitigate the risks of reintroducing cancer cells with transplanted ovarian tissue, methods to isolate and culture individual follicles from banked tissue are practical approaches. The aim of this method is to develop oocytes from in vitro culture of follicles and later produce viable embryos for transfer to the uterus.

Flowchart 3: Options for fertility preservation in women.



(ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization; IVM: in vitro maturation)

A lot of work has been going on in animals on this technology; however, it still remains experimental in humans.[77,78]

Ovarian Follicle Transplantation (Artificial Ovary)

Researchers have been working hard to develop an artificial ovary comprising cryopreserved ovarian tissue along with other ovarian cells, which are assembled on a 3D matrix scaffold. The artificial ovary comprises a biodegradable scaffold made of substances such as alginate hydrogel, which maintains the interaction between the oocyte and the granulosa cells during the time revascularization occurs at the transplanted site. This helps in creating an optimal microenvironment for the growth and survival of follicles and ovarian cells and also reduces the risk of transmission of malignant cells.

The artificial ovary would potentially restore both fertility and endocrine function once transplanted into the patient.[79-82] Animal studies have shown production of ovarian follicle, sex hormones (estrogen and progesterone),[83] and development of vascularization in these ovarian grafts. However, further robust trials are needed before it comes into clinical practice.

Oogonial Stem Cells

Oogonial stem cells (OSCs) are an option for cancer patients when no healthy follicles are retrieved from the ovarian tissue. Then, other sources of cells carrying the patient's genetic material are considered, including OSCs, embryonic stem (ES) cells, or induced pluripotent stem (iPS) cells.[84] Recently, a study reported successful production of oocytes from ES cells, also in mice.[85] These findings provide proof-of-concept support for future methods that may be able to produce new oocytes for cancer patients who have lost all of their oocytes as a result of chemo- or radiation therapy. These methods might also have applications in the treatment of premature ovarian failure (POF).

In Vitro Activation of Ovarian Follicles

Ovarian tissues collected from prepubertal cancer patients contain immature primordial follicles that must be activated in order to enter the growing pool and produce mature oocytes that can be fertilized. The same is true for ovarian tissues from patients with primary ovarian insufficiency who have a reduced ovarian reserve.[86] Researchers have been successful in inducing primordial follicle activation using ovarian fragmentation, drilling, and laser techniques.[87] These approaches disrupt the ovarian Hippo signaling pathway and promote actin polymerization in somatic and granulosa cells, which activates the growth of primordial follicles in the ovarian reserve.[88] This work supports the hypothesis that primordial ovarian follicles are held by surrounding cells in a state of restricted growth and that local Hippo signaling regulates the location of growing follicles and interfollicle communication.[82] Once activated, the follicles are treated with Akt stimulators, PI3K activators, and PTEN inhibitors before being used in autotransplantation.[89,90] This approach has resulted in a successful live birth.

Figure 7 summarizes the potential applications of the whole ovary and cortex fragments cryopreserved for fertility preservation in women.[91]

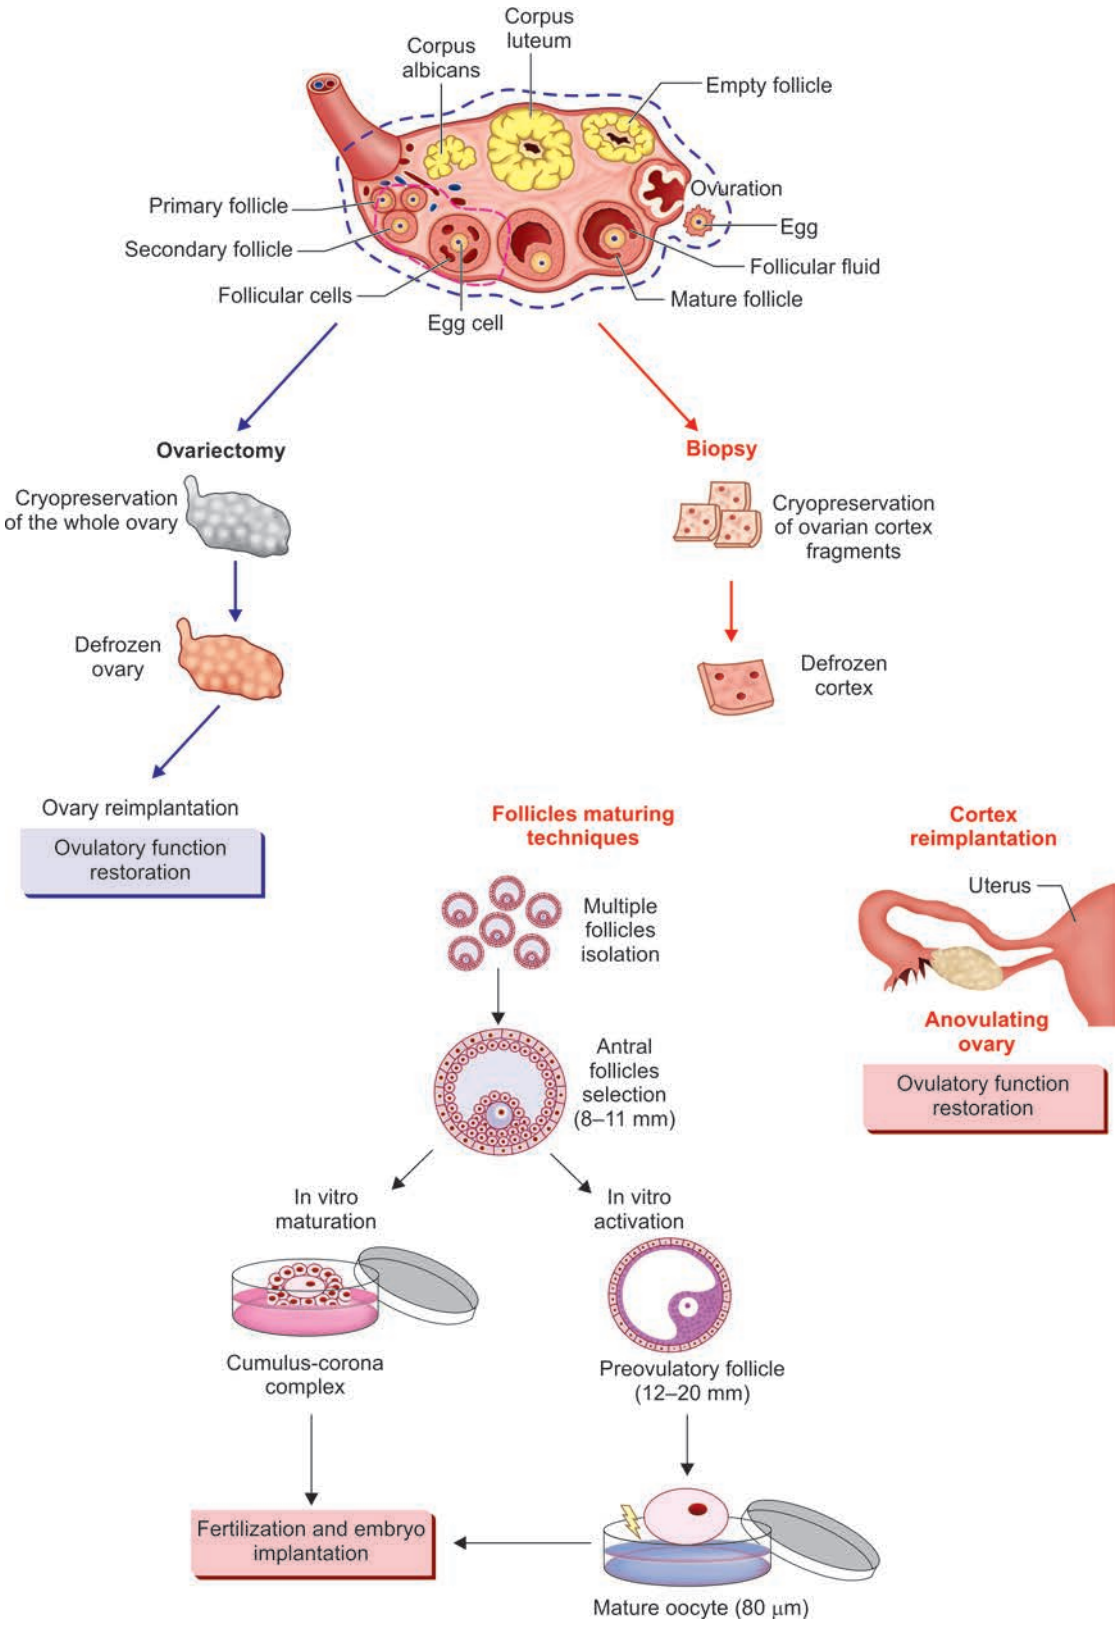


Fig. 7: Potential techniques for fertility preservation in women.[91]

Administration of Drugs for Specific Target Tissues

Use of Nanoparticles

A chemotherapeutic agent encapsulated inside nanoparticles has the specialty to reach target cancer cells without causing any systemic side effects. A lot of research is going on in animals to confirm its efficacy.[92,93]

Use of Fertiprotective Reagents

Fertiprotective reagents are drugs which not only kill cancer cells but also at the same time protect oocytes against

TABLE 2: Comparison of various fertility preservation methods in women.

FP method	*Ideal patient*	*Success rate*	*Advantages*	*Disadvantages*
Oocyte cryopreservation	Postpubertal women without a male partner or who do not wish to use donor sperm	Pregnancy rate per cycle of 50.2% or per embryo transfer 55.4%	• Well-established method • Can be offered to single women also • No risk of reimplanting malignant cells	• Time is required for ovarian stimulation • Can be done in postpubertal women only
Embryo cryopreservation	• Has a male partner or is willing to use a donor • Has time for ovarian stimulation before start of treatment	Cumulative pregnancy rate of 66% among women with cancer	• Well-established method • No risk of reimplanting malignant cells	• Can be offered to postpubertal women who have a male partner • Time is required for ovarian stimulation
Ovarian tissue cryopreservation	Prepubertal girls or young women who do not have time for ovarian stimulation to retrieve eggs	Pregnancy rate of 25% among women with cancer	• Can be offered to prepubertal girls also • Can be done at any time and thus does not delay start of oncologic treatment	• Age limitation can be done only at the age of <35 years • Involves laparoscopic surgery for procurement and transplantation of ovarian tissue • Risk of retransmission of malignancy
Fertility sparing surgery	Women with certain early-stage gynecological malignancies	• Cumulative conception rate after trachelectomy 53% • Pregnancy rate after progestin therapy for endometrial cancer 34.8%	Ovaries and/or uterus are preserved	
Hormone suppression			• May have some medical benefits not invasive • Does not need delaying in oncologic therapy • Can be used in association with cryopreservation techniques • Reduce the risk of hypermenorrhea associated with hematologic malignancies or myelosuppressive treatments • Low cost	• Uncertain efficacy for fertility preservation • Symptoms of estrogenic deprivation • Transient alterations of bone metabolism not significant for therapy duration <6 months • Limited clinical evidences in patients with disease other than breast cancer

(FP: family planning)

chemoradiation. Tamoxifen, granulocyte colony-stimulating factor (G-CSF), imatinib, AS101, sphingosine-1-phosphate, and triiodothyronine (T3) are various fertiprotective reagents which are under research. They all protect oocytes by blocking/altering apoptotic pathways involved in follicular growth.[94-97]

Wallace et al., Angarita et al., and Brancati et al. in their articles discussed about the various methods available for fertility preservation and their pros and cons. These are summarized in **Table 2**.[22,98,99]

POSTHUMOUS REPRODUCTION

What is Posthumous Reproduction?

Posthumous reproduction refers to the retrieval of gametes and reproductive tissue after a person's death or after they have become incapacitated and their death is imminent. It also deals with the storage and the use of these gametes and reproductive tissue after the person's death. It refers to a situation where the person will be deceased at the time their gametes are used and any resulting child is born.

The Opinion of the Ethics Committee of the American Society for Reproductive Medicine on the posthumous retrieval and use of embryos (2018):[100]

- Posthumous retrieval and use of gametes or embryos for reproductive purposes is ethically justifiable if written documentation from the deceased authorizing the procedure is available.
- In the absence of written documentation, centers may consider requests for posthumous reproduction only if such requests are initiated by the surviving partner.

- Adequate time for grieving and counseling is imperative before initiating the process of posthumous reproduction.

The psychological, ethical, and legal considerations in posthumous reproduction:

- The deceased will not be present to rear the child born through posthumous reproduction. The well-being of any children resulting from posthumous reproduction needs to be considered.
- To consider the choice or interests of the surviving partner regarding the use of the deceased's gametes/embryos or the choices of others who cared about the deceased such as surviving partner. However, their interests need to be weighed against the interests of the deceased.
- Can tissue be taken from a person who has not consented to its retrieval?
- If tissue is retrieved, who holds responsibility for its storage and use?
- If a child is conceived with a deceased person's gamete, what are that child's inheritance rights?
- The impact of posthumous reproduction on the deceased's wider family, including any existing children/siblings.

The only guideline available in India regarding posthumous reproduction is "The Assisted Reproductive Technologies (Regulation) Rules - 2010" drafted by the Indian Council of Medical Research (ICMR), New Delhi. Section 3.16.5 of "Guidelines for ART Clinics in India" allows insemination of the women with husband's semen after death of the husband. However, it states that sperm must have been collected while the husband was alive and who may or may not be under imminent death but was in sound mind. Consent is therefore taken at the time of cryopreservation from the male/female partner in case of sperm or oocyte freezing and from both partners in case of a couple regarding the fate of the cryopreserved gametes/embryos in case of their death. However, there are no guidelines for postmortem retrieval of sperm from the deceased husband.[101]

As per the ART Regulation Bill 2020, "prior consent" of the commissioning couple is needed before posthumous collection of gametes can take place. However, in situations of sudden death where no prior gamete retrieval has been performed by clinics or banks and there is no written consent for posthumous reproduction, inferred consent may be ascertained from the surviving partner of the deceased to determine if the deceased had discussed a wish for posthumous gamete retrieval and would have approved of such a procedure. While a child born to a woman artificially inseminated with the stored sperm of her dead husband is considered as the legitimate child of the couple, the legal status of the child born through the process of postmortem sperm retrieval (PMSR) still needs to be defined.

The New York hospital guidelines, also known as the Cornell guidelines, are the only wholesome guidelines available related to PMSR and may be referred to in the Indian scenario. Some important considerations addressed in these guidelines are as follows:[94]

- In the absence of the deceased's consent, only the consent of the wife matters as the next of kin because she is the woman with whom the deceased had intended to have children.
- Sperm retrieval and its cryopreservation should be done within 24 hours.
- There should be a gap of at least 1 year before the use of retrieved sperm by the wife. This time period will help the wife to go through the period of bereavement and not take any emotional decisions.
- Psychological counseling of the wife must be done so that she can understand the procedure, success rate, potential benefits, limitations, and risks of such procedures. She should also be counseled about rearing a child single-handedly and about the legal status of the child.

Posthumous reproduction is banned in Canada, France, Germany, and Sweden.[102-104] The ethical committee of ASRM suggests that posthumous use of stored sample is justifiable provided written consent from the deceased authorizing the procedure is available.[105] In the absence of written documentation, such requests should only be entertained if it comes from the surviving spouse. It is very important to allow adequate time for grieving and counseling prior to the posthumous use of gametes or embryos for reproduction. The ESHRE Task Force on ethics and law on posthumous reproduction recommends a waiting period of 1 year before any such procedure is initiated.[97]

Social Egg Freezing

In 2013, the ASRM declared that oocyte cryopreservation was no longer an experimental procedure and could be used as an option for fertility preservation.[106]

Argyle et al. in 2016 conducted a study to compare the results from fresh versus frozen oocytes. They found that IVF pregnancy rates with frozen oocytes are similar to those with fresh oocytes.[107]

The term "social freezing" is used when eggs are frozen for nonmedical causes and used later in life. It is also referred to as "anticipated gamete exhaustion (AGE) banking" (oocyte banking for AGE) as it involves cryopreservation of oocytes to protect the woman against age-related fertility decline and ineffective fertility treatments at older ages.[108] It also enhances a woman's reproductive autonomy and allows them to feel more socially, psychologically, and financially stable before motherhood. Oocyte cryopreservation allows a woman to conceive with children who are biologically related to her at a later age.

The most common reasons for opting for egg freezing include:

- Delay in marriage due to absence of a partner suitable for creating a family
- Professional reasons where the woman feels that delay in childbearing is required in order to complete her education, for her career advancement, or due to inflexibility at her workplace.

The Australasian Certificate of Reproductive Endocrinology and Infertility (CREI) constituted an expert panel to evaluate the best practices for oocyte cryopreservation to guide clinicians who are working with women who are considering oocyte cryopreservation for fertility preservation.[109]

Their recommendations are referred to as the ACCEPT (Australasian Certification in Reproductive Endocrinology and Infertility Consensus Expert Panel on Trial evidence) consensus and are summarized in **Table 3**.

Varlas et al. in 2021 published a review article on social egg freezing.[108] The main findings of their review are highlighted below:

- Oocyte cryopreservation is an elective method for fertility preservation for age-related infertility and involves ovarian hormonal stimulation, oocyte retrieval, freezing, and oocyte storage.
- Ovarian stimulation protocols can be initiated at any moment in the menstrual cycle and the protocols which can be used are random start or DuoStim.
- Ovarian stimulation does not raise the embryo aneuploidy rate.
- Vitrification is the technique of choice for oocyte cryopreservation. It is associated with a 90–97% survival rate, 71–79% fertilization rate, 17–41% implantation rate, and 4.5–12% clinical pregnancy rate per vitrified oocyte.
- Women's age at the time of storage and the number of mature oocytes retrieved are predictors for future live births. The optimal timing for a woman to freeze her eggs is under 35 years. Mesen et al. found maximum benefits when cryopreservation is performed between 32 and 37 years, with little benefit at ages of 25–30 years.[110]
- The number of oocytes retrieved depends upon the patient's age, clinical profile, and the ovarian reserve. A woman can attempt a maximum of four oocyte retrieval cycles. A total of 15–20 oocytes retrieved will ensure a balance between the procedure's safety and efficacy with individualized stimulation protocols. Goldman et al. proposed a mathematical model to predict the probability of live birth rate based on the number of cryopreserved oocytes and the woman's age at the moment of cryostorage and said that 10, 20, and 61 eggs are required to obtain a 75% cumulative live birth rate (CLBR), for women at ages 34 years, 37 years or 42 years respectively.[111]
- Artificial intelligence (AI) has been introduced recently to assess the quality of embryos and oocytes in order to

TABLE 3: ANZSREI ACCEPT consensus statement on elective oocyte cryopreservation.

Recommendation	*Level of evidence*
Vitrification is currently the most effective method for mature (MII) oocyte cryopreservation	Level 1A
Women should be made aware that not all oocytes will survive warming	Level 1A
To minimize the risk of OHSS, the recommended stimulation strategy is an FSH/GnRH antagonist regimen with planned GnRH agonist trigger	Level 4
Ovarian reserve testing should be offered to women prior to oocyte cryopreservation and counseling provided regarding expected oocyte yield per stimulated cycle	Level 4
Women should be informed that microinjection of sperm is required to fertilize warmed oocytes	Level 4
Women should be aware that warmed oocytes may create fewer blastocysts compared with fresh oocytes	Level 1B
The best age to freeze oocytes is before the age of 35 years. Women over 35 years achieve poorer pregnancy outcomes from vitrified oocytes related to oocyte quality deterioration with advancing maternal age	Level 4
Women should be informed that there is a chance that they may not need to use their frozen oocytes and oocyte cryopreservation does not guarantee future live birth	Level 3
Safety outcomes for births from vitrified oocytes are to date reassuring with no evidence of increased risk compared with IVF births. Safety data remain preliminary. Long-term follow-up studies for all cryopreservation techniques remain essential	Level 3
Women should be counseled at the time of cryopreservation of oocytes that if they achieve pregnancy at an advanced maternal age, they will be at increased risk of perinatal and obstetric complications	Level 3
The probability of live birth is mainly dependent on the number of mature oocytes and the age of the woman at the time of storage	Level 2A

(ACCEPT: Australasian Certification in Reproductive Endocrinology and Infertility Consensus Expert Panel on Trial evidence; ANZSREI: Australian and New Zealand Society for Reproductive Endocrinology and Infertility; FSH: follicle-stimulating hormone; GnRH: gonadotropin-releasing hormone; IVF: in vitro fertilization; MII: metaphase II; OHSS: ovarian hyperstimulation syndrome)

create a highly predictable model for ART. Cavalera et al. used AI to differentiate between competent and incompetent oocytes with an accuracy of 91.03%.[112] Yanez et al. reported that a lack of embryonic viability is associated with certain gene expression transcriptomes of oocyte maturation.[113]

- Neonatal outcomes and risk of genetic diseases and congenital anomalies are the same when using vitrified oocytes as compared to natural conception or following IVF treatment with fresh oocytes. Also, prolonged cryopreservation in liquid nitrogen does not affect the euploidy rate or IVF success.

Counseling, both at the beginning and at the end of the cycle, has to be done to ensure that the women who have undergone oocyte cryopreservation for fertility preservation should not have a false sense of security regarding their fertility potential later in life. It is also important to spread awareness regarding the availability of this fertility-preserving technique. It is also important for women to understand that the success of oocyte cryopreservation resulting in live birth is strongly dependent on the age of the woman at the time of egg freezing. In a survey conducted by Anderson et al., it was observed that most women opted for oocyte freezing at age above 35 years, where the success rates are limited.[106]

RECOMMENDATIONS FOR FERTILITY PRESERVATION

Although continuous work has been going on in the field of fertility preservation, there are still several controversial issues which need to be addressed. As recommended by the ASCO and the European Society for Medical Oncology (ESMO), sperm cryopreservation and embryo/oocyte cryopreservation are standard strategies for fertility preservation in male and female patients, respectively. Other strategies (e.g., pharmacological protection of the gonads and gonadal tissue cryopreservation) are still generally considered experimental techniques. However, still there are several unanswered controversial questions regarding safety and efficacy of fertility preservation in cancer survivors.

International recommendations for fertility preservation according to the ASCO and ESMO Clinical Practice Guidelines for Fertility Preservation in cancer patients are as follows:[5,7,16,114]

- Ovarian stimulating drugs with standard treatment protocols may be administered in subfertile/infertile women without increasing the risk of developing breast cancer (III, B). The long-term use of clomiphene outside the current limited indications [i.e., first-line therapy of World Health Organization (WHO) group II anovulatory infertility] should be discouraged because of a possible increase in breast cancer risk (III, B).
- Pregnancy in cancer survivors, after adequate treatment and follow-up, should not be discouraged, including among patients with endocrine-sensitive breast cancer (III, A).
- All patients with potential interest in keeping their fertility should be referred to a fertility unit for adequate determination of risk of infertility, chances of future conception, and how to proactively preserve it (V, A). However, some cancer patients will not require the help of a fertility clinic after cancer treatment (V, B). Since several patient- and treatment-related factors are associated with the risk of developing infertility, the oncofertility counseling should be tailored to the individual patient (V, A).
- In men, sperm cryopreservation is an easily accessible and widely available option in >95% of patients and should be encouraged for those who want to preserve fertility (III, A). On the contrary, from 2 to 65% of women undergo one of the available cryopreservation options: Oncologists should discuss with them the fertility issues and secure proper counseling in appropriate centers prior to cancer treatment (IV, A).
- Paucity of data is available on fatherhood after cancer. Although most of the published data are reassuring, some recent conflicting results suggest a potential increased risk of birth defects, particularly among the children born closer to a paternal cancer diagnosis, and caution should be taken in counseling these patients (V, B for discussion with patients); data on children conceived after ART are too scarce to draw any conclusion although in the general population, available evidence for the outcomes of progeny after ART suggests safety of the techniques themselves (V, B for discussion with patients).
- The current limited data suggest the safety of a COS in cancer patients (III, B). "Random start protocols" can be employed to avoid delays in anticancer treatment initiation (III, B). GnRH agonist ovulation triggering should be adopted in patients at moderate–high risk for ovarian hyperstimulation syndrome (OHSS) (I, A). Letrozole (or tamoxifen) should be incorporated in the protocol for COS in cancer patients with hormone-responsive tumors (III, B).
- Embryo and oocyte cryopreservation are standard options for fertility preservation (III, B). Vitrification showed a better performance than slow freezing (II, B). During oncofertility counseling, patients should be aware that data on the success of these strategies derive from infertile women in general and that a different ovarian response to stimulation might be expected in cancer patients (IV, B).
- The best candidates for OTC are prepubertal girls (III, A). The technique may also be proposed to patients scheduled for treatments with a high risk of POI who cannot delay anticancer treatments or who have already received chemotherapy or with contraindications to

COS (III, B). Patients with cancer with a high risk of malignant contamination to the ovaries (e.g., aggressive hematologic malignancies) should not be considered eligible for ovarian tissue autotransplantation (V, B).

- In order to optimize the procedure in terms of both patient management and cost-effectiveness, the harvesting of the tissue can be performed locally but subsequent sample freezing and storage should be centralized (III, B). A well-organized network between fertility units is required (III, B).
- Ovarian suppression with the use of GnRH agonist during chemotherapy should be considered a reliable strategy to preserve ovarian function and fertility, at least in breast cancer patients, given the availability of new data suggesting that both the safety and the efficacy of the procedure have become available (I, A).

The recommendations for fertility preservation as given by the Fertility Preservation Society (India) are given below:[115]

- *Recommendations for family planning (FP) in prepubertal children:*
  - Parents of children and adolescents should be informed about the risk to fertility with cancer treatment. Adolescents need to be counseled individually and with parents (II, A).
  - For prepubertal children, the only fertility-preservation options are ovarian and testicular cryopreservation. Testicular tissue freezing is still investigational, but OTC is no longer experimental (III, B).
  - In postpubertal children, established methods of fertility preservation such as semen or oocyte cryopreservation should be offered (III, B).
- *Should ovarian reserve testing be done routinely prior to initiation of computed tomography (CT)?*
  - Ovarian reserve should be assessed before cancer therapy by estimating AMH and AFC (III, A).
  - AMH levels should be done before and 1 year after gonadotoxic therapy as they predict recovery of ovarian function (III, A).
  - Pretreatment AMH levels should not be used as an indicator of posttreatment fertility (IV, D).
  - When estimating the risk of posttreatment ovarian insufficiency, age, proposed gonadotoxic treatment type and dose, and pretreatment AMH levels should be taken into consideration (IV, B)
- *Fertility preservation in the male:*
  - Sperm cryopreservation is effective and sperm banking should be advised to postpubertal males receiving cancer treatment (II, A).
  - Testicular tissue cryopreservation and reimplantation is still experimental but is the only option in prepubertal boys for fertility preservation and should be considered as a part of clinical trials.
  - Hormonal therapy in men is not successful in preserving fertility. It is not recommended (I, C).
  - All male patients should be informed about the potentially higher risk of genetic damage in sperm collected after initiation of chemotherapy (II, B).
- *What is the role of fertility-sparing surgeries in the men?*
  - Partial orchiectomy should be done in selected patients when the testicular mass is small.
  - Sperm banking prior to surgery, even in patients undergoing partial orchiectomy, is advisable (III B).
  - In men with azoospermia undergoing orchidectomy, sperms can be extracted from the epididymis and vas deferens of the orchiectomy specimen or contralateral noncancerous testis.
- *Fertility preservation in the females:*
  - Embryo and oocyte vitrification are established methods of cryopreservation (II, A).
  - OTC in prepubertal, postpubertal girls, and women. OTC is considered as an established technique now (II, B).
  - Patients with high risk of secondaries in ovaries should not be considered eligible for ovarian tissue autotransplantation (IV, B).
- *Effect of COS on cancer prognosis:*
  - For ovarian stimulation in women seeking fertility preservation for medical reasons, the GnRH antagonist protocol is recommended for its feasibility in urgent situations, short time, and safety reasons (IV, A).
  - Random-start protocols can be employed to avoid delays in anticancer treatment initiation (II, C).
  - Double stimulation can be considered if time is available so that more number of oocytes/embryos can be cryopreserved (II, D).
  - GnRH agonist ovulation triggering should be adopted in patients to prevent OHSS (I, A).
  - Letrozole or tamoxifen should be incorporated in the protocol for COS in cancer patients with hormone-responsive tumors.
  - Where pelvic radiotherapy is planned, women may be offered ovarian transposition with the aim to protect the ovaries from radiation to prevent POI (IV, C).
  - Women with decreased ovarian reserve and women at risk of having ovarian metastases should not be offered ovarian transposition.
- *After treatment and pregnancy in cancer patients:*
  - Before the use of stored material, fitness for pregnancy should be evaluated, taking into consideration the late effects of treatment, age of the patient, and the interval since the last gonadotoxic treatment (IV, B).
  - Preconception counseling and appropriate obstetric monitoring in consultation with oncologist and physician are recommended in women intending

to become pregnant after gonadotoxic treatments (II, A).
    - A minimum interval of at least 1 year is suggested before attempting pregnancy following chemotherapy completion in order to reduce the risk of pregnancy complications (IV, A).
- *Fatherhood after cancer:*
    - Fatherhood after cancer treatment is safe (IV, B).

CONCLUSION

Fertility preservation is gaining importance as to complete management of cancer in young survivors. It requires a multidisciplinary approach involving oncologists, oncosurgeons, infertility specialists, and embryologists. Infertility specialists/oncologists must discuss regarding potential gonadotoxicity caused by cancer treatment and options available to preserve the same. Ideally, fertility preservation should be done prior to initiating cancer treatment. Sperm cryopreservation in men and embryo/oocyte cryopreservation in women are the established methods of fertility preservation. In prepubertal girls, OTC can be offered. In prepubertal boys, testicular tissue can be cryopreserved, but strategies for transplantation need to be established. Instructions should be specified about the disposition of stored gametes, embryos, or gonadal tissue in the event of the patient's death, unavailability, or any other contingency.

CHAPTER 22

Counseling in Infertility

Prathap Tharyan, Sudeepa Chaparala

INFERTILITY IS A GLOBAL PROBLEM

Infertility is a common problem worldwide. Precise epidemiological estimates of its reported prevalence vary considerably, depending on the variations in different aspects of the definition of infertility.[1] These include the source of the sample (population vs. clinic); the time period used to define infertility (1 year, 2 years, or more); whether primary or secondary infertility is estimated; the role of current contraception versus the continuous use of contraception; the intent or desire to conceive; whether single, regularly cohabiting, or married; and the outcome measure used (pregnancy or live births).[1,2] Shorter exposure times such as 1–2 years are important from a clinical perspective to initiate treatment, but from an epidemiological and population perspective, these tend to misclassify women as infertile, since some women could give birth without any intervention if longer exposure times such as 5 years are used. Applying a standard definition of infertility that estimated live births in sexually active women over a 5-year period to data from 53 selected demographic and health surveys done in 26 countries in Africa, Asia, the Middle East, Eastern Europe, and South America from 1990 to 2008, age-standardized estimates for primary infertility were 0.6–3.4% and 8.7–32.6% for secondary infertility.[2]

Based on these estimates, it can therefore be assumed that roughly a tenth to a third of the population of women in the reproductive age group across the world do not have children in spite of attempts to have one. There are also indications that infertility is more common, and the childless state also more perceived as undesirable in less developed countries than in more developed countries.[3,4]

INFERTILITY, AND ITS TREATMENT, IS ASSOCIATED WITH CONSIDERABLE DISTRESS

Infertility can be due to factors in the male, the female, both, or due to unknown causes. Parenthood is generally considered by couples and society as a desired social role and the desire to have a child can be considered, with some exceptions, a universal phenomenon. The nature and extent of distress caused by childlessness varies between men and women, and though men also experience pressures and distress related to infertility, affected women worldwide tend to show more distress. This is, in part, related to the greater importance that women attach to having a child; with childlessness perceived more as a direct blow to their identity as women, while for men, the effects are largely mediated by the effects of childlessness on their wives, and due to a sense of responsibility for this distress.[4] However, women's reactions to childlessness are also largely influenced by gender-specific cultural expectations and societal reactions. In many traditional societies in low- and middle-income countries, particularly in South Asia, women are considered responsible for childlessness, even when the cause of infertility is due to the male partner, as the female is blamed for this state by their in-laws, often their male partners, and by society; and infertile women are often stigmatized, and subjected to various forms of emotional, verbal, and physical abuse, discrimination, separation, and social ostracism.[4-10]

The psychological reactions seen in infertile couples include depression and anxiety, grief, guilt, shame, suicidal attempts, feelings of inadequacy, low self-esteem, social isolation, dissatisfaction with marital and sexual functioning, and impaired quality of life.[4,11-13] Socioeconomic status, societal and personal expectations, religious beliefs, and attitudes influence the distress associated with childlessness. Individual copying styles and previous psychological status; the quality of marital functioning; the duration of infertility; the availability of social networks and support structures; and whether professional services are available or used, and the quality of these services are also important mediators of the distress associated with infertility.

Infertile couples are increasingly seeking assistance to have children, and advances in medical technology such as in vitro fertilization (IVF) and microinjection [intracytoplasmic

sperm injection (ICSI)] have helped millions of infertile couples worldwide. The numerous claims of success of assisted reproductive technologies (ARTs) also contribute to expectations of success in childless couples, and to distress and disappointment at failures. Estimates of successful pregnancies and live births vary. The best estimates are that around 50% of those seeking treatment will have a child, but in many surveys, the rates of success with ART are considerably lower.[14,15] Many couples also drop out of treatment after their first experience of failure. Although, infertility is considered a crisis (often ranked in impact similar to having a life-threatening illness or having lost a loved one),[16] and reactions to crises typically resolve with time; resolution of the crisis caused by childlessness may not be possible for many, and unresolved grief and depression continue to be experienced by women and men, after unsuccessful ART, many years after discontinuing treatment.[17]

Couples seeking ART may also experience considerable distress, inconveniences, and costs associated with the treatment. Couples often have to not only understand complex biological processes and treatment procedures, or face delays and failures, and the emotional effects of intensive, protracted, and invasive medical treatments; they also have to face complex decisions associated with choice of techniques, disposal of embryos, the possibility of complications associated with treatments (often related to the causes of infertility) that may result in pregnancy or birth complications, more frequent need for assisted deliveries, low birth-weight or premature babies, and babies with congenital abnormalities, leading to poorer neonatal outcomes.[18] There is also the possibility of multiple pregnancies and choices may have to be made related to fetal reduction. Many couples may have ethical and religious issues associated with donated sperm and embryos, and surrogacy. Those in contact with ART services as donors or surrogates also face considerable stresses that may require formal supportive services.[12] Some of these techniques also have legal implications that vary in different parts of the world.

Thus, people with infertility seeking ART as patients, donors, or surrogates, face complex issues, which span biological, psychological, social, legal, spiritual, and ethical domains and the attention paid to the medical and technical aspects of ART should not overshadow these needs or neglect these domains.

COUNSELING IN INFERTILITY AND ASSISTED REPRODUCTIVE TECHNOLOGY

Counseling refers to a confidential interaction between a health professional and a client aimed at enabling the client to cope with stressful situations and take personal decisions related to problem areas. Counseling aims to enable people to arrive at realistic solutions to their situations, and improve their ability to cope with stresses and thereby develop a sense of control, and reduce distress associated with their situation.

The aims of counseling in the context of infertility are to help couples to explore, understand, and resolve issues arising from infertility and infertility treatment, and to help them identify ways of dealing with these more effectively. The counseling process should consider the needs of the patient as well as any other person who might be affected by the treatment process (not ignoring the rights of the unborn child), and the decisions that have to be made. Considering the range of complex issues faced by couples with infertility, counseling in infertility often involves discussions of matters far beyond the medical or biological aspects of infertility; though these are also integral to the content of counseling.

The Need for Counseling in People with Infertility

While studies have documented higher levels of distress and psychological indices of ill-health in infertile couples compared to control populations, not all couples or individuals surveyed have been found to express such levels of distress after the initial reaction to the diagnosis; and studies have also documented that many couples who were offered counseling support do not take up this offer. On average, only around 20–30% avail counseling services, even when they are available.[19] The remaining 70–80% of people who do not take up counseling services are presumed to have coping mechanisms that are adequate to meet the demands imposed by their childless state.[20] However, this premise has not been systematically studied in less developed countries, where infertile women face more stigma and rejection within families and in their social circles.

In recent times, the concept of resilience has emerged as a possible protective factor against distress caused by life's vicissitudes, and resilient individuals develop coping skills and a problem-solving approach to improve their self-esteem, their social relationships, and their quality of life in spite of adversity.[21] Systematic enquiry in infertile couples has documented that resilience can be considered as a nonspecific protective factor against infertility-specific distress and poor quality of life, and this suggests that improving the resilience of distressed infertile couples who seek help should be considered a goal of counseling, irrespective of the outcomes of ART.[22]

Specific Indications for Counseling in Infertility

While not everyone requires counseling (though ideally every couple seeking ART should be offered psychosocial help and counseling), counseling is specially indicated under certain circumstances. These include people experiencing high distress, those undergoing social pressures, marital problems, unrealistic expectations, and prior failures;

people who need donated gametes, surrogacy, adoption, or fetal reduction; those with past histories of psychiatric or psychological problems; and those who require genetic counseling. In addition, counseling may be required at treatment-related time points, for mood fluctuations, failures, commencements, and delays associated with treatment.

Legal Mandate for Counseling

The nature, scope, and timing of counseling in infertility; who delivers counseling and their qualifications; and the specific aspects of ART services where counseling is considered mandatory are often decided by legal requirements in force in Australia, Canada, and some countries in Europe, UK, USA, and New Zealand. In many of these jurisdictions, counseling can only be provided by a trained and certified mental health professional, often requiring additional special training in the setting of infertility services, and requiring demonstration of involvement in continuous professional education.[23] In resource-constrained countries, such mandated requirements are impractical, considering the scarcity of trained mental health professionals to meet the demands of standard mental health needs. Numerous professional bodies also endorse the provision of psychological care and support to people seeking ART, and the guidelines of these bodies delineate the specific counseling requirements for different aspects of ART.[23] The endorsement for the need for psychological support is also echoed in surveys of people seeking help with assisted reproduction, who often report dissatisfaction with the lack of sensitivity provided for their emotional and psychological needs; however, integrated care within the context of the multidisciplinary team where their psychosocial needs were also attended was valued more frequently than specialized psychological referral and treatment, except in those with high infertility-related distress or with interpersonal problems or due to the social consequences of infertility.[24]

Outcomes with Counseling for Infertility

Whether psychological stress is a causative factor for infertility is an area surrounded by controversy, with no reliable evidence to support a causative role for stress in the majority of people with infertility. Some studies have suggested that pretreatment anxiety and depression affect outcomes with ART.[25] Based on this notion, psychosocial treatments have been devised to improve pregnancy outcomes with ART.[26] However, a systematic review of psychosocial interventions concluded that current evidence, from the eight studies identified of which three suggested benefit, was not robust enough to support this view, or to recommend psychosocial interventions as a primary method of improving pregnancy outcomes with ART.[27]

However, this systematic review did find that certain form of psychosocial interventions showed evidence of positive effects in reducing distress and improving mood in people presenting with infertility-related distress, though not changing preexisting maladaptive patterns of behavior, or dysfunctional relationships.[27] The beneficial psychosocial interventions were those that provided education specific to people's problems with infertility and that improved coping skills and problem-solving abilities; while interventions aimed only at providing support and an opportunity to ventilate their distress, or at exploring the meaning of childlessness were associated with less wide-ranging benefits.[27] The results of this systematic review are concordant with the literature on the potential benefits of increasing resilience in general as a useful goal for counseling and psychosocial care in infertile couples, irrespective of whatever specific theoretical models of psychological support are used.[22]

Psychiatric Interventions in Infertility

Not all people with infertility-related distress require psychiatric assessment or treatment, as psychological methods are usually what is required. However, people with preexisting psychiatric disorders or those who develop psychiatric problems, such as major depression, severe anxiety, or obsessive symptoms, are best dealt with in liaison with a psychiatrist, preferably one who has had some experience with the biological and psychosocial issues related to infertility. People with depression undergoing ART and treated with a combination of antidepressants and psychological support have better mental health and pregnancy-related outcomes than those not undergoing this treatment.[28]

The couples undergoing the infertility treatment have stress and anxiety. Couples should be given proper time to discuss the issues, and patient hearing and interactive discussion help decrease anxiety. Counseling regarding the need of stress management and impact of stress and anxiety on the treatment outcome have to be discussed. Stress and anxiety levels are elevated in most patients. Studies show that women with lower stress and anxiety levels on the day prior to oocyte retrieval had a higher pregnancy rate.[29]

Types of Counseling, Psychosocial Support, and Care in Infertility and with Assisted Reproductive Technology

Evaluation and Screening

Traditionally, the role of a mental health professional in infertility treatment clinics had been to screen aspiring couples and individuals for their vulnerabilities, expectations, social supports, coping skills, and financial solvency, in order to identify those couples who would be most suitable for ART. Often, in the absence of trained counselors or mental health professionals, this eligibility

screening was done by a doctor or a nurse with a special interest and some experience of counseling. In some countries, this screening or evaluation of couples seeking ART now also requires assessment of their suitability to be parents, keeping the welfare of the child as a priority. This may require background checks for criminal records, or records of sexual assault or had a child in there care removed away by a child protection order. Such eligibility assessments are often more stringent in the case of embryo donors or those wishing to be surrogates.[23] Current roles of counseling in ART clinics go far beyond screening couples for suitability, though this continues to be an expectation of the role of mental health professionals in ART services.

Various tools have been developed to help identify couples likely to be distressed with IVF procedures, though they are less widely used in developing countries. SCREEN IVF is a pretreatment screening tool that helps medical staff to identify patients with positive scores that predict high levels of distress with treatment, and who need referral to psychological support services.[30] An internationally validated tool exists that can help assess the quality of life of people with infertility. The Fertility Quality of Life Tool (FertiQoL) is a sensitive, reliable, and valid measure of quality of life for men and women experiencing fertility problems, and the 36-item self-rated questionnaire assesses the subjective rating of the excellence of the infertile patient's life within their cultural, emotional, social, and environmental context. FertiQoL assesses the influences of fertility problems in multiple domains of the infertile person, such as self-esteem, emotions, general health, partnership, family and social relationships, work life, and future life plans.[31] An optional FertiQoL treatment module assesses the potential burden and tolerability of fertility treatment, and can aid assessment of risk factors for poor adjustment to infertility treatment. FertiQoL is available for free download from //psych.cf.ac.uk/fertiqol/download/index.html, and the scoring key is also available from //psych.cf.ac.uk/fertiqol/scoring/index.html.

The Continuum of Patient-Centered Care, Counseling, and Psychotherapy

A distinction is also made between those aspects of care that are considered part of good clinical practice, such as providing information, discussing options, and assessing implications, versus the more specialized psychological techniques for helping distressed people.[32] These often form a continuum with some degree of overlap in the middle of the continuum that are often provided both by medical personal and nurses in the infertility clinic as well as by mental health professionals, while the ends of this continuum are best dealt with by the respective specialists. The domains of this continuum are described in **Table 1**[32] and the contents and focus are elaborated subsequently.

Information Gathering and Assessment

Assessing people presenting with infertility is the primary responsibility of the medical and nursing staff of the infertility clinic. Presenting people with information about infertility, the common emotional and other problems associated with infertility and its treatment, and the specific issues related to ART can be done using written material, videos, and even by telephone to supplement face-to-face discussions with clinic staff, and through self-help groups of patients that can empower them, aid information sharing, as well as normalize the experience of infertility.[33] However, these issues often come up in counseling sessions, and

TABLE 1: The continuum of patient-centered care, counseling, and psychotherapy in relation to infertility and assisted reproductive technology (ART).[32]

Domain in the continuum	*Type of counseling*	*Focus*	*Delivered by*
Patient-centered care	• Information gathering and assessment • Implication and decision making	• Evaluation of medical and biological factors associated with infertility and eligibility for ART • Discussing the implications of infertility and options for treatment and helping people make decisions regarding treatment	Medical and nursing staff of fertility clinic
Infertility counseling	• Supportive counseling • Crisis counseling	• Providing emotional support to patients in distress • Short-term support in crises (e.g., acute grief) • Long-term support for people with multiple or longer term problems	Trained clinic counselor (medical or nursing staff or mental health professional such as a counselor, psychologist, psychiatric social worker)
Psychotherapy	Therapeutic counseling	Specific psychotherapeutic techniques such as problem-solving, interpersonal therapy, cognitive behavior therapy for long-standing problems	Qualified mental health professional (counselor, psychologist, psychotherapist, psychiatrist)

infertility counselors need to be conversant with these issues as well.

Implications and Decision-making Counseling

Patients need to be helped to understand the implications of infertility on their lives and their emotional reactions; the implications of the different forms of ART offered or chosen; the implications of dealing with failures; and also the implications of success and their roles as parents of a child born through ART. The primary role of medical personnel in this is to provide accurate information, provide opportunities for patients to clarify their doubts, express their concerns, and to work with them to understand the implications of their choices and make necessary practical arrangements. Counselors may also be required to help patients make sense of these decisions and fully understand the implications and the changes required in their lifestyles to ensure better outcomes. Implication counseling is specially important in the context of sperm and egg donation and surrogacy, and is also important when discussing issues such as adoption, termination of treatment, disclosure to future children of the circumstances associated with their conception, and the impact of their changed status as parents as well. This discussion may also help them identify patients at potentially high risk of distress and to arrange for more formal support, if needed.

Supportive Counseling

Supportive counseling aims to support patients experiencing distress arising from the psychosocial problems related to infertility, the desire to have a child, the financial pressures, and practical difficulties associated with ART, and the limitations of these technologies in guaranteeing success. Concerned family members may also need support. Supportive counseling may be needed at specific periods associated with treatments such as for men facing the pressure to perform, the waiting period or during delays in treatment, during phases of intensive assessment, and with failure to achieve pregnancy, and when there are conflicts between partners related to treatment options, or with clinical staff in relation to treatment options or termination of treatment. Clinic-based counselors may sometimes need to refer some patients to mental health services outside the clinic if these latter conflicts impede the counseling and therapeutic relationship.

The principles of supportive counseling include the facilitation of the expression of concerns and the distress experienced, the validation of these concerns and distress, the normalization of such experiences, provision of information, and correction of misconceptions or unwarranted misgivings, strengthening coping mechanisms (encouraging resilience), and mobilizing social and family support. A problem-solving approach and specific techniques to aid relaxation are also useful in some patients experiencing high levels of distress.

Crisis Counseling

Patients with infertility often face acute emotional crises related to their infertile state as well as to specific issues of ART treatment that for some are more distressing than for others. Failure of an IVF cycle, miscarriages, and abortions, or exacerbations of marital conflicts or interpersonal problems are often traumatic. Acute grief reactions can follow losses and can be devastating for some patients. In such situations, patients need immediate help and assessment of their coping and support. Working with grieving patients requires knowledge of the stages of normal grief: From numbness and disbelief, through anger and protest, to despair and depression, till eventual resolution as they make new plans, and reinvest in life. Normalizing these experiences while using the principles of supportive counseling, supplemented by specific techniques related to grief work, help many patients come to terms with their losses. These crises are best averted by supportive counseling that aims to provide patients with opportunities to anticipate potential losses, and to learn and practice new adaptive behaviors that could enhance their ability to cope with infertility and the associated medical procedures, and failures. The emphasis should be on providing both positive and negative information, identifying coping strategies and strengthening resilience, and helping them redefine their future, if treatment fail's; and helping to strengthen their relationships.

Psychotherapy

Psychotherapy may be required for people going through specific issues arising out of infertility or of failed treatment, or the consequences of treatment. Mental health professionals often use specific psychological techniques, such as psychodynamically oriented psychotherapy; cognitive behavior therapy aimed at identifying dysfunctional attitudes and beliefs and cognitive distortions that influence emotional responses, and providing alternate rational explanations; interpersonal therapy aimed at dealing with distressing relationships; and problem-solving approaches.

However, the features common to all forms of psychotherapy and supportive counseling that are likely to benefit patients in distress, irrespective of the theoretical models employed,[34] are:

- Having an unconditional positive regard for the patient
- Providing the opportunity for a confiding relationship with a helping person, often with the participation of a group or others to help.
- Facilitating the expression of distress and of emotional arousal; this is often a prerequisite to attitudinal and behavioral changes.

- Providing a rational explanation of the cause of the patient's distress and a method for relieving it.
- Provision of new information concerning the nature and sources of the patient's problems and possible alternative ways of dealing with them.
- Strengthening the patient's expectations of help through the personal qualities of the therapist that emphasize compassionate professionalism; this is often enhanced by the status (or reputation) of the therapist in society and the setting in which he or she works.
- Providing patients with hope and the experience of success, in coping with their problems through simple practical measures, which can further heighten the patient's hopes and also enhance their sense of mastery, interpersonal competence, or capability.

Specific Issues in Counseling for Infertility

Gender, Sexuality, and Sexual Functioning

Gender differences in the reactions of infertility in couples who seek help relate to the greater distress and the need to express distress, and the need for emotional support in women; while men tend to use problem-solving approaches more. Male partners of infertile women often tend to be seen as emotionally unsupportive due to these differences in dealing with emotional distress, and couples need to be helped to understand these differences and to support each other. Women also tend to avoid reminders of their childlessness due to the distress it arouses, and helping them confront, rather than avoid, these issues and enhance resilience and coping mechanisms, using practical suggestions is important. Infertile couples also have many problems with their sexual lives, and the pressure of timed intercourse with IVF treatments is one of the causes of this dissatisfaction that will need to be dealt with by enhancing the pleasurable aspects of their sexual relationship, rather than focusing on pregnancy outcomes. Couples need to be approached with the view that, irrespective of pregnancy outcomes, the principal focus of counseling is on strengthening their marital relationship and their quality of life, while helping them cope with the pressures of treatment.

Dealing with Multiple Gestations

Since the possibility exists for multiple gestations, information sharing and implication counseling is an opportunity to broach this possibility and encourage reflections on the implications of dealing with multiple pregnancies. This is in keeping with the expectations of counselors to always keep the welfare of the unborn child or children as part of the focus of counseling. Early discussion of potentially distressing issues such as fetal reduction, if required, is also important to prevent subsequent distress, if multiple gestations occur.

Counseling in Serodiscordant Couples

The discordant couples either of who is human immunodeficiency virus (HIV) positive should be counseled regarding how to prevent transmission to their partner and child, and advantages of ART procedures in decreasing the risk of HIV sexual transmission.

- *HIV-positive men:* Sperms are not infected by HIV virus. Most recent studies show that sperms lack the CD4 and CCR5 receptors on the surface, which allow viruses to bind and enter the cell. HIV is probably found in higher concentration in the white cells in the semen. To prevent transmission to HIV-negative wife, options can be given to couple regarding:
  - Intrauterine insemination (IUI) with washed semen sample
  - IVF
  - ART with donor semen.
- *HIV-positive women:* They should be counseled regarding the ART options available and advantages, the retroviral treatment and blood tests, and frequent visits needed. Counseling is done regarding the risk of transmission to child, importance of delivery in multidisciplinary setting involving relevant health professionals, and measures to be taken to decrease the risk of spread to child.

Donor Insemination, Egg Sharing, Oocyte Donations, and Other Third-Party Treatments

There are many aspects of ART that require the involvement of a third party, other than the couple, that may need to be dealt with in counseling. Some of these include: semen donation, oocyte donation, embryo donation, surrogates, gestational surrogacy, lesbian couples, single women without a partner, disclosure of information to donor-conceived children or adults, concluding treatment without achieving pregnancy, adoption, and fertility preservation for medical or social reasons.[23]

Some issues to focus on in counseling are as follows:

- Helping couples understand the implications of third-party treatments on their relationships, particularly the implications for the genetically unrelated partner.
- The emotional reactions and motivations of the third-party donor who will not conceive and the future boundaries and expectations of the third-party donor.
- The legal, moral, spiritual, and emotional issues raised by third-party treatments.
- Issues related to confidentiality, the nature and timing of disclosure to future offspring, family, and others of third-party treatments.[34]
- Counseling and assuring of the patient regarding the prior screening of donors with communicable diseases that endangers the recipient health.

Counseling in situations of third-party treatments is particularly difficult and limited evidence indicates that considerable distress exists long after the treatments in people who were involved in such treatments, often related to the lack of counseling, but sometimes perceived to be due to the mandated provision of counseling that left them feeling stigmatized.

There is insufficient qualitative or quantitative research from developing countries on the distress associated with third-party treatments and the provision of counseling services to those involved.

NEGATIVE COUNSELING

The need of negative counseling is more in the patients where the IVF success rate is low due to low ovarian reserve, advanced maternal age, highly compromised semen parameters, recurrent pregnancy loss, etc., as there is high risk of aneuploidies, and increase in financial burden. But the routine negative counseling of patients may increase the stress and anxiety, which may impact the outcome.

KEY POINTS

- Infertility is a common problem and affects between a third and a tenth of women worldwide.
- Infertility is associated with considerable distress that is influenced by personal expectations and coping styles, and interpersonal relations, but influenced considerably by gender-specific special pressures and attributions.
- Women all over the world experience more distress due to infertility than men, but in parts of the developing world, also face considerable stigma, discrimination, abuse, and neglect.
- ARTs have brought hope to millions of infertile couples, but couples entering treatment with these technologies are not guaranteed success; the treatment is complex and protracted; and associated with psychological, social, financial, legal, religious or spiritual, and medical challenges and dilemmas that require the offer and provision of psychosocial support and care.
- Counseling in infertility includes evaluation, patient-centered care, infertility counseling, and psychotherapy that overlap to form a continuum of care.
- This continuum hopes to provide suitable patients and couples information and help with understanding their condition, treatment options, and their implications, in order to reduce the distress associated with their chosen treatments and the outcomes.
- Some couples will also require supportive and crisis counseling, and fewer still will require psychotherapeutic help from trained mental health professionals.
- Legal provisions exist in some countries as to what aspects of this continuum are mandatory and who is qualified to provide such services.
- In developing countries, all members of the treating team need to have knowledge and some expertise in the provision of patient-centered care and infertility counseling, though therapeutic counseling is best done by trained mental health professionals.
- The forms of psychosocial treatments that have shown the best outcomes in infertile couples are those that improve their sense of mastery and control, and problem-solving techniques that enhance reliance, rather than only providing the opportunity for emotional expression and introspection.
- Counseling for infertility and with ART is a developing field that needs more trained professionals and further research to better delineate who needs to be counseled, the components of counseling that are effective, and the perceptions of those being counseled, particularly from the developing world.
- Finally, reversing the state of childlessness is the focus of treatment of the medical team, while strengthening the relationship of the couple and improving their quality of life, irrespective of pregnancy outcomes, should be the focus of infertility counseling.

CONCLUSION

Counseling should be given by trained and certified professional, who makes couple understand, explore and to resolve issues arising from infertility and infertility treatment. Psychological impact on infertility is no longer considered a negligible area as studies show evidence of positive effects on improving ART outcome after treating the stress.

In patients with psychosocial disturbances counseling should not be a single step procedure, counselors should help couple make sense of the decisions and fully understand the implications, lifestyle changes required. Support patients experiencing the distress arising from psychological problems and to deal with emotional crisis (like miscarriage, abortions etc.,) psychotherapy may be required for people going through special issues arising out of infertility or failed treatment or consequence of treatment.

CHAPTER 23

Assisted Reproductive Technology in Patients with Chronic Medical Disorders

Anuradha Kumari, Devi R

INTRODUCTION

The majority of women undergoing assisted reproduction are healthy and relatively young. However, the tendency to postpone the marriage and childbearing to later on in life is leading to the concurrent conditions that may have implications for in vitro fertilization (IVF), pregnancy, and its outcome. Assisted reproductive technology (ART) treatments in women with underlying chronic diseases have become increasingly frequent. Some of the most prevalent chronic diseases in women during their reproductive years are ulcerative colitis, Crohn's disease, rheumatoid arthritis, multiple sclerosis, epilepsy, hypertension, and diabetes mellitus (DM). Patients at risk for thrombosis could pose tremendous challenges during assisted reproduction treatment and subsequent pregnancy. The research area on the efficacy of ART in women with different chronic diseases is still new, and the amount of literature is limited.

PRECONCEPTION COUNSELING

Despite tremendous advances in prenatal care, certain adverse pregnancy outcomes such as preterm delivery and birth defects have not changed. The principal goal of preconception counseling is to maximize the quality of fetal, maternal, and newborn life through primary prevention. The four main components of preconception care are—(1) risk assessment, (2) health promotion, (3) interventions to eliminate risk factors, and (4) adequate counseling.

ASSISTED REPRODUCTION IN PATIENTS AT RISK OF THROMBOSIS

The clinical association between VTE and IVF is primarily due to ovarian hyperstimulation syndrome (OHSS) in which thromboembolic complications may have fatal consequences. Sometimes patients presenting for IVF might have a previous history of VTE or may be at increased risk of developing thromboembolic complication while undergoing IVF treatment due to a pre-existing condition which increases the risk for the same. The prevalence of venous thromboembolism (VTE) in patients undergoing assisted reproduction (0.1–0.2%) is 10x higher than the general population (2.2/10,000).[1,2] This risk is increased to 100-fold in patients who develop ovarian hyperstimulation (1.7%).[1] Although the absolute numbers of VTE events in assisted reproduction are low, it can be potentially fatal with serious morbidity or mortality. With increasing use of assisted reproductive techniques (ARTs), especially in women with advanced age, obesity, and smoking, it is extremely important as clinicians to identify women who are at increased risk, provides appropriate counseling, and risk-reduction strategies to make treatment safer.

Mechanism of Thrombosis in Assisted Reproductive Technology

The pathogenesis of venous thrombosis is complex. The hyperestrogenism resulting from ovarian hyperstimulation is a known thrombotic agent. It causes increase in procoagulant factors (fibrinogen, von Willebrand factor, factors VIII and V, and increased activated protein C resistance), enhanced activation of coagulation (D-dimer), reduced fibrinolysis (reduced tissue plasminogen activator and plasminogen activator inhibitor type I), and reduced natural anticoagulants (antithrombin III and protein S).[3,4] Changes in Von Willebrand factor and Von Willebrand factor-cleaving protease have also been reported. Tissue factor pathway inhibitor values progressively and significantly decreased throughout the ovarian stimulation and negatively correlated with estradiol.[5] Indeed, during IVF treatment, the action of coagulation factors seems to be associated less with the level of serum estradiol concentrations (which may reach levels 10x higher than in physiological cycles but remain below those occurring in pregnancy) than with the biochemical changes that occur after the triggering of final oocyte maturation with human chorionic gonadotropin (hCG). The predominant contribution of hCG rather than estradiol to the etiology of

VTE after ovarian stimulation is supported by the clinical observation that frozen thaw cycles (when estrogens but not hCG are administered) are not associated with an increased risk compared to natural conceptions. It has been seen that activation of the coagulation cascade system (fibrinogen and factors II, V, VII, VIII, and IX) was elevated within 2 days after hCG, reaching a maximum approximately 8 days after hCG administration.[6] Although hemostatic risk is more during the stimulation phase, the final event is often attributable to exogenous hCG. In severe OHSS excessive vasoactive substances produced by the ovaries causes increased permeability of blood vessels leading to escape of fluid from the vascular compartment to the third space (ascites, hydrothorax, and hydropericardium) and contribute to hemoconcentration, hypovolemia, and thromboembolism. Careful monitoring and preventive measures to avoid OHSS are important in patients at risk of thrombosis.

Risk Assessment and Screening

All patients proceeding to IVF treatment should be individually assessed for their risk of thrombotic complications. Women who should be considered at increased risk include those with congenital or acquired thrombophilias, hyperhomocysteinemia, previous history of OHSS, advanced age, smoking, and obesity.[1] Women with a previous episode of VTE are at increased risk for recurrence, particularly when exposed to high-risk conditions.[7] Universal screening for thrombophilia in pregnancy or prior to IVF is not recommended routinely for the prevention of VTE. However, screening for thrombophilia should be considered in women with a history of recurrent miscarriage or personal or family history of VTE. Screening should include plasma antithrombin III, activated proteins S and C resistance, antiphospholipid antibodies, and testing for factor V Leiden mutation and MTHFR 677T.[8]

In Vitro Fertilization Management

- Risk assessment for thrombosis before starting the treatment.
- Couples should be counseled in detail about risk of thromboembolism during IVF stimulation[9] and pregnancy and genetic counseling should be provided in indicated cases.
- Modifiable risk factors, e.g., medical conditions and obesity, should be optimized prior to starting treatment.
- IVF stimulation and embryo transfer protocol should be modified to prevent thrombosis as stimulation with higher dose of gonadotropins elevated estradiol levels hCG trigger, OHSS, multiple pregnancy and use of exogenous estrogen for frozen-thawed embryo transfer (FET) increase the risk of developing thromboemolism.
- Mild stimulation, antagonist protocol for ovarian stimulation with use of GnRH agonist trigger.
- Coadministration of letrozole with gonadotropin during ovarian stimulation. Letrozole is an aromatase inhibitor, lowers the level of estrogen by preventing conversion of androgen to estrogen and decreased estrogen concentrations in serum possibly reduces the risk of OHSS and thromboembolic events.[10] Letrozole can be used in a dose of 5 mg/day in two divided doses from day 1 of controlled ovarian hyperstimulation till the day of trigger.
- Preventing OHSS.
- Frozen embryo transfer (FET), in natural cycle, avoiding hCG exposure.
- Single embryo transfer and avoiding multiple pregnancies.
- Use of prophylactic or therapeutic anticoagulation if indicated.
- If the patient develops OHSS and is pregnant, thromboprophylaxis should continue till 12 + 6 weeks. If not pregnant, it should be continued for 4 weeks after resolution of OHSS.[11]

Thromboprophylaxis

All women should be assessed for risk of VTE as per the Royal College of Obstetricians and Gynaecologists[12] or ACOG guidelines before starting stimulation.

Indications of thromboprophylaxis are enumerated in **Box 1**.[11]

Thromboprophylaxis should be initiated at the start of stimulation. Women who have suffered previous episodes of VTE having an underlying cause, already under long-term anticoagulant therapy with warfarin presenting for IVF, should be switched to low-molecular-weight heparins (LMWH) prior to starting ovarian stimulation and should be stopped 24 hours prior to the procedure, restarting in the evening or next day after oocyte retrieval. Advised doses of LMWH in this case are enoxaparin 0.5–1 mg/kg 12 hourly or dalteparin 5,100 IU/kg 12 hourly, with an aim of achieving anti-Xa levels of 0.7–1.0.[9]

If therapeutic doses of LMWH are required, enoxaparin 1 mg/kg 12 hourly or dalteparin 90 IU/kg 12 hourly are advised. Specialist advice will be required to determine the

BOX 1: Indications of thromboprophylaxis.[13]

- Previous history of deep venous thrombosis (DVT)
- Severe ovarian hyperstimulation syndrome (OHSS) and moderate OHSS requiring hospital admission
- Antithrombin deficiency
- Acquired or hereditary thrombophilias in combination with other risk factors such as age over 40 years and/or smoking
- When multiple risk factors such as high BMI, poor mobility, and smoking are identified
- Women with mechanical heart valves, VTE with APAS, recurrent VTE, or antithrombin deficiency

(APAs: antiphospholipid antibodies; BMI: body mass index; VTE: venous thromboembolism)

TABLE 1: Management strategies for various clinical conditions before and after ovarian stimulation.[9]

Clinical situations	*Management*
• Single previous VTE (not pregnancy- or "pill"-related) associated with a transient risk factor and no additional current risk factors such as obesity	Surveillance or prophylactic doses of LMWH +/compression stockings.
• Single previous idiopathic VTE or single previous VTE with underlying thrombophilia and not on long-term anticoagulant therapy, or single previous VTE and additional current risk factor(s) (e.g., obesity)	Prophylactic doses of LMWH from starting of ovarian stimulation +/ compression stockings.
• More than one previous episode of VTE, with no thrombophilia and not on long-term anticoagulant therapy	Prophylactic doses of LMWH with graduated elastic compression stockings at time of starting controlled ovarian stimulation and continued throughout pregnancy
• Previous episode(s) of VTE in women receiving long-term anticoagulants (e.g., with underlying thrombophilia)	Switch from oral anticoagulants to LMWH therapy prior to controlled ovarian stimulation and continue throughout pregnancy +compression stockings
• Thrombophilia (confirmed laboratory abnormality) but no prior VTE	Surveillance or prophylactic LMWH +/compression stockings. The indication for LMWH prophylaxis in the antenatal period is stronger in antithrombin deficiency women than the other thrombophilias, in symptomatic family members compared to asymptomatic relatives and also where additional risk factors are present
• Risk factors for VTE present prior to controlled ovarian stimulation but no previous VTE or thrombophilia	Risk assessment for VTE. If multiple risk factors present or if single major risk factor present, consider LMWH thromboprophylaxis +/ compression stockings
• Develops VTE	Therapeutic doses of LMWH with specialist advice for duration of therapy, but usually for at least 6 months with therapeutic or prophylactic treatment continued until at least 6 weeks postpartum

(LMWH: low molecular weight heparins; VTE: venous thromboembolism)

TABLE 2: Prophylactic and therapeutic dose of LMWH (RCOG recommendations).[12]

	Enoxaparin	*Dalteparin*	*Tinzaparin*
Prophylactic dose:			
<50 kg	20 mg/day	2,500 units/day	3,500 units/day
50–90 kg	40 mg/day	5,000 units/day	4,500 units/day
>90–130 kg	60 mg/day	7,500 units/day	7,000 units/day
131–170 kg	40 mg/12 hourly	10,000 units/day	9,000 units/day
>170 kg	0.6 mg/kg/day	75 U/kg/day	75 U/kg/day
Therapeutic dose	1 mg/kg 12 hourly	90 U/kg 12 hourly	90 U/kg 12 hourly

(LMWH: low-molecular-weight heparins; RCOG: Royal College of Obstetricians and Gynaecologists)

duration of therapy, but normally a minimum of 6 months of therapeutic dose is advised, followed by prophylactic doses continuing until 6 weeks postpartum.[9,11]

Management strategies for various clinical conditions before and after ovarian stimulation are enumerated in **Table 1**.[9]

Prophylactic and therapeutic dose of LMWH are enumerated in **Table 2**.[12]

SUMMARY

- Occurrence of thrombosis after ovarian stimulation is usually very uncommon.
- Ovarian hyperstimulation must be prevented by use of antagonist cycle, cotreatment with letrozole during stimulation, mild stimulation and use of gonadotropin-releasing hormone (GnRH) agonist trigger.
- Thromboprophylaxis with LMWH is started along with the stimulation in high risk cases.
- On the day of oocyte retrieval, the dose should be omitted and to be restarted the following day or in the evening after oocyte retrieval. Prophylactic or therapeutic dose is decided based on the risk factors and in association with hematologist advice.
- Cryopreservation of all embryos and natural cycle FET avoids the use of hCG completely.
- Single embryo transfer is preferable to avoid the risk of multiple pregnancies.

AUTOIMMUNITY AND IN VITRO FERTILIZATION

INTRODUCTION

Systemic autoimmune diseases (SADs) comprise a heterogeneous group of chronic immune-mediated disorders including systemic lupus erythematosus (SLE), antiphospholipid antibody syndrome (APS), rheumatoid arthritis (RA), systemic sclerosis (SSc), Sjogren's syndrome (SS), mixed connective tissue disease (MCTD), idiopathic inflammatory myopathies (IIM), and vasculitis. SADs often occur in women of childbearing age and can affect fertility.

SYSTEMIC LUPUS ERYTHEMATOSUS

It is a chronic multisystem autoimmune disease with a heterogeneous pattern of clinical and serological manifestations with unpredictable course, alternating between periods of flares with remissions. Disease etiology is not fully known, but a strong genetic component has been shown to play a key role in the predisposition of this disease. Genes of the major histocompatibility complex (MHC), particularly *HLA-A1*, *B8*, and *DR3*, have been linked to SLE, as well as certain single-nucleotide polymorphisms (SNPs) that are associated with its clinical manifestation.[14]

Pathogenesis of this disease involves a complex interaction between gene susceptibility, hormonal influences, and certain environmental triggers which induce autoantibody production, formation of immune complexes, activation of T-lymphocytes, dysregulation of apoptosis, and production of proinflammatory cytokines.[15] The prevalence ranges from 20 to 150 cases per 100,000 persons and appears to be increasing due to better diagnosis and survival.[16] It occurs nine times more often in women than in men, especially in women of childbearing age, and tends to be more severe among the black population.[17] The predilection for women, particularly of childbearing age, combined with improved survival has led to increasing numbers of women with lupus considering pregnancy.

The reproductive system may be affected in women and men, as a result of disease activity and through iatrogenic cytotoxic treatments. Autoantibody positivity does not appear to impact fertility but it has been found to be associated with a decreased rate of embryo implantation and clinical pregnancy.[18]

Classification criteria for SLE are enumerated in **Table 3**.[19]

TABLE 3: Classification criteria for SLE (American College of Rheumatology).[19]

Clinical criteria	*Laboratory criteria*
• Malar rash • Discoid rash • Photosensitivity • Oral ulcers • Nonerosive arthritis • Pleuritis/pericarditis • Renal disorder(Persistent proteinuria or cellular casts) • Neurological disorder(seizure or psychosis)	• Hematological disorder (hemolytic anemia with reticulocytosis or leukopenia or lymphopenia or thrombocytopenia • Immunological disorder (anti-dsDNA or anti-Sm or antiphospholipid antibodies) • Antinuclear antibodies
Four out of the 11 clinical or laboratory criteria to be met for diagnosis of SLE (95% specificity and 85% sensitivity).	
(anti-dsDNA: anti-double stranded DNA; anti-SmAb: anti-Smith antibody)	

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

Antiphospholipid syndrome (APS) is an acquired thrombophilic disorder in which autoantibodies are produced to a variety of phospholipids and phospholipid-binding proteins.[20] Secondary APS occurs in 30% of SLE patients and is well recognized to cause spontaneous abortions, stillbirths and premature births as well as venous and arterial thrombotic events. A more direct link, however, between aPL and infertility remains controversial and assessment for aPL is not routinely indicated in women undergoing IVF.

Revised Sapporo criteria for diagnosis of APS are mentioned in **Table 4**.[21]

Causes of Infertility in Patient with Systemic Lupus Erythematosus and Antiphospholipid Syndrome

According to recent evidence autoimmunity per se is not a likely cause of infertility. Nonrheumatic autoimmune disease of thyroid, ovary, and adrenal failure may cause infertility by interfering with endocrine function. Therefore, in the absence of severe disease and with a normal ovarian function, fertility in women with lupus is similar to that of the general population.

- *Age:* Onset of SLE is often during the early reproductive years and patients are counseled to avoid pregnancy while disease is active and advised to wait for a period of disease remission and drug washout before conception. These patients get older when they try to conceive and may encounter age-related difficulties and reduced fertility.[22]
- *Menstrual disturbances:* Amenorrhea may occur, not only as a result of cyclophosphamide (CYC) treatment causing ovarian failure, but also as a result of the disease itself. Episodes of amenorrhea has been found to be associated with anticorpus luteum antibodies and with raised follicle-stimulating hormone (FSH) levels, suggestive of an autoimmune, SLE-related menstrual dysfunction. Menstrual irregularities have also been attributed to high-dose corticosteroids administration.

TABLE 4: Revised Sapporo criteria (Miyakis et al.) for diagnosis of APS.[21]

Clinical criteria	*Laboratory criteria*
• Vascular thrombosis in any tissue or organ • Pregnancy morbidity • ≥3 unexplained consecutive spontaneous abortions (<10 weeks of gestation) • ≥1 unexplained fetal death (>10 weeks gestation) of morphologically normal fetus • ≥1 premature delivery (<34 weeks gestation) of morphologically normal fetus due to eclampsia, severe preeclampsia or placental insufficiency	• Positive LAC (on two occasions at least 12 weeks apart) • Positive medium or high titers of IgG OR IgM anticardiolipin antibodies (>40 GPL or MPL, or >99th centile) on two occasions at least 12 weeks apart • Positive titers of IgG or IgM anti-β2-glycoprotein-1 antibodies (>99th centile) on 2 occasions at least 12 weeks apart
One clinical plus one laboratory criteria to be met for diagnosis of APS	

(APS: antiphospholipid syndrome; GPL: immunoglobulin G phospholipids units; IgG: immunoglobulin G; IgM: immunoglobulin M; LAC: lupus anticoagulant; MPL: immunoglobulin M phospholipids units)

- *Hypothalamic-pituitary-ovarian (HPO) axis dysfunction due to renal failure:* Patients with chronic renal failure secondary to lupus nephritis may develop infertility through hypothalamic-pituitary dysfunction due to raised prolactin that reduces the production of gonadotropin-releasing hormone from the hypothalamus, which manifests as a menstrual irregularity and anovulatory cycles.[23]
- *Premature ovarian failure (POF):* Cyclophosphamide (CYC) is a known gonadotoxic agent that can cause POF by depleting the healthy oocytes. Its toxicity is associated with the cumulative dose of CYC and the age at which the drug is administered.[24] It is recommended to delay the conception, until at least 3 months after the last dose, to avoid the risk of teratogenicity.
- *Luteinized unruptured follicle (LUF):* The use of nonsteroidal anti-inflammatory drugs NSAIDs in women with lupus might increase the risk of infertility due to persistent luteinized unruptured follicles. Women having problems in conceiving should be advised to stop NSAIDs, but not all women on NSAIDs who wish to become pregnant have to stop them on the basis of present evidence.[25]
- *Psychosocial aspects influencing fertility:* SLE is associated with fatigue and depression and subsequent loss of libido/sexual function in women as well as men. Therefore, an apparent reduction in fertility may actually reflect reduced frequency of sexual intercourse. Moreover, drugs used in the treatment of SLE may diminish libido further.[26]

Systemic Lupus Erythematosus in Male

- *Testicular damage:* A study by Kenney et al., showed a significant reduction in testicular volume in men with SLE as determined by ultrasound imaging, which correlated with the degree of sperm abnormalities.[27] It was suggested that this reduction was most likely due to damage by SLE to the seminiferous tubules.
- *Impaired spermatogenesis:* Cyclophosphamide (CYC) destroys dividing cells, thereby impairing the spermatogenesis during treatment.[27] Methotrexate (MTX) and sulfasalazine (SSZ) used in the treatment of SLE, can also reduce sperm count leading to infertility.

TREATMENT STRATEGIES TO PRESERVE FERTILITY

General Principle

When CYC is prescribed for patients with severe lupus activity, it should be at the lowest effective dose and for the shortest duration. When it is necessary to give CYC to prevent renal failure, gonadal protection should be considered in those patients due to increased risk of premature ovarian failure.

Patients should be counseled properly for disease recurrence during pregnancy and must be assessed for disease remission, disease burden, presence of organ involvement such as lupus nephritis, the presence of aPL and anti-Ro antibodies, medication regime prior to conception, to ensure avoidance of any drugs that are not safe in pregnancy.

Gonadotropin-releasing Hormone Agonist (Leuprolide)

Treatment with gonadotropin releasing hormone (GnRH) agonists during CYC therapy is used to minimize ovarian toxicity, although the degree of benefit is still debatable. Mechanisms by which GnRH agonist reduces chemotherapy induced gonadotoxicity are—(i) simulating prepubertal hypogonadotropic effect, (ii) decreased ovarian perfusion due to hypoestrogenism, (iii) direct ovarian effect, (iv) upregulating sphingosine-1-phosphate (an ovarian protecting molecule), and (v) germ-line stem cell preservation.[28]

A study conducted by Brunner et al., suggested that GnRH-a should be administered 22 days before CYC is

started. It is nevertheless recommended to start the GnRH-a prior or concomitantly to initiation of CYC.[29] GnRH agonist therapy should not be started during the follicular phase, as it can stimulate the ovaries and worsen ovarian damage.

Oocyte and Embryo Cryopreservation

Cryopreservation of either oocyte or embryo may be considered as a fertility preservation option for stable inactive SLE patients.

Ovarian Tissue Cryopreservation

This domain is primarily a research procedure at this time but improved techniques in the future could make this an ideal method for fertility preservation in prepubertal SLE patients requiring CYC therapy.

IMPACT OF ASSISTED REPRODUCTION TECHNIQUE ON SYSTEMIC LUPUS ERYTHEMATOSUS AND ANTIPHOSPHOLIPID SYNDROME

Women with SLE and APS undergoing controlled ovarian hyperstimulation (COH) and IVF are at increased risk of hormone-associated flare and venous and arterial thromboembolism due to the hypercoagulable state induced by high serum estradiol (E2) concentrations, as well as enhanced risk of maternal and fetal complications.[30,31] A planned individualized ovarian stimulation with administration of prophylactic corticosteroids and anticoagulants, in the stable phase of the disease, is safe and reduces the risk of complications.

EFFECT OF SYSTEMIC LUPUS ERYTHEMATOSUS AND ANTIPHOSPHOLIPID SYNDROME ON PREGNANCY

Pregnancy in women with SLE/APS is associated with the increased risk of fetal complications due to placental insufficiency, including miscarriage, intrauterine death, hypertension, preeclampsia, FGR, low birth weight, and preterm delivery. There is increased risk of fetal heart block and cutaneous neonatal lupus in women with positive anti-Ro or anti-La antibodies and may lead to fetal demise.[32]

There is an increased risk of maternal death due to pulmonary hypertension and is reported in 14% of patients with lupus.[33]

PRECONCEPTION COUNSELING

Couples should be counseled about the risk of disease flares, thromboembolism, maternal and fetal complications, and risk of neonatal lupus syndromes in pregnancy. They must be educated about the need for optimal disease control with pregnancy safe medications before conception.

MANAGEMENT DURING IN VITRO FERTILIZATION

Assisted reproductive technology are generally safe, if the patient has quiescent disease and is on appropriate prophylactic therapy with antithrombotic or immunosuppressants if aPL positive. Efficacy of IVF in terms of pregnancy rate is comparable with that in the general population (up to 30%).[31]

For IVF cycle programming, combined OC pills may be given, using the lowest possible dose of ethinylestradiol (30–35 mg), if disease is in remission phase, without high titers of antiphospholipid antibodies, negative lupus anticoagulant, no previous clinical history of thrombosis, and no previous exacerbation of the lupus activity with administration of estradiol.[34,35] In ovulation induction, antiestrogen is the first line of treatment, with clomiphene citrate being the drug of choice.[36] Letrozole would also be an alternative option. At present, no particular type of gonadotropin offers any advantage over others in terms of reducing the risk of thrombosis.[37]

Contraindications of ovarian stimulation/pregnancy in women with SLE are enumerated in **Box 2**.[31]

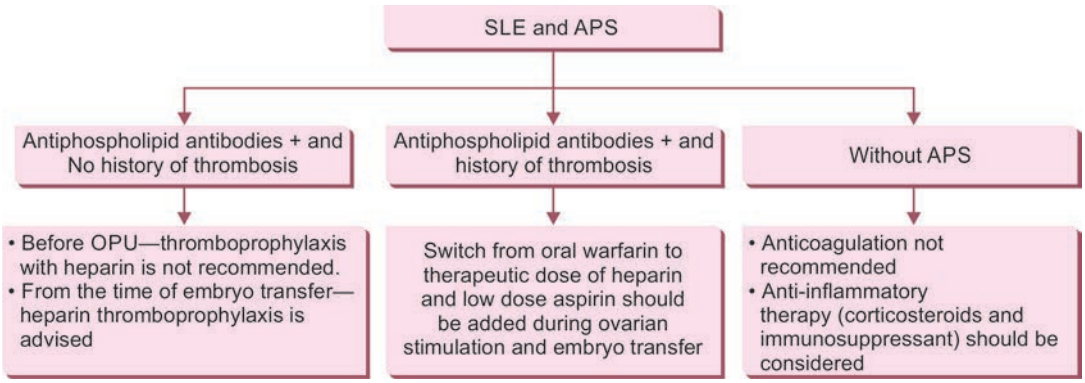
It is recommended to use friendly ovarian stimulation to avoid high serum estrogen and OHSS using antagonist protocol, mild stimulation protocols, GnRH agonists trigger, embryo freezing and single-embryo transfer to reduce complications related to multiple pregnancies.[31] To minimize the risk of OHSS and thrombosis due to very high estrogen levels, aromatase inhibitors (letrozole) can be used in these patients during ovarian stimulation to lower the levels of serum estrogen.[38] Risk of both lupus flare and thrombosis is greater if the diagnosis of SLE is not known at the start of the cycle.[31]

Coadjuvant therapy (anticoagulation, corticosteroids, and immunosuppressants) should be advised during and after ovarian stimulation for the prevention of thrombosis or lupus flares.[39] The natural cycle should be considered as the first option in case of FET. When estrogens are used for endometrial preparation, less procoagulant natural estrogens should be used and transdermal route should be preferred over oral. Similarly, natural progesterone through

BOX 2: Contraindications of ovarian stimulation/pregnancy in women with systemic lupus erythematosus (SLE).[31]

- Acute flare (and the following 6–12 months)
- Pulmonary hypertension
- Uncontrolled arterial hypertension
- Severe renal impairment
- Severe restrictive lung disease
- Valvulopathy or heart disease
- High titer of antiphospholipid antibodies and anti-Ro/anti-La antibodies

Flowchart 1: Systemic lupus erythematosus and antiphospholipid antibody syndrome.



(APS: antiphospholipid antibodies syndrome; SLE: systemic lupus erythematosus)

vaginal administration is preferable compared to synthetic progesterone because it avoids the first-passage effect in the liver.[31]

Sometimes, patients with severe lupus damage such as significant renal insufficiency, may be suitable for IVF stimulation but not for pregnancy, as they might tolerate ovarian hyperstimulation but not the hemodynamic stress of pregnancy. So, IVF followed by embryo transfer to a gestational surrogate would be an option for such patients.

With respect to anticoagulation in women with SLE and APS the most appropriate approach seems to be the following **(Flowchart 1)**.[40]

KEY POINTS

- Preconception counseling and planning pregnancy in remission phase.
- Friendly ovarian stimulation
- GnRH agonist trigger
- Avoid OHSS
- Single embryo transfer
- *Coadjuvant therapy*: Anticoagulation, corticosteroids, and immunomodulators
- *Frozen embryo transfer*: Natural cycle, natural estradiol, transdermal route to be preferred.
- *Luteal phase support*: Natural progesterone and vaginal route.

FERTILITY AND ASSISTED REPRODUCTIVE TECHNOLOGY IN WOMEN WITH CHRONIC KIDNEY DISEASE AND RENAL TRANSPLANT RECIPIENTS

INTRODUCTION

Chronic kidney disease (CKD) is associated with reduced fertility and decreased pregnancy rates compared to the general population[41] and are estimated to affect 3% of women of reproductive age.[42] Women with end-stage renal disease can manifest with sexual dysfunction and infertility resulting from endocrine disturbance, vasomotor dysfunction leading to reduced libido, medications and psychological factors.[43] Overall, it can be estimated that pregnancy rates in the kidney transplant population is approximately 10% of the pregnancy rates of the general population, and pregnancy rates in the dialysis population are approximately 1% of the general population.[41]

FACTORS AFFECTING FERTILITY IN WOMEN WITH CHRONIC KIDNEY DISEASE

Endocrine Disturbances

The kidney plays an important role in the regulation of female sex hormones. In patients with CKD there is loss of GnRH pulsatility, which results in impaired luteinizing hormone (LH) and FSH cyclicity leading to hypoestrogenemia. The lack of cyclicity of gonadotropins and ovarian hormones, as well as persistent hypoestrogenemia and elevated LH and FSH results in anovulation.[44] Serum FSH concentration is normal or just slightly elevated due to loss of pulsatile GnRH release.

Graphic representation of the normal menstrual cycle and the menstrual cycle in chronic kidney disease is depicted in **Figures 1A and B**.[41]

Prolactin levels are also increased in 30–65% women with CKD, which may contribute to an anovulatory state. In women with CKD, reduction in renal clearance leads to increased serum prolactin, as well as decreased sensitivity to dopaminergic inhibition of prolactin synthesis causes upregulation of its production.[45] An increased serum prolactin concentration also contributes to HPO axis dysfunction. High prolactin inhibits gonadotropin secretion, leading to hypogonadotropic hypogonadism.

Mechanism of hypothalamic-pituitary-ovarian dysfunction in women with CKD is depicted in **Figure 2**.[41]

Menstrual Disorders and Functional Menopause

It has been observed that women with chronic kidney disease attain menopause approximately 5 years earlier than the general population.[46] These women often have a functional state of menopause which may be reversed after kidney transplantation or increasing the frequency of hemodialysis, with return of menstruation, ovulation, and fertility.[47]

Reduced Ovarian Reserve

Women with chronic kidney disease have lower anti-Mullerian hormone (AMH), as compared to the general population. A prospective cohort study of 163 women with CKD vs. healthy matched controls was conducted by Wiles K et al., and serum AMH levels were compared among these two groups and it was observed that AMH levels were significantly lower in women with CKD (stage 1–5).[48] It has been postulated that the interaction of uremic toxins and the ovary may play a role in decreased AMH secretion. Furthermore, CKD is a chronic inflammatory state, the inflammatory changes related to kidney dysfunction may be, in part, responsible for the reduction in ovarian reserve.[49]

Reduced Libido and Sexual Dysfunction

Sexual dysfunction among women with CKD is due to psychological and/or organic factors. Among chronically hemodialyzed women, 60–70% suffers from sexual dysfunction.[50]

MANAGEMENT OF INFERTILITY IN WOMEN WITH CHRONIC KIDNEY DISEASE

These approaches include intensive hemodialysis, kidney transplantation, and ART.

Intensive Hemodialysis

The effect of dialysis modality on fertility in women with end stage kidney disease (ESKD) is poorly understood. Various studies reveal that the pregnancy rates for women on hemodialysis are approximately twice the pregnancy rates for women on peritoneal dialysis.[51] The reason for the same is unclear.

Kidney Transplantation

Hypothalamic-pituitary-ovarian axis improvement after successful kidney transplantation in women with end stage renal disease, leads to return of menses and ovulation resulting in ten-fold increase of pregnancy rate as compared to women on hemodialysis. However, despite this improvement the pregnancy rate in kidney-transplanted women remains 10% of the general population.[47]

Fertility Preservation

Cyclophosphamide, an alkylating agent used to treat CKD due to glomerulonephritis, has gonadotoxic effect and decreases ovarian reserve. Use of cyclophosphamide should be avoided in young women if possible. Fertility preservation should be considered for all premenopausal women prior to initiation of cyclophosphamide therapy.[27] Ovarian protection with GnRH agonist throughout cyclophosphamide treatment should be considered.

Artificial Reproductive Techniques

It has been observed in various studies that the success rates of IVF in this population are similar to healthy controls and obstetric outcomes are comparable to natural pregnancy in stable kidney transplant recipients.[52]

IVF MANAGEMENT

- Women with renal transplantation should be counseled to plan pregnancy after 1 year of receiving renal transplant as the risk of rejection is highest in the first year.[53]
- Couples should be informed about risks involved with IVF treatment as well as the maternal and fetal risks during pregnancy including risk of OHSS, graft rejection, hypertension, and risk of prematurity and inherited renal disease.
- The patient should be advised to consult a nephrologist before planning fertility treatments to optimize renal function and shifting to immunosuppressant drugs that are safe in pregnancy. Mycophenolate mofetil should be stopped and patients should be switched to using tacrolimus or azathioprine 3 months prior to the infertility treatment.[54]
- The American Society of Transplantation Consensus Opinion recommends optimizing renal function before planning the pregnancy (serum creatinine <1.5 mg/dL, with <500 mg/24 h protein excretion).[55]
- If a patient is taking antihypertensive drugs like angiotensin-converting enzyme (ACE) inhibitors, then it should be replaced with pregnancy safe antihypertensives (i.e., labetalol or methyldopa) before pregnancy.[53,55]
- There should be no concurrent infections, no rejection in the past year and maintenance immunosuppression at stable dose before starting treatment.[55]
- Ovarian stimulation should be done with GnRH antagonist protocol using low dose gonadotropin and GnRH agonist trigger for final oocyte maturation to reduce the risk of OHSS and should be monitored closely. As renal transplant recipients are at higher risk for OHSS compared to the general population due to reduced renal clearance of gonadotropins that may lead to enhanced effect as approximately 10% of

gonadotropin is excreted through the kidneys.[56] OHSS can result in increased risk of thromboembolism and acute kidney injury resulting from ischemia or obstructive nephropathy.[57]

- The position of the transplanted kidney should be known before starting IVF treatment, because if the allograft kidney is situated in the pelvis that might lead to difficulty in accessing the ovaries during ovum pick up.
- A senior IVF consultant should be involved throughout the IVF treatment and oocyte retrieval.
- Single embryo transfer should be done due to increased risks of preeclampsia, diabetes, prematurity, and low birth weight babies in multiple pregnancies.
- For conditions such as Alport's syndrome, polycystic kidney disease, and preimplantation genetic testing (PGT) should be considered with appropriate genetic counseling.[54]
- Lastly, in patients with proteinuria and/or antiphospholipid antibodies, low molecular weight heparin prophylaxis and aspirin should be considered during the IVF process to decrease the risk of thrombosis.[58]
- Recent data demonstrated a live birth rate of around 75% in women who conceived a pregnancy after renal transplantation,[46,51] miscarriage and ectopic pregnancy rates were similar to the general population[47]

MATERNAL AND FETAL RISKS IN PREGNANCY[54,56]

- Hypertension in pregnancy is reported in 52–69% renal transplant recipients. Preeclampsia or eclampsia is also common and has been seen in 27% of them.
- There is a slightly increased risk of graft loss in pregnancy. Risk factors for graft loss include; prepregnancy hypertension, elevated prepregnancy creatinine, and proteinuria.[55]
- Risks in pregnancy such as miscarriage, preeclampsia, thrombosis, fetal growth restriction (FGR), preterm delivery, and stillbirth are increased.[41]
- Slightly increased risk of urinary tract infection and risk of other infections such as *Cytomegalovirus*, toxoplasmosis, varicella, human immunodeficiency virus (HIV), herpes and hepatitis B or C virus due to immunosuppressive therapy.[41]
- Increased risk of anemia in pregnancy that can be treated with iron (oral/intravenous if necessary) and erythropoietin.[52]

INFLAMMATORY BOWEL DISEASE AND ASSISTED REPRODUCTIVE TECHNOLOGIES

BACKGROUND

Inflammatory bowel diseases (IBDs) include Crohn's Disease (CD) and ulcerative colitis (UC). Women with inflammatory bowel disease (IBD) are often young and of childbearing age. The disease per se along with the medications used for its treatment may reduce fertility.

IMPACT OF INFLAMMATORY BOWEL DISEASE ON FERTILITY

Ulcerative colitis without previous pelvic surgery and inactive Crohn's disease do not impair fertility and have similar infertility rates as the general population.[59] However, active disease can impair fertility via various mechanisms including pelvic inflammation of the fallopian tubes and ovaries, reduced ovarian reserve, dyspareunia secondary to perianal disease, and adhesion or scarring from previous surgeries. Voluntary nulliparity due to fear of intimacy and disease transmission to offspring, poor body image (colostomy, perianal disease) and depression also play a role in fertility reduction.[60] Ileal pouch anal anastomosis (IPAA) in patient with ulcerative colitis leads to tubal dysfunction due to postoperative adhesion and scarring resulting in reduced fertility.[61] Delaying abdominal surgeries that spare the pelvis, such as colectomy with ileorectal anastomosis/subtotal colectomy, rectal stump creation and ileostomy, until childbearing is complete; they are all temporary measures that may preserve female fertility. Inflammatory bowel disease may reduce the ovarian reserve due to chronic inflammation, altered immune response, and the indirect influence due to use of anti-IBD medicines.[62,63] Therefore, patients with IBD should be referred to ART earlier than the general population, even as early as 6–12 months of attempts.[59]

EFFECT OF IBD ON ART AND PREGNANCY

A nationwide large data based Danish study concluded that the chance of a live birth following an IVF treatment was reduced in women with ulcerative colitis and Crohn's disease, compared to normal women and live birth was significantly reduced further in women with history of prior surgery.[64] However, recent studies have reported that the pregnancy and live births rates after IVF in patients with ulcerative colitis and Crohn's disease are comparable to that of the general population.[65,66]

Women with IBD are more likely to have pregnancy complications compared to age-matched controls. These include spontaneous abortion, small for gestational age (SGA), preterm birth and labor, and delivery complications. They are correlated with disease activity. The risk of congenital abnormalities in offspring from women with inflammatory bowel disease does not seem to be increased.[67]

IMPACT OF PREGNANCY ON INFLAMMATORY BOWEL DISEASE

During implantation and pregnancy, many physiological changes occur leading to fluctuation of immunological states. During implantation phase, proinflammatory Th1 state is prevalent while later Th2 response predominates till just before delivery.[68] So, these two diseases behave differently in pregnancy because Crohn's disease is known to be a Th1/Th17 disease, whereas UC is more Th2/Th17 driven.[69] Women with IBD who conceive during the remission phase, approximately 80% of them remain in remission throughout the pregnancy and in the postpartum period.[70] A recent study by Nielson et al., also demonstrated that the relapse rates of IBD in pregnant women were similar to that in nonpregnant women.[71]

MANAGEMENT DURING IN VITRO FERTILIZATION

- Preconception counseling, reviewing and optimizing medications, confirming disease remission (fecal calprotectin/colonoscopy) and ensuring optimal levels of vitamin D and hemoglobin levels are important measures before planning pregnancy in these women.
- Patients should be advised to start supplemental folic acid preconceptionally. Higher doses of folic acid supplementation should be prescribed [4–5 mg/day] for women taking sulphasalazine[59]
- Women should be in remission for at least 3–6 months before conception.[59]
- Methotrexate should be discontinued at least 6 months prior to conception because it may persist in tissues for long periods.[72] Thalidomide should be discontinued at least 1 month before planning for pregnancy.[73]
- If a patient with IBD is not able to conceive 6 months after surgery, they should be counseled for ART.
- Couples should be informed about the risk of IBD in offspring. The risk is greater for Crohn's disease and is much greater when both parents are affected.[58] A population-based study have shown that the risk of CD in first degree relatives of a CD case is almost 8-fold increased, whereas the risk of ulcerative colitis (UC) in first degree relatives of a UC case is 4-fold increased When both parents have IBD, the risk of developing IBD in the offspring was approximately 30% in a population-based study.[74] In Crohn's disease, transmission is more common from mother to child than from father to child, and female offspring are at higher risk than male offspring **(Table 5)**.[75]

TABLE 5: Safety of inflammatory bowel diseases (IBD) drugs in pregnancy.[25]

Risk in pregnancy	*Drugs*
Low risk	Sulfasalazine, mesalazine, thiopurines, corticosteroids, and antitumor necrosis factor (TNF) agents
Contraindication Methotrexate and thalidomide	
Avoid in first trimester	Metronidazole and ciprofloxacin

- Couples should be counseled regarding higher risk of small for gestational age, low birth weight, stillbirth, preterm prelabor rupture of membranes, and preterm delivery.[58]
- IVF stimulation protocols or anti-inflammatory/immunosuppressive agents do not significantly reduce the chance of a live-born child and women should continue on their current IBD regimen to maintain disease remission.

A Cochrane review on use of preimplantation steroid use concluded that there is no evidence that steroids helped to improve live birth rates in ART, but the use of glucocorticoids in a subgroup of women undergoing IVF was associated with an improvement in the pregnancy rates of borderline statistical significance.[76] The use of prophylactic antibiotics should be at the discretion of the gynecologist, but most gastroenterologists would suggest that unless absolutely necessary, avoid the use of antibiotics as some can cause a flare of disease.[58]

SUMMARY

- It is very important to maintain disease remission preconception at least 3–6 months before and throughout pregnancy.
- Pelvic dissection surgery as is done with creation of an ileal pouch anal anastomosis markedly affects fecundity.
- Active disease at time of conception and during gestation has been shown to lead to worse pregnancy outcomes.
- Rates for IBD flares are comparable in pregnant women and nonpregnant controls in women with clinical remission.
- All IBD medications except for thalidomide and methotrexate can be continued in patients who are planning on conceiving and in pregnant patients.
- A patient, who had IBD surgery and not conceived after 6 months, should be counseled for ART.
- Pregnancy and IBD increase the risk of VTE events. VTE risk assessment should be performed before conception and during pregnancy, especially in patients with active disease.

ART IN PATIENT WITH EPILEPSY

INTRODUCTION

Epilepsy is a major public health problem in all countries including India. Women of childbearing age account for 25% of people with epilepsy, and 3–4 pregnancies in every thousand occur in women with epilepsy.[77] Women with epilepsy are high-risk, all pregnancies in women with epilepsy should be planned, with optimization of medication regimens and seizure control occurring preconceptually to improve the outcome.[78]

PATHOPHYSIOLOGY OF REPRODUCTIVE AND ENDOCRINE DYSFUNCTION IN EPILEPSY

Reproductive endocrine disorders are common among men and women with epilepsy, resulting in lower rates of childbearing and reduced fertility.[79,80] The reasons for the changes in reproductive endocrine function are multifactorial and include psychosocial factors, comorbidity, the use of antiepileptic drugs and the epilepsy itself. The possible explanations for reproductive endocrine disorders related to epilepsy or antiepileptic drugs are as follows:[81,82]

- Direct influence of the epileptogenic lesion, epilepsy, or antiepileptic drugs on the hypothalamic-pituitary axis.
- Effects of antiepileptic drugs on peripheral endocrine glands and the metabolism of hormones and binding proteins.
- Secondary endocrine dysfunction of antiepileptic drugs related to weight changes or changes of insulin sensitivity.

Epileptic seizures and interictal epileptiform discharges, particularly with temporal lobe involvement, may disrupt the hypothalamic-pituitary axis by interfering with gonadotropin-releasing hormone (GnRH) pulsatility.[83] Sexual dysfunction, hormonal and neuroendocrine abnormalities, hypothalamic amenorrhea, premature menopause, polycystic ovary syndrome (PCOS), and anovulatory cycles are more common in women with epilepsy compared to the general population.[84,85]

Antiepileptic drugs (AEDs) may also have an effect on fertility, which induce the cytochrome P450 system (carbamazepine, phenobarbital, phenytoin, oxcarbazepine, primidone, and eslicarbazepine acetate) and leads to abnormal sex hormone levels.[86] Among the antiepileptic drugs, valproate (VPA) is more commonly associated with reproductive endocrine disorders such as hyperandrogenism, polycystic ovaries, menstrual disorders, anovulatory cycles, and PCOS. It has been suggested that valproate inhibits the conversion of testosterone to estrogen and also directly induces androgen synthesis in ovarian theca cells.[87]

Studies of reproductive function and fertility in men with epilepsy are fewer, but altered testosterone metabolism, hyposexuality, reduced testicular volume, reduced sperm concentration and motility as well as increased incidence of morphologically abnormal sperm has all been reported in association with epilepsy or AEDs.[88]

EFFECT OF HORMONES ON EPILEPSY

Female sex hormones affect neuronal excitability, with estrogens being mainly proconvulsant and progesterone and its metabolites being anticonvulsant.[82]

Excitatory effect of estrogen is primarily by influencing N-methyl-D-aspartate (NMDA), but also non-NMDA types of glutamate receptors are involved. Neural tissue and pituitary contain the enzyme 5 alpha reductase, which is able to convert progesterone to 3α,5α-THP within the brain. Production of this very effective anticonvulsant neurosteroid and intracellular progesterone receptors are responsible for the anticonvulsant effect of progesterone and its metabolites.

EFFECT OF EPILEPSY AND ANTIEPILEPTIC DRUGS ON IN VITRO FERTILIZATION

Recent studies suggest that the chance of live birth per embryo transfer is similar after IVF in women with and without epilepsy.[89] Regarding antiepileptic drugs, data are reassuring that these medications do not reduce the chance of live birth rate.

IMPACT OF EPILEPSY AND ANTIEPILEPTIC DRUGS ON PREGNANCY

Obstetric Complications

Most women (around 93–95%) with epilepsy have uncomplicated pregnancies and normal deliveries.[90] However, pregnancies of women with epilepsy pose a greater risk of complications particularly premature contractions, premature labor, delivery, stillbirths and neonatal deaths.[90,91] The risks of trauma, status epilepticus, or even death due to seizures and the psychosocial consequences need to be considered in all these women.[92] Tonic-clonic seizures have the highest risk for sudden unexpected death in epilepsy (SUDEP) and seizure related injuries.[93]

Fetal Complications

Impact of Antiepileptic Drugs

Automated external defibrillators have an effect on fetal and embryonic development and lead to an increased risk for major congenital malformations, neurodevelopmental delay and maladaptive behaviors, minor congenital anomalies such as facial dysmorphism and intrauterine growth retardation.

The risk of congenital malformations in children of women with epilepsy not using AEDs is found in the range of 1.1–3.3% and is similar to the risk of malformations in the general population (2.1–2.9%).[94] The risk of congenital defects in children of women with epilepsy and using AEDs is 4–9% and further increases with valproate and polytherapy.[95-97]

Monotherapy with newer antiepileptic drugs such as levetiracetam, lamotrigine, and oxcarbazepine is relatively safe in pregnancy.[98-100] The incidence of defects in children of mothers treated with AEDs depends not only on the type of AED but also on its dose. The risk of a defect increases with higher doses of a drug.[99] If women with epilepsy are required to continue AEDs during pregnancy then it is safer to use single AED with low teratogenicity and at the lowest effective doses possible.

Impact of IVF and Pregnancy on Epilepsy

Majority of women with epilepsy (55–80%) do not have seizures during pregnancy, whereas a third of them may experience an increase in the number of epileptic seizures. The data from the Epilepsy Pregnancy Registry report that seizures are observed in 14–32% of pregnant women.[101] Literature suggests that lamotrigine performs worse in seizure control while levetiracetam is one of the best drugs among newer antiepileptic groups in controlling maternal seizures during pregnancy.[102] The number of epileptic seizures occurring before pregnancy may predict seizure control during pregnancy. The occurrence of seizures one month before pregnancy increases the risk of seizures during pregnancy by 15-fold.[103]

An increase in the frequency of epileptic seizures may be due to decrease of plasma antiepileptic drugs level that may be because of increase in the volume of distribution, reduced plasma protein concentrations, increased renal clearance, and enhanced metabolism.[104]

In addition to pharmacokinetic factors, physiological factors (e.g., sleep deprivation, nausea, and vomiting), metabolic factors (increased sodium and water retention), hormonal factors (changes in estrogen and progesterone levels), and psychological factors (stress, anxiety, and noncompliance) also contribute to the increased frequency of epileptic seizures in pregnant women.[105,106]

PRECONCEPTION COUNSELING

Preconception counseling is very important for women with epilepsy and is a time to inform these patients about optimal care before, during, and after pregnancy. Ideally a joint obstetrician and neurologist counseling service should be available.

- Women with epilepsy should be informed to control the seizure at least 9–12 months prior to conception, as the best predictor of seizure control during pregnancy is the seizure control prior to pregnancy.[101]
- Couples should be informed in detail about the course of epilepsy during pregnancy.
- Re-evaluation of the diagnosis and need for continuation of antiepileptic medications should be decided prior to planning conception and strict compliance to antiepileptic medications should be encouraged and ensured during IVF and pregnancy.[107]
- Women should be reassured that risk of congenital malformations is low if they are not exposed to antiepileptics in the periconceptional period.[94]
- Risks of teratogenicity and possible adverse effect on long-term cognitive and neuro-developmental delay of the newborn following in utero exposure to antiepileptics should be informed. Based on limited evidence, in utero exposure to carbamazepine and lamotrigine does not appear to adversely affect neurodevelopment of the offspring.[98,99]
- Risk of congenital abnormalities in the fetus is dependent on the type, number and dose of antiepileptics.[99]
- If treatment with AEDs is necessary, monotherapy, and controlled release drugs should be used if possible to avoid the increased risk of congenital malformations associated with polytherapy regimens.[96]
- Appropriate medicine at the lowest effective dose with the least teratogenic risk should be offered to control the severity and frequency of seizures. Lamotrigine and levetiracetam that are not associated with significant increased risks of congenital malformations.[95] Lamotrigine blocks voltage-gated sodium channels and stabilizes their inactive state and levetiracetam inhibits the release of the excitatory neurotransmitter by binding to synaptic vesicle protein synaptic vesicle glycoprotein 2A (SV2A).
- If a change of antiepileptic drug is necessary, it should be done before pregnancy. The risks and benefits of reducing or changing medication should be fully discussed with the patients.
- It is recommended that all women with epilepsy planning conception should take folic acid (5 mg/day) before and during the early stages of pregnancy, primarily to reduce the risk of major congenital malformations and in particular neural tube defects.[78] Prepregnancy folic acid may be helpful in reducing the risk of AED-related cognitive deficits.
- Genetic counseling should be done, especially in case of maternal/paternal idiopathic epilepsy and a positive family history. The risk of a child developing epilepsy is dependent on the type of seizure disorder and the number of affected relatives. The risk of passing epilepsy to the child is very low; however, in specific cases, there is a risk of ~5–20% if one affected first-degree relatives and 25% if two first-degree relatives are affected.[108]

The risk of inheritance is lower if only the father has epilepsy compared with if only the mother has epilepsy.

The overall risk of a mother passing on idiopathic generalized epilepsy is 9–12%.[109] Most of the inheritable syndromes which include epilepsy in their phenotype are autosomal recessive, and there is therefore a low risk of children developing the condition.

MANAGEMENT DURING ASSISTED REPRODUCTIVE TECHNOLOGY

Assisted reproductive technology treatment for women should be started once antiepileptic drug dose and seizure control are optimized. Neurologist consultation is a must for fitness for general anesthesia and also carrying the pregnancy. Women undertaking IVF treatment should be made aware of the potential influence of ovarian stimulation, effect of estrogen and the stress of IVF on seizure frequency. Strict compliance to medications must be ensured before and during the treatment. Standard protocol for ovarian stimulation can be used and OHSS should be avoided.

MANAGEMENT IN EARLY PREGNANCY

Ideally pregnant women with epilepsy are considered high risk and careful management by both neurological and obstetric teams is essential. Women should be encouraged to continue to take high-dose folic acid throughout pregnancy. Ultrasonography (USG) should be done at 11–13 weeks to identify the neural tube defects and maternal serum α-fetoprotein to be measured at 14–16 weeks. The fetal anomaly scan at 18 + 0 – 20 + 6 weeks of gestation can identify major cardiac defects in addition to neural tube defects.[104] Serial growth scans are required for detection of small-for-gestational-age babies and to plan further management in women taking antiepileptic drugs. Based on current evidence, routine monitoring of serum AED levels in pregnancy is not recommended routinely, however it may be considered if suspicion of nonadherence, toxicity and intractable seizures is present.[110]

ART IN WOMEN WITH HYPERTENSION

INTRODUCTION

Chronic hypertension currently affects 1–3% of women of childbearing age, and is continuing an upward trend due to increasing maternal age and rising obesity rates.[110]

IMPACT OF HYPERTENSION ON IN VITRO FERTILIZATION OUTCOMES

Risks of hypertension in IVF patients are mainly related to its association with an increased incidence of hypertensive disorders in pregnancy.[111] There is no evidence that hypertension directly affects the success rate of IVF in terms of ongoing pregnancy rates or incidence of first-trimester pregnancy loss.[112] However, patients who undergo IVF are generally older and primiparous, which can affect the prevalence of chronic hypertension, as well as the risk of obstetric complications. Women with pre-existing hypertension are at risk of abnormal placental development predisposing to preeclampsia, FGR, and small for gestational age, gestational diabetes mellitus (GDM), placental abruption, preterm delivery, and stillbirth.[113] However, in patients with hypertension secondary to renal disease, pregnancy may cause renal dysfunction with potential irreversible loss of kidney function.

IMPACT OF IN VITRO FERTILIZATION ON HYPERTENSION

Women who conceive through ART are at increased risk of hypertensive disorders in pregnancy, including preeclampsia,[114] although the risk is variable and depends on the presence of pre-existing conditions (including chronic hypertension, obesity and PCOS) and the multiple gestations. Recent evidence has shown that FET is associated with higher risk of preeclampsia compared to fresh embryo transfer.[115,116] Although the mechanism by which IVF/ICSI increases the risk is unknown, the possible cause is attributed to a larger proportion of multiple births and to a higher prevalence of preeclampsia risk factors among women who conceive through ART, such as advanced maternal age, obesity, and medical comorbidities compared to women who conceive spontaneously.[117] However, the altered hormonal profile due to ovarian stimulation or the technology in itself, may play a role. Supraphysiologic concentrations of estrogen due to ovarian stimulation and its effect on increment of angiotensinogen and insulin-like growth factor I production by liver, increased sympathetic activity and increased expression of angiotensin-1 (AT1) receptor in the kidneys may increase the risk of hypertension and preeclampsia.[118,119]

The possible mechanism for the increased risk of hypertensive disorders of pregnancy in autologous frozen and donor oocyte fresh and frozen transfer is absence of the corpus luteum. Recent data suggests that the absence of the corpus luteum is associated with deficient maternal circulatory adaptations during early gestation[120] and increases the incidence of preeclampsia.[121,122] With oocyte donation cycles, it is possible that autoimmune factors associated with the use of donor gametes[123] as well as increased maternal age may also contribute to increased risk for hypertensive disorders.

There is no evidence to suggest that IVF treatment per se worsens pre-existing chronic hypertension in the long term.

However, in patients with hypertension secondary to renal disease, pregnancy may aggravate renal dysfunction with potential irreversible loss of kidney function.

PRE IVF AND PRECONCEPTION WORKUP AND ADVICE

- A detailed history, examination, and relevant investigations should be done to identify the cause of hypertension, especially to exclude any secondary causes. The most common secondary causes of hypertension in patients of childbearing age are renal and cardiac diseases.
- Women with newly diagnosed hypertension, onset before 30 years of age and without any positive family history, who are not evaluated previously should be evaluated thoroughly before any fertility treatment.
- Women with hypertension considering pregnancy should undergo investigations including a complete blood count, blood urea, serum creatinine level, liver function test, and a 24-hour urine collection to test protein and creatinine clearance[124,125]
- Additional testing includes evaluation of target organ damage, i.e., electrocardiogram (ECG) to detect left ventricular hypertrophy. If hypertrophy is detected, obtaining an echocardiogram should be considered. Ophthalmological examination to rule out hypertensive retinopathy and renal ultrasound examination to exclude renal scarring and hydronephrosis, polycystic kidney disease (especially in those patients with a positive family history that suggests an autosomal dominant inheritance pattern) should be performed if indicated prior to planning conception.
- Couples should be counseled regarding the risk of adverse pregnancy outcomes, lifestyle modification (weight management, exercise, healthy diet, and lowering the amount of salt in diet), strict adherence to antihypertensive medications and need of close monitoring in pregnancy.
- Genetic counseling and prenatal screening may be required in case of hypertension secondary to a hereditary condition (e.g., polycystic kidney disease).
- Women with hypertension should be advised to meet a general physician/cardiologist for optimization of blood pressure preconception.
- Couples should be informed about the risk of congenital malformations, if patient is on angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) drugs and should be advised to stop these drugs and switch to pregnancy safe antihypertensives.[126,127]
- Women with chronic hypertension not on treatment and planning to conceive should be offered antihypertensive if they have sustained systolic blood pressure of 140 mm Hg or higher or sustained diastolic blood pressure of 90 mm Hg or higher.[124]
- Home blood pressure monitoring should be explained and target blood pressure (BP) should be 135/85 mm Hg.[125]

ANTIHYPERTENSIVE MEDICATIONS

Patients should be advised to continue antihypertensive medications if they are safe in pregnancy, if not, then change to safer ones. First-line antihypertensive drugs are labetalol (combined α and β-adrenergic blocking agents) and methyldopa (α-adrenergic agonist).[110] Long-acting formulations of nifedipine (a calcium channel blocker) can be used as an additional second-line agent if blood pressure is not adequately controlled by labetalol or methyldopa.[110,128]

Propranolol has been associated with premature labor, and atenolol has been associated with intrauterine growth restriction; thus, these drugs are best avoided.[129] Angiotensin-converting enzyme (ACE) inhibitors should be avoided, as they have been shown to cause fetal anomalies such as renal dysgenesis and malformations of the cardiovascular and central nervous systems.[126,127] Diuretics are also contraindicated because of their presumed effect on placental blood flow, although accurate studies are lacking.[130]

Notably, antihypertensive treatment in pregnancy does not reduce the incidence of preeclampsia, rather provides protection against adverse outcomes due to severe or malignant hypertension **(Table 6)**.

IN VITRO FERTILIZATION MANAGEMENT

Patients with chronic hypertension should have blood pressure monitoring before, during and after IVF treatment, and secondary causes of hypertension and relevant comorbidities (e.g., diabetes mellitus and obesity) should be treated and monitored accordingly. Some studies have reported a higher incidence of pregnancy-induced hypertension after OHSS[131] but this was not found by others.[132]

TABLE 6: Recommendation for anti-hypertensive drugs.[111,129]

Drugs	*Indication*	*FDA category*	*Initial dose*	*Maximum dose*	*Potential side effects*
Methyldopa	First line	B	125–250 mg BD	500 mg QID	Lethargy psychosis
Labetalol	First line	C	100 mg BD	400 mg QID	Asthma exacerbation
Nifedipine	Second line	C	10–20 mg BD	40 mg BD	Synergistic action with magnesium sulfate for neuromuscular depression

Aspirin supplementation has been shown to reduce the risk of preeclampsia in high risk patients (e.g., a previous episode of severe preeclampsia, chronic hypertension, chronic kidney disease, and autoimmune disease). Low dose aspirin (75–150 mg/day) should be started from 12 weeks of pregnancy and continued until delivery to prevent preeclampsia.[124] Based on a recent meta-analysis, routine use of aspirin in IVF patients did not reduce the risk of hypertensive complications of pregnancy or preterm delivery.[133] Routine use of aspirin in all patients undergoing IVF should not be recommended.

There is no conclusive data on prescription of calcium supplements prior to IVF treatment, making its safety, and efficacy in IVF patients questionable.[134] Antioxidants (including vitamin C and E supplementation) do not reduce hypertensive complications of pregnancy.[135]

In patients with chronic hypertension, natural cycle FET protocol is preferred to avoid exogenous estrogen and single-embryo transfer is recommended to reduce the risk of blood pressure related adverse pregnancy outcomes in multiple gestation.

ART IN WOMEN WITH DIABETES MELLITUS

INTRODUCTION

Diabetes mellitus is a major public health problem worldwide.[136] Although the incidence of type 1 diabetes is growing slowly, there has been a very steep rise in the number of young adults diagnosed with type 2 diabetes.[137,138]

Reproductive dysfunction is seen in 20–40% of women with type 1 diabetes, manifesting as delayed puberty, primary amenorrhea, menstrual cycle disturbance, subfertility, pregnancy complications, and early menopause.[139-141] Type 2 diabetes in young women, particularly in the second and third decades of life, is associated with potential fertility and pregnancy implications.[138] The mechanisms of reproductive dysfunction in type 2 diabetes could be largely attributable to concomitant obesity, PCOS, and endogenous and exogenous hyperinsulinemia.

DIABETES AND FERTILITY

In type 1 diabetes, hyperglycemia due to insulin deficiency and hyperinsulinemia due to exogenous insulin leads to hypogonadism, polycystic ovarian morphology, and hyperandrogenism, resulting in reduced fertility.[139] Hypogonadotropic hypogonadism is seen in patients with type 1 DM having absolute insulin deficiency, as insulin is an important regulator of the hypothalamic-pituitary-gonadal axis[142,143] and another postulated mechanism being inhibitory effect of hyperglycemia on the hypothalamic secretion of GnRH.[144]

Insulin, insulin resistance, and hyperglycemia contribute to ovarian dysfunction in both type 1 and type 2 diabetes.[145] Exogenous or endogenous hyperinsulinemia in diabetes leads to stimulation of ovarian granulosa cells, increasing follicular recruitment and prevents the recruitment and growth of dominant follicles, leading to anovulation, polycystic ovarian morphology, and subfertility **(Fig. 3)**.[146,147]

IMPACT OF DIABETES ON ASSISTED REPRODUCTIVE TECHNOLOGY OUTCOMES

Evidence on the efficacy of ART in women with type 1 and type 2 diabetes is sparse. A nationwide Danish cohort study was conducted by Larsen et al., and it was concluded that biochemical pregnancy and live birth rate per embryo transfer was significantly lower in women with type 2 diabetes as compared to women without diabetes and

similar results were observed in both normal weight and obese women.[148] While, women with type 1 diabetes had biochemical pregnancy, clinical pregnancy and live birth rate similar to women without diabetes **(Flowcharts 2 and 3)**.[149-151]

Maternal diabetes may impair oocyte quality and its developmental competence by disturbing the metabolism in granulosa cells and their communications with the oocyte.[152,153]

Risks due to DM in pregnancy for both mothers and children are well established, and could be influenced by the type and duration of diabetes, glycemic control, and diabetes related complications. Fetal risks include miscarriage, preterm delivery, stillbirth, perinatal mortality, congenital anomalies, small/large for gestational age (SGA/LGA), shoulder dystocia and birth injury, neonatal hypoglycemia, polycythemia, hypocalcaemia, and respiratory distress syndrome.[154]

EFFECT OF IVF AND PREGNANCY ON DIABETES

In vitro fertilization stimulation per se does not affect the blood sugar level. Various studies suggest that pregnancy resulting from ART treatment, particularly blastocyst transfer as compared to cleavage stage embryo, is associated with slightly increased risk of GDM, therefore proper monitoring is needed during pregnancy.[155] The higher rate of GDM in these patients, independent of age and parity, may be due to cause of infertility, types of drugs used, changes in the hormonal environment due to increased hormone levels during ovarian stimulation and early pregnancy and presence of underlying metabolic and vascular factors[156] However, recent studies has observed that ART was not associated with increased risk of GDM when adjusted for age, parity, and body mass index (BMI).[157] Women with diabetes may have progression of their disease during pregnancy, and careful management of diabetes is necessary before and during pregnancy. Maternal complications for women with preexisting diabetes include worsening of preexisting retinopathy and nephropathy, as well as increased risk for hypertension, preeclampsia and operative delivery.[158]

PRECONCEPTION CARE AND IN VITRO FERTILIZATION MANAGEMENT

- Prepregnancy planning and counseling in women with type 1 and type 2 DM has beneficial effects in terms of reducing congenital malformation by 50%, perinatal mortality by 80% and preterm delivery by 50%.[159]
- Couples should be counseled to achieve optimal diabetes control before planning the pregnancy, as glycemic control can avoid risk of malformations and reduce the risk of miscarriage, stillbirth, and neonatal death. The American Diabetes Association (ADA) 2016 guideline defines an optimal preconceptional control as preprandial glucose <100 mg/dL, postprandial <140 mg/dL and glycated hemoglobin (HbA1c) of <7%.[160]
- Couples should be informed and educated about the association between HbA1C levels >7.0% at the time of conception and increased risk for major congenital malformations.[160] Mechanism of congenital malformation is not clear, although animal studies have revealed that pregestational diabetes mellitus induces oxidative stress that activates cellular stress signaling leading to dysregulation of gene expression and excessive apoptosis in target organs, including neural tube and embryonic heart.[161]
- Patients should be counseled for behavioral modification (diet and exercise) and weight reduction before conception. American college of obstetricians and gynecologists (ACOG) 2018 guidelines on pregnancy and obesity recommends a 5–7% weight loss before conception.[162]
- Periconceptional folic acid 5 mg is recommended as diabetes increases the risk of neural tube defects by 3 fold.[160]
- Detailed history and evaluation should be done, all medications should be reviewed and drugs with teratogenic risks should be replaced with pregnancy safe medications. Glyburide and metformin are classified as Food and Drug Administration (FDA) category B drugs and can be continued in pregnancy if sugar level is well controlled on these two drugs.
- Couples should be counseled about maternal and fetal risks during pregnancy.
- Ophthalmological, renal and cardiac evaluation should be done before starting fertility treatment. Multidisciplinary team approach including obstetrician, fertility specialist, ophthalmologist, nephrologist, and cardiologist is advisable.
- Thyroid function tests should be done in women with type 1 diabetes, as 10–20% of these women have autoimmune thyroid disease.[159]
- Relative contraindications to pregnancy include retinopathy requiring light amplification by stimulated emission of radiation (LASER) treatment until treatment is undertaken or eye status is stabilized, nephropathy with serum creatinine >200 μmol/L or HbA1c level >10%.[159]
- IVF and embryo transfer should be planned only after adequate blood glucose control.
- Single embryo transfer is recommended to avoid complications due to multiple gestations.

CONCLUSION

Assisted reproductive technology treatments in women with underlying chronic medical conditions have become increasingly frequent and nowadays the average women's age at marriage and child bearing is increasing which further increases the risk of medical illnesses. These patients may pose a significant risk during ovarian stimulation, embryo transfer or during pregnancy as their medical problems may get aggravated or may cause life-threatening risk during pregnancy or teratogenic effects on the fetus or

obstetric complications. Therefore, it is important for clinicians to identify women who are at increased risk, to provide appropriate and detailed counseling, and follow risk-reduction strategies. Prior identification and preparation of the patient at increased risk of complications will enable the clinician to avoid problems in advance, anticipate the necessary management and optimize the outcomes. A multidisciplinary team approach is necessary for management of these patients. All pregnancies in such women should be planned with optimization of the clinical conditions while in the remission phase of the disease to improve the maternal and fetal outcome. Presentation for fertility treatment offers an excellent opportunity for clinicians to improve the preconception health and maximize obstetric outcome in these patients. The literature on the efficacy of ART in women with different chronic diseases is still limited and further research is needed in future.

SECTION

4 Male Infertility

CHAPTER 24

Etiopathogenesis of Male Infertility

Haritha Mannem, Sathya Balasubramanyam

INTRODUCTION

Infertility has become a public health problem affecting approximately 1 in 10 couples globally.[1] Male infertility alone contributes to nearly 60% of the problem and has turned out to be a key health concern; the incidence of male infertility ranges from 2.5 to 12% across different regions around the world **(Fig. 1)**.[2]

The impaired spermatogenesis and functions can be associated with factors which act at pretesticular level, at the level of testis, or at post-testicular level. Primary testicular failure is responsible for nearly 75% of all infertility due to male factor, while genetic factors can be acknowledged in around 15% of cases [congenital hypogonadotropic hypogonadism (cHH), primitive testicular failure, and congenital absence of vas deferens (CAVD)].

The factors implicated in male infertility can also be grouped as:

- *Congenital factors:*[3]
  - Anorchia
  - CAVD
  - Cryptorchidism
  - Genetic anomalies [karyotype anomalies such as Klinefelter syndrome (KS), microdeletions in the Y chromosome, Kallmann syndrome (KLS), partial or mild androgen insensitivity syndrome, and mutations in genes which are involved in hypothalamic–pituitary–gonadal axis].
- *Acquired factors:*[3]
  - Testicular torsion
  - Testicular trauma
  - Subobstruction or obstruction of proximal and/or distal part of urogenital tract

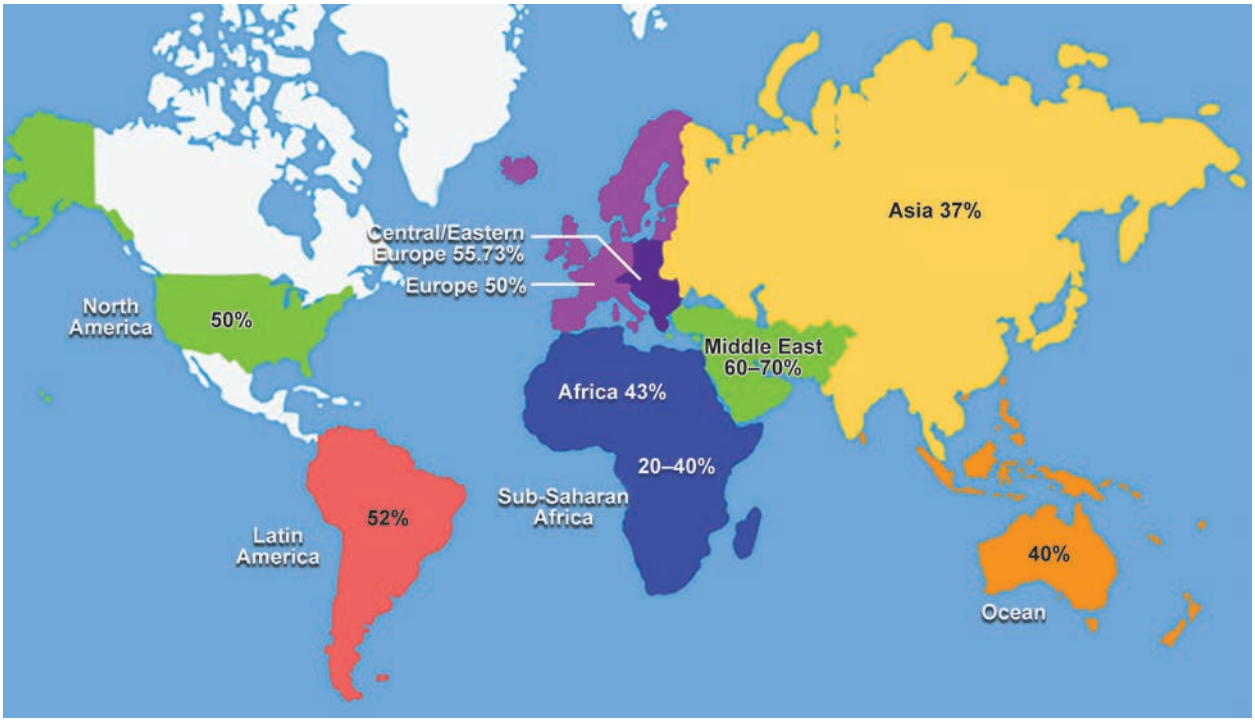

Fig. 1: World map containing percentages of infertility cases per region that are due to male factor.

BOX 1: Causes of male infertility [World Health Organization (WHO)].

- Idiopathic
- Isolated abnormalities of semen and sperm parameters
- Varicocele
- Immunological infertility
- Genital tract infection
- Primary testicular failure
- Kallmann syndrome
- Klinefelter syndrome
- Cryptorchidism
- Obstruction
- Ejaculatory dysfunction
- Erectile dysfunction
- Genetic causes: Y chromosome microdeletion

Note: The exact etiopathological mechanism through which varicocele and antisperm antibodies contribute to male infertility remains to be elucidated.

  - Postinflammatory forms (orchitis, epididymitis)
  - Recurrent urogenital infections, prostatitis, and prostatovesiculitis
  - Systemic diseases such as cirrhosis of liver and renal failure
  - Varicocele
  - Exogenous factors such as medications, irradiation, cytotoxic drugs, and heat
  - Surgeries which can cause damage to the testicular vascularization
  - Erectile or ejaculatory dysfunction
  - Acquired hypogonadotropic hypogonadism (AHH).
- Idiopathic forms:[3]
  - Unknown etiology (around 50%).

In a large World Health Organization (WHO) study (involving in excess of 8,500 couples from 25 countries), a standardized classification system for categorizing the several etiologies of male infertility was published **(Box 1)**.[4] This study showed that the most common etiology of male infertility belonged to the *idiopathic abnormalities of the semen* category (25%), followed by varicocele.[5]

A diagnostic evaluation is necessary (1) to identify reversible or treatable ailments, (2) to select patients for assisted reproductive techniques, and (3) in genetic counseling and preventive measures such as preimplantation or prenatal diagnosis to protect the offspring.[3] Mostly, the diagnosis of male infertility is based on a single laboratory value of the semen analysis, which decides the plan of treatment for the infertile male. So, it is not the patient who is being treated, but the sperm which has turned into the cellular patient. The semen analysis picture, in majority of the situations, does not give any hints to the underlying pathology.[6]

PRETESTICULAR CAUSES

This etiological classification of infertility comprises chiefly two types of pathological disorders, i.e., hypogonadotropic hypogonadism (HH) and coital disorders such as erectile dysfunction and ejaculatory disorders, i.e., ejaculatio precox and retrograde ejaculation.

Hypogonadotropic Hypogonadism

The deficit of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion can be congenital or acquired, i.e., associated with a primary lesion in the pituitary gland or secondary to inadequate hypothalamic gonadotropin-releasing hormone (GnRH) production.[7,8] Hypogonadotropic hypogonadism is of the following types:

- Congenital
- Secondary (hypogonadotropic) hypogonadism, i.e., secondary testicular failure
- Idiopathic HH
- Hyposmic or anosmic (KLS)
- Normosmic
- Acquired, i.e., tumors in:
  - Diencephalon such as craniopharyngioma or meningioma
  - Hypothalamus or pituitary
- Skull base fractures
- Empty sella syndrome
- Granulomatous illnesses
- Hyperprolactinemia
- Ischemia or hemorrhagic lesions in hypothalamus
- Radiotherapy
- Drugs or anabolic steroids.

Congenital Hypogonadotropic Hypogonadism

Patients with cHH have faulty or reduced secretion of GnRH, manifesting as pubertal delay and low levels of gonadotropins. cHH when associated with anosmia or hyposmia is known as Kallmann syndrome (KLS). Patients with KLS and cHH could present as sporadic or inherited cases with autosomal dominant, autosomal recessive, and X-linked modes of inheritance. KLS (cHH with olfactory abnormalities) is caused by mutations in genes concerned with the development and migration of GnRH neurons, while mutations in genes which are implicated in GnRH secretion at the level of hypothalamus cause normosmic cHH.[9] Kisspeptin-1 (encoded by the *KISS1* gene) is the most potent regulator of GnRH secretion and puberty onset. Patients with these mutations have azoospermia which is resistant to gonadotropin stimulation.[10,11]

Kallmann Syndrome

Patients with KLS have HH, delay in puberty, infertility, and anosmia or hyposmia.[12] The incidence of KLS is around 1 in 10,000 male births and is inherited as a sporadic condition or as an X-linked recessive trait.[13] KLS has both genetic and phenotypic heterogeneity with multiple genes.[14] KLS 1 (*KAL1*) and fibroblast growth factor receptor 1 (*FGFR1*)

are the *KLS* genes which are most researched. As men with this syndrome have paucity of GnRH-releasing neurons, endocrine assessment shows untraceable levels of LH and FSH and very low testosterone. These males with failure to achieve puberty, barring a few cases of spontaneously reversible KLS,[15] have paucity of intratesticular testosterone, lack of FSH, and hence incomplete spermatogenesis. The defective development of the olfactory tract can be diagnosed by scanning with magnetic resonance imaging (MRI). In some cases, other defects such as cerebellar dysfunction, cleft palate, red–green color blindness, and congenital deafness are present.[16]

Diagnosis can be made by genetic testing guided by the pattern of inheritance and additional phenotypic features.[17,18] After diagnosing, hormonal treatment is planned to accomplish two key purposes: inducing virilization and normal development, thus improving fertility status. In patients with prepubertal hypogonadism, androgen replacement alone is sufficient to attain normal androgen levels and development of secondary sexual characteristics. On the other hand, stimulus for sperm production requires treatment with human chorionic gonadotropin (hCG), i.e., hCG in conjunction with human menopausal gonadotropins (hMGs) or recombinant FSH or urinary FSH, but if the origin of HH is hypothalamic, a substitute to hCG treatment is pulsatile GnRH.[19]

Acquired Hypogonadotropic Hypogonadism

Acquired hypogonadotropic hypogonadism, as opposed to cHH, is postnatal onset of disorders which damages or changes the functioning of pituitary gonadotroph cells and/or GnRH neurons. Though tumors of the pituitary gland (chiefly prolactinoma) are the major cause of AHH, other disorders such as tumors of the sella or hypothalamic or infundibular cyst, iron overload, infiltrative and vascular disorders, head trauma, pituitary surgery, and cranial or pituitary radiotherapy may also lead to AHH.[20,21] The clinical presentations of AHH are subject to age of onset, the rapidity of its onset, the amount of gonadotropin deficit, and the relationship to other pituitary deficiencies or excess. These men lack stamina, suffer from erectile dysfunction, and have decreased libido and overall poor quality of life with low self-esteem. If the hypogonadism is of acute onset, the general physical examination is typically normal. Decreased facial and body hair, reduced muscle mass, gynecomastia, facial wrinkles, and hypotrophic testes are seen in chronic and complete AHH.

Men with AHH having significant testosterone deficiency improve with testosterone replacement therapy, i.e., by using an injectable testosterone ester. Fertility can be restored rather fast as long as there is no primary testicular damage and the spouse is fertile.[22] Serious illness, acquired immunodeficiency syndrome (AIDS), stress, malnutrition, illicit drug intake, excessive alcohol consumption, exhausting exercise, systemic illnesses such as hemochromatosis, and sarcoidosis may also be linked with transient HH.[23]

Coital Disorders

This category includes disorders such as erectile dysfunction and ejaculatory disorders (ejaculatio precox and retrograde ejaculation). To make precise diagnosis, a systematic andrological workup is required so as to exclude organic causes of erectile dysfunction (i.e., neurogenic and vascular) and other coexisting morbidities. Retrograde ejaculation or anejaculation is seen in patients with diabetes mellitus, postretroperitoneal lymph node dissection, bladder neck surgery, multiple sclerosis, and in patients with spinal cord injury. Retrograde ejaculation is diagnosed on the basis of absence of spermatozoa in the semen but its presence in the urine postmasturbation, and in such circumstances in vitro fertilization with embryo transfer (IVF with ET) is the only dependable option. In patients with anejaculation caused by spinal cord injury, the effective methods for sperm retrieval are electroejaculation and vibrostimulation, while pregnancy can be achieved by intracytoplasmic sperm injection (ICSI). Medical treatment is an extensively available option for most patients with premature ejaculation and erectile dysfunction. Psychosexual therapy is an effective therapeutic choice for patients affected by psychogenic erectile dysfunction and premature ejaculation.[24,25]

TESTICULAR CAUSES

Primary Testicular Disease

Primary testicular disease is the most common type of decreased male fertility. Testicular deficiency is due to primary spermatogenic failure as a result of conditions barring hypothalamo–pituitary axis disorder and obstructed male genitourinary tract. Testicular deficiency has multiple etiologies, and it manifests as severe oligoasthenoteratozoospermia (OAT) or nonobstructive azoospermia (NOA).[26]

Etiologies of Testicular Deficiency

- Congenital, i.e., anorchia
- Genetic anomalies such as karyotypic aberrations and Y chromosome deletions
- Dysgenetic testes or cryptorchidism
- Acquired, i.e., trauma to the testis
- Torsion of the testis
- Testicular tumor
- Postinflammatory types, mainly mumps and orchitis
- Varicocele
- Systemic diseases such as cirrhosis of liver and renal failure
- Miscellaneous extrinsic factors such as anabolic or cytotoxic drugs, radiotherapy, and heat

- Surgical procedures which compromise testicular vascularization and cause testicular atrophy
- Unknown etiology: Idiopathic.

Testicular Dysgenesis Syndrome

Increasing trends have been observed in testicular malignancies and congenital abnormalities of the male reproductive tract with a drift toward poorer quality of semen. Additionally, many of these illnesses have similar risk factors. Skakkebæk et al. in the year 2001 recommended the term testicular dysgenesis syndrome (TDS) for this group of conditions that represent a syndrome of disorders caused by similar underlying entity, which leads to disturbance in the testicular development during fetal life.[27] TDS has an unclear etiology, but the rapid upsurge in male reproductive disorders in a few generations indicates environmental changes and changes in the lifestyle instead of genetic factors as the likely causes **(Flowchart 1)**.[28]

Testicular Dysfunction Syndrome

Basic etiological factors in TDS are genetically determined in utero and environmental factors such as endocrine disrupting compounds, toxins, and lifestyle factors like dietary habits, lack of exercise, and obesity act as contributing factors. The consequence is androgen insufficiency predisposing to testicular maldescent and Sertoli cell dysfunction leading to impaired spermatogenic function. Impaired germ cell (GC) differentiation can also lead to testicular carcinoma in situ.[27]

Cryptorchidism

Cryptorchidism is the most frequent congenital defect in male newborns. It can either occur as isolated defect or as syndromic cryptorchidism (i.e., in conjunction with other congenital anomalies).[28] Two key hormones and their receptor systems are involved in testicular descent, namely testosterone and its receptor, i.e., androgen receptor (AR) and insulin-like factor 3 (INSL3), and its G protein-coupled receptor, i.e., relaxin family peptide 2 (RXFP2).[29] The INSL3/RXFP2 system is vital for the first phase of descent of testis, while the inguinal phase requires the involvement of androgens. Syndromic cryptorchidism is predominately a result of mutations in the *AR* gene.[30] It is believed that increased temperature exposure to the intra-abdominal testicles leads to the damage of seminiferous tubules and GCs. Another contributing factor in partially maldescended testis positioned in the inguinal canal or at the root of the scrotal neck is much easily exposed to the risk of trauma. Possibility of torsion is also very high in a maldescended testis.[31,32]

GENETIC CAUSES

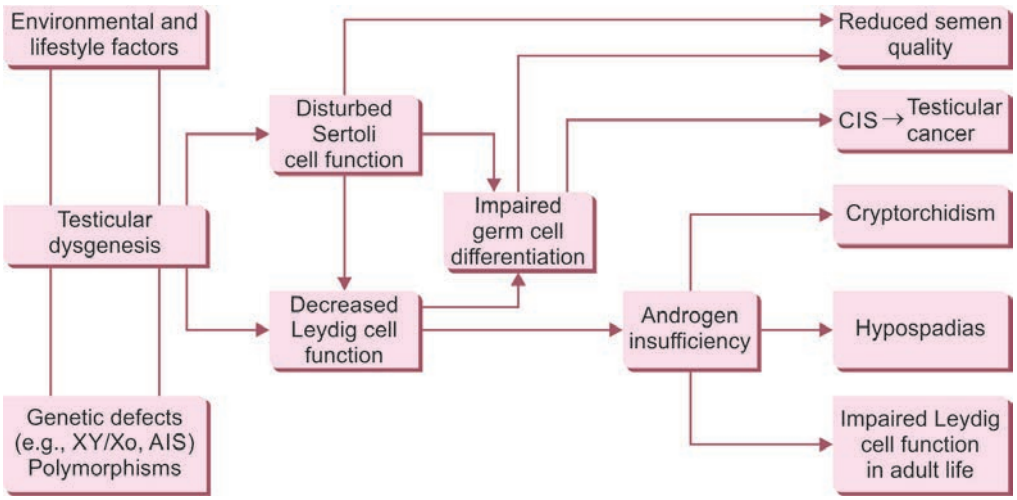
Chromosomal Abnormalities

Spermatogenesis needs the concerted action of more than 2,000 genes and mutation of any of these genes may be accountable for infertility. With progresses in genetics and diagnostic methods, a lot of the men previously labeled under "idiopathic" are reclassified as having genetic etiology of male infertility. The genetic factors can be transmitted as autosomal dominant, autosomal recessive, X-linked, and Y-linked traits.

There is a higher incidence of chromosomal aberrations among infertile men, mainly aneuploidy, and its incidence ranges from 2 to 15%, which depends on the severity of impairment of spermatogenesis.[33]

Autosomes can undergo recombination along their full length while pairing and recombination of X–Y sex chromosomes is limited to small homologous pseudoautosomal areas, and this is why sex chromosomal aneuploidies are the most common genetic anomalies in men.[34]

Flowchart 1: Schematic representation of pathogenetic links between the components of testicular dysgenesis syndrome.



(AIS: androgen insensitivity syndrome; CIS: carcinoma in situ)

The majority of chromosome aberrations are caused during the meiotic phase.[35] Severely impaired production of sperm is often in association with a higher frequency of structural and numerical chromosomopathies.

Patients having less than 10 million sperms/mL have 10 times more incidence (i.e., around 4%) of autosomal structural defects in comparison to the common population. Men with severe oligozoospermia (i.e., less than 5 million sperms/mL) have an increased frequency (7–8%), while men with NOA have the highest frequencies (15–16%).[36]

Klinefelter Syndrome

Klinefelter syndrome (47,XXY) is the most common karyotyping aberration in males with severe infertility and azoospermia, followed by terminal deletions in the Y chromosome (Yq-) and structural autosomal aberrations. The incidence of KS is 1 in 500. Most patients with KS have 47,XXY karyotype while around 20% bear 47,XXY/46,XY mosaics or structurally abnormal X chromosome or higher grade sex chromosomal aneuploidy. The starting point of an extra X chromosome is nondisjunction in meiosis I. This extra X chromosome is derived paternally in around 60% of the patients with KS. Increased maternal age is associated with KS while increased paternal age is contentious.[37]

It manifests clinically as infertility, cognitive disorders, and hypergonadotropic hypogonadism. The spectrum of phenotype varies with the presence of mosaicism and the amount of genetic inactivation.[38,39] There is a progressive degeneration of Sertoli cells and GCs after puberty in patients with KS.[40] Microsurgical testicular sperm extraction (microTESE) (sperm recovery rate of 30–50%) with ICSI may allow patients with Klinefelter to have their own progenies.[41-45]

Fluorescence in situ hybridization (FISH) studies have questioned the genetic integrity of gametes and a research based on ICSI in combination with preimplantation genetic diagnosis (PGD) reported a substantial drop in the frequency of normal embryos in Klinefelter couples, i.e., 54% as compared to 77.2% in controls.[46]

Other Sex Chromosomal Abnormalities

The karyotype 47,XYY has an incidence of 1/1,000 live births and it is the second most common sex chromosomal aneuploidy.[47] Nondisjunction during meiosis II gives rise to the extra Y chromosome. These men may have a normal phenotype, but other characteristics such as infertility, clinodactyly, high stature, cognitive impairment, hypertelorism, and hostile behavior can be seen. Increased incidence of spermatozoa with chromosomal abnormality, especially sex chromosome disomies in the semen of men with this karyotype, is reported.[48,49]

A rare chromosomal anomaly is a 46,XX male which is seen in 0.9% of azoospermic males. Delay in puberty, infertility, and gynecomastia are the common manifestations, while genital ambiguity like cryptorchidism and hypospadias are a rarity. Two variations of this condition are known.

The first variant is the sex-determining region Y (SRY) + XX males, which accounts for majority (80–90%) of the cases and is due to the translocation of the *SRY* gene. Men with this variant usually have a normal male phenotype, but all are azoospermic.[50] The other variation is the SRY – XX males, in whom no copy of SRY is found. The male phenotype in these cases is either owing to mutations in X-linked genes or autosomal genes which are involved in the sex-determining cascade, such as *DAX1* and *SOX9* genes, that substitute the SRY. Patients with this variant are more probable to have incomplete masculinization.[51,52]

Autosomal Abnormalities

The commonly found abnormalities in men with oligozoospermia are Robertsonian translocations, paracentric inversions, reciprocal translocations, and marker chromosomes. The underlying relationship between chromosome abnormalities and impaired production of sperm is recommended to be a structural effect related to modifications in the chromosomal synapsis during meiosis.[53,54]

Robertsonian Translocations

Robertsonian translocations take place when there is a fusion of long arms of two acrocentric chromosomes (13, 14, 15, 21, and 22), resulting in genetic material loss on the short arms. These are the most common structural abnormalities, seen in 0.9% of infertile men and in 1/1,000 live births.[9] These men have a higher incidence of aneuploidy in the sperm with a likelihood of passing on the translocation to progeny.[55] Thus, chromosomal composition of their sperm should be analyzed; PGD should be done and genetic counseling for the couples should be offered.[56]

Autosomal Inversions

Autosomal inversions are structural chromosomal derangements, which do not cause loss of genetic material and are of utmost relevance for male infertility, seen in 3–5% of the men with infertility.[57,58] Carriers of inversions in chromosome 9 may show normozoospermia, oligospermia, azoospermia, or asthenozoospermia. These males have an increased incidence of sperm aneuploidy as well.[59]

Y Chromosome Microdeletions

It is the most common molecular genetic cause of severe spermatogenesis impairment, seen in around 10% of NOA and 3–5% of men with idiopathic oligozoospermia.[60] The euchromatin zone in the long arm of the Y

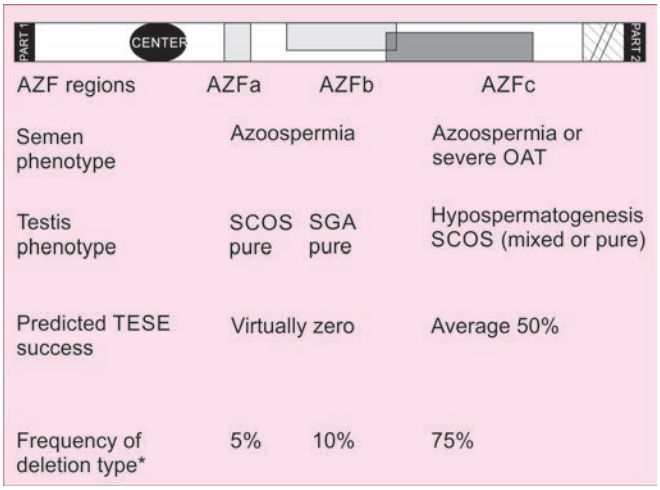


Fig. 2: Classification of azoospermia factor (AZF) region. (OAT: oligoasthenoteratozoospermia; SCOS: Sertoli cell-only syndrome; SGA: spermatogenic arrest; TESE: testicular sperm extraction)

*Rest 10% of deletions are due to deletion of more than one AZF region.

chromosome (Yq11) contains the azoospermia factor (AZF) region, which has genes important for spermatogenesis. Based on their location, these genes are grouped into three groups, namely—AZFa, AZFb, and AZFc **(Fig. 2)**.[61]

- The group AZFc is positioned in the distal part of Yq11 which accounts for 60% of all Y chromosome microdeletions.[62,63] AZFc group has numerous genes, and the DAZ (deleted in azoospermia), a group of four genes which are involved in spermatogenesis, has been the most researched.[64] Men who have AZFc deletions frequently present with severe azoospermia. By using microTESE, viable sperm can be collected in around 50–60% of the men with azoospermia.[65] Yq microdeletions have to be identified for diagnosing and in prognosticating prior to testicular biopsy (TESE).[66,67] Biopsy of the testis is not recommended when there are complete AZFa and AZFb deletions of the Y chromosome as the probability of finding spermatozoa is essentially zero. Y deletions which are compatible with the sperms being there in the ejaculate or in the testis are transmitted to the male progeny; thus, the role of genetic counseling is vital.

Mutations and Polymorphisms Affecting the Androgen Receptor

The *AR* gene is positioned in the long arm of the X chromosome (Xq11–12). *AR* gene mutations are infrequent, seen in 1/20,000–1/64,000 males. Around 300 mutations have been reported in the *AR* gene. These mutations lead to a variable phenotype from a phenotypic female in case of complete androgen insensitivity syndrome to an underandrogenized male having ambiguous genitalia in case of partial androgen insensitivity syndrome.[68-71]

Syndromic Monogenic Defects

Bardet–Biedl Syndrome

This group of disorders is characterized by mental retardation, obesity, hypogonadism, polydactyly, renal anomalies, and retinal pigmentary dystrophy.[72,73] Other additional characteristics are small stature, dental anomalies, diabetes mellitus, and deafness. Male hypogonadism includes micropenis, cryptorchidism, and hypospadias. It is a rare syndrome with incidence <1 in 100,000 newborns. Bardet–Biedl syndrome is mainly inherited as an autosomal recessive disorder, but other complex types of inheritance patterns exist.[74,75]

Prader–Willi Syndrome

Prader–Willi syndrome is a neurobehavioral group of disorders which affects both females and males and it manifests clinically as infantile hypotonia, mental retardation, delay in achieving developmental milestones, obesity, and hypogonadism. The prevalence of Prader–Willi syndrome ranges from 1/10,000 to 1/15,000.[76]

Primary Ciliary Dyskinesia

Primary ciliary dyskinesia is also called immotile cilia syndrome. It constitutes a group of disorders which are genetically heterogeneous, caused due to poor motility or complete immotility of the cilia leading to the lack of mucociliary clearance of the airways and other ciliated organs.[77] Most males suffering from primary ciliary dyskinesia are infertile due to functional and structural abnormalities in the central portion of the sperm flagella leading to immotile spermatozoa. About 50% of these patients also show situs inversus and then this condition is known as Kartagener syndrome. The mode of inheritance is autosomal recessive in the majority of cases.

Noonan Syndrome

Noonan syndrome is characterized by short stature, facial dysmorphism with posteriorly rotated ears, and congestive cardiac failure (mainly hypertrophic cardiomyopathy or pulmonary stenosis). 50% of the patients with this syndrome have oligozoospermia or azoospermia because of bilateral cryptorchidism. The mode of inheritance of Noonan syndrome is autosomal dominant with incidence around 1/1,000–1/5,000 newborns.[78]

Monogenic Defects in Post-testicular and Primary Testicular Forms of Male Infertility

Post-testicular Form: Congenital Absence of the Vas Deferens

The congenital unilateral absence of the vas deferens (CUAVD) is associated with oligozoospermia. Congenital

bilateral absence of the vas deferens (CBAVD) is a post-testicular disease which is characterized by the absence of the vas deferens bilaterally, leading to blockade in transport of the spermatozoa from the testis or epididymis to the distal genitourinary tract. CBAVD is also seen in the majority of male patients with cystic fibrosis (CF), the most common autosomal recessive disease in Caucasians. CF has an incidence of 1 in 2,500 newborns.[79] It is caused by mutations in CF-transmembrane conductance regulator (*CFTR*) gene, present on chromosome no. 7 that encodes CFTR protein (anion channel) which is involved in chloride conduction across epithelial cell membranes like in the lung and pancreas.[80-82] In 80% of males with CBAVD, mutations in the *CFTR* gene are seen. In excess of 1,950 CFTR mutations have been recognized.[83] Patients with severe mutations progress to developing CF, the most common lethal genetic disease in Caucasians, whereas men with mild mutations may present only with CBAVD which is seen in about 1% of infertile men, and in up to 25% of men with obstructive azoospermia (OA). The ejaculatory ducts and seminal vesicles may also be absent in these patients.[84] A meta-analysis showed that 78% of men with CBAVD have a minimum of one CFTR mutation, and 46% with two mutations. Men with CBAVD are candidates for sperm retrieval from testis or epididymis coupled with ICSI.[85,86] Genetic testing for *CFTR* mutation is obligatory, not only for patients with CBAVD but also for their spouses, as 1 out of 25 individuals are asymptomatic carriers of a mutation.[79]

Association of CBAVD with OA and chronic sinopulmonary disease is known as Young syndrome, which was thought to be associated with CF. However, no increased frequency of *CFTR* mutations is found in these patients, suggestive of the fact that Young syndrome is a CF-independent disorder and probably owing to mercury poisoning in childhood.[87]

Epigenetics

Epigenetics is the study of various processes [such as deoxyribonucleic acid (DNA) methylation, chromatin remodeling, post-translational histone modifications, and regulation of microribonucleic acids (miRNAs)] which change the expression of genes without altering the DNA sequence. Changes in these epigenetic factors are involved in the pathophysiology of numerous male infertility conditions and are possibly accountable for various cases of idiopathic male infertility.[88] Additionally, these epigenetic processes may well be the mechanism by which various conditions such as obesity and environmental exposure affect spermatogenesis and thus affect the progeny.[89-91]

Deoxyribonucleic Acid Damage

Deoxyribonucleic acid damage is caused due to breaks in the single strand and double strand which are not repaired. These breaks in the strands are created during meiosis I, to let recombination happen, as well as during spermiogenesis, to avoid supercoiling and to allow unwinding of the nucleosomal structure.[92] These breaks may perhaps also be made due to the release of reactive oxygen species (ROS) because of various causes, such as prolonged epididymal transit, incomplete apoptosis, varicocele, environmental chemical exposures, and diabetes mellitus.[93-95] During spermatogenesis, GCs with more amount of irreparable DNA fragmentation may be directed toward apoptosis,[96] but some escape it and become defective sperm. Both these mechanisms lead to male infertility, and increased DNA fragmentation has been linked with decreased rates of pregnancy.[97-99]

Acquired Testicular Causes

Varicocele

Varicocele is defined clinically as a palpable, elongated, tortuous, and dilated testicular pampiniform plexus of veins in the spermatic cord. It is the most common treatable cause of infertility due to male factor. Its prevalence in men with primary infertility is around 35%,[100,101] whereas approximately 70–85% of men with secondary infertility present with varicocele.[102] As per a study involving 9,034 men, varicocele affected 11.7% of the total male population. This estimate has risen to 25.4% among infertile males with abnormal semen parameters. Likewise, decline in the motility and concentration of sperm has been seen in men with varicocele.[103,104]

Torsion Testis

Testicular torsion is a surgical emergency which is due to twisting of the spermatic cord and its contents. Its annual incidence is 3.8 per 100,000 males (<18 years).[105] Torsion testis is a diagnosis which is made clinically, with manifestations such as severe acute pain in the unilateral scrotum, nausea, and vomiting.[106-108] The degree of damage caused by torsion directly depends on time duration between the onset of torsion and intervention. Sometimes, this is misdiagnosed as epididymo-orchitis and the patient is put on conservative management for many days and ends up with complete loss of testicular function.

The various mechanisms which cause testicular deterioration in cases of torsion are:

- Cellular hypoxia or ischemia
- Ischemia or reperfusion injury
- Microcirculation changes
- Leukocyte or endothelin interaction
- Reactive nitrogen species and ROS
- GC apoptosis or caspase pathway
- Postinflammatory obstruction
- Proteolytic enzymes.[109]

Subfertility is seen in 36–39% of the patients following torsion. In long-term follow-up of these cases, only 5–50% may have normal semen analysis. Detorsion with early surgical intervention (with mean torsion time <13 hours) preserves fertility. Fertility is jeopardized with prolonged periods of torsion (mean torsion time ~70 hours) and following orchiectomy.[110]

Trauma

Trauma to the testis is fairly uncommon regardless of the vulnerable location of the testis. The likely reason attributed to low incidence of severe injuries is the mobility of scrotum. Injuries to the testis deserve a cautious approach as it is important to preserve fertility. On the basis of mechanism of injury, there are three types of testicular injuries: (1) Blunt trauma, (2) penetrating trauma, and (3) degloving trauma. These kinds of traumatic injuries are usually seen in the 15–40 years age group.[111]

There are two factors that provide protection to the testes from minor trauma:

1. Physiologic hydrocele: Small amount of serous fluid which separates the tunica albuginea from the tunica vaginalis so that the testis can slide freely within the scrotal sac.
2. The testes are allowed to move freely within the genital area because they are suspended by spermatic cord within the scrotum.

Secondary to trauma, intratesticular hematoma and edema develop which exert pressure on the vascular architecture of testis compromising the arterial supply which in turn leads to ischemic injury.[112]

Infections (Orchitis)

This is another common cause of acute scrotum, which usually coexists with epididymitis. The causative agents may be subdivided into viral and bacterial. Viral orchitis is most common because of the hematogenous spread, and the causative organisms may be paramyxovirus (the virus that results in mumps), coxsackie, varicella, lymphocytic choriomeningitis, and Marburg virus.[113,114] Mumps orchitis is rare in prepubertal boys but may occur in 15–30% of pubertal or postpubertal men. Mumps orchitis may be associated with infertility in 25% of bilateral cases and testicular atrophy is a sequelae in 30–50% of affected testicles. Bacterial orchitis may be caused by the spread of bacteria from the epididymis. Common pathogens include gonorrhea, chlamydia, gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas*), and gram-positive cocci. Orchitis may present with testicular swelling, pain, fever, and acute hydrocele. Acute infections may be associated with a transient reduction in semen parameters, which often recover after resolution of the infection. In addition, orchitis may affect fertility by the direct effect of the organism as well as pressure-induced necrosis of the seminiferous tubules due to parenchymal edema within the testicle.[115-117]

Tumors (Testicular Cancer)

It is one of the most common cancers among young men. Its etiology is unclear; however, it has been proposed that testicular cancer in situ (CIS), which is a precancerous condition of testicular GC tumor, starts during the fetal life, and thus the disease originates prenatally.[118,119] Testicular cancer leads to impaired quality of semen and infertility even before the cancer develops.[120,121] Its incidence has risen over the past 40–50 years in most of the developed countries.[122,123]

Gonadotoxic Drugs and Radiation

Ionizing radiation poses risk of damage in all living creatures, but the testes in mammals are far more susceptible to damage by ionizing radiation as they lie outside the body.[124] The level of damage is proportional to the dose of radiation and exposure time to radiation. It has been reported that there is reduction in sperm count after treatment with low-dose irradiation to testis while moderate- to high-dose irradiation can result in severe reduction in sperm count or even azoospermia. On an average, a person is exposed to 2.1 mSv natural radiation annually.[125] Sources of artificial radiations include radionuclides present in eating and drinking materials, X-rays used in medical diagnostic procedures, and gamma rays produced as by-products in the nuclear industry and products formed during atmospheric nuclear testing.

A multicenter prospective study conducted at Center for the Study and Conservation of Eggs and Human Sperm (CECOS) network of France has published interesting data on radiotherapy and sperm parameters. The results showed significant reduction in sperm count and sperm motility at 3 months postirradiation, which remained significantly low until 12 months. The sperm count and motility reached control values only after 24 months postirradiation.[126,127] Spermatozoa cryopreservation must be advised to all patients before treatment. It may be advisable to go for GC preservation in patients who have not achieved puberty and in whom spermatogenesis has not yet begun.

A large number of patients need medications for a long duration of time starting at an early age. These medications can affect male reproduction through direct gonadotoxic effects, central hormonal effects, effects on sperm function, etc., but these effects are often inadequately considered and studied **(Table 1)**.[128]

Immunological

Antisperm antibodies (ASA) are present in 3–12% of men being evaluated for infertility. Their production may arise from:

TABLE 1: Medications negatively affecting male fertility.

Drug class	*Specific medications*
Antibiotics	Erythromycin, gentamicin, neomycin, nitrofurantoin (high dose), tetracycline
Antihypertensives	Alpha-blockers, beta-blockers, CCBs, spironolactone, thiazide diuretics
Chemotherapeutic agents	Busulfan, carmustine, chlorambucil, cisplatin cyclophosphamide, cytarabine, lomustine, melphalan, mustine, nitrogen mustard, procarbazine, vinblastine
Hormones	Anabolic steroid, antiandrogens, estrogens, progesterone derivatives, testosterone
Miscellaneous agents	Allopurinol, cimetidine, colchicine, cyclosporine, sulfasalazine
Psychotherapeutic agents	Lithium, MAOIs, phenothiazines, SSRIs, TCAs

(CCB: calcium channel blocker; MAOIs: monoamine oxidase inhibitors; SSRIs: selective serotonin reuptake inhibitors; TCAs: tricyclic antidepressants)

- Breakdown of blood–testis barrier (BTB)
- Inoculation of host with sperm antigens
- Failure of immunosuppression.

Infection of the genitourinary tract is a potential risk factor for developing ASA. It has been postulated that ASA affects fertility by the agglutination of sperm, prevention of cervical mucous penetration, and the inhibition of the oocyte–sperm fusion.[113]

Lifestyle Factors

Reports of decreasing semen quality have prompted interest in the potential impact of environment and lifestyle on male reproductive potential. For the last 40 years, there has been a dramatic turnaround in the factors which can cause changes in semen parameters. These factors include the excessive use of cell phones, sudden upsurge in usage of marijuana,[129] opioids, and growth in the population of cigarette smokers.[130] Moreover, obesity rates have rapidly increased,[131] and physical activity rates and levels of environmental pollution have decreased. Meanwhile, global surface temperatures have increased substantially. It is important for providers and patients to recognize and manage modifiable risk factors that can improve fertility potential for men.[132]

Post-testicular Causes

Post-testicular causes constitute around 15% of all infertility in the male. This category includes the subobstructive or obstructive lesions of the seminal tract (proximal or distal), inflammations and infectious illnesses of accessory glands, and autoimmune infertility. In bilateral obstructive lesions, there is azoospermia, i.e., no spermatozoa in the ejaculate. Disorders which affect the accessory glands characteristically have low volume of ejaculate since around 90% of the ejaculate finds its origin from the seminal vesicles and prostate. However, in other post-testicular conditions, a different grade of impairment in the sperm parameters (i.e., sperm count, motility, and morphology) is seen.[133] The presence of leukocytes in excess of 1 million/mL is suggestive of inflammation of accessory glands. In cases labeled as having autoimmune infertility (seen in <5% of infertile males), there is an autoimmune reaction against the spermatozoa. The ASA are the result of past inflammations and infectious diseases of the testis or epididymis, which led to the disruption of the hematotesticular barrier. If >80% of motile spermatozoa are coated by ASA, it is suggestive of a pure immunological factor as the likely cause and the lone therapeutic option available in such a scenario is IVF.[134,135]

Obstructive Lesions

Obstructive lesions that affect the male genital tract can be congenital or acquired. Intratesticular obstruction is infrequent and can involve seminiferous tubules or the rete testis. Intratesticular obstruction is seen in 15% of males with OA.[136] Acquired forms (i.e., postinflammatory or post-traumatic) are more common compared to the congenital forms. The network channels which form the rete in the mediastinum of the testis are obliterated by fibrous tissue. There is no reduction in testicular size as sperm production is normal.

- *Epididymal obstruction:* This is the most common cause of OA, which affects 30–67% of men with azoospermia. Congenital obstruction of the epididymis frequently manifests as CBAVD and is often in association with at least single mutation of the *CF* gene in approximately 82% of the cases.[137] Congenital epididymal obstruction comprises Young syndrome, i.e., chronic sinopulmonary infections. On the other hand, acquired forms which are secondary to subclinical (e.g., chlamydial) and acute (e.g., gonococcal) epididymitis are the most common. Trauma or surgical interventions may be the other causes.[136,138]
- *Vas deferens obstruction:* This is the most common cause of acquired obstruction after vasectomy; therefore, around 2–6% of these patients undergo vasectomy reversal.[139-142] Vas deferens obstruction may also happen following repair of hernia. CBAVD is the most common congenital cause of vas deferens obstruction, which is frequently accompanied by CF. Unilateral agenesis is associated with contralateral seminal duct anomalies in 80% of the cases, while it is associated with renal agenesis in 26% of the cases.[143,144]
- *Ejaculatory duct obstruction:* This is seen in around 1–3% of cases of OA[145] and has two main types: cystic or postinflammatory. Postinflammatory obstructions commonly occur due to urethroprostatitis,[146,147] while

cystic obstructions are mostly congenital (i.e., Müllerian duct cyst or ejaculatory duct cysts or urogenital sinus) and are classically located in the midline. Complete obstructions are usually associated with low semen volume, acidic pH, and decreased or nil seminal fructose. There is typical dilatation of seminal vesicles (anterior–posterior diameter >15 mm).[137,148,149]

- *Functional obstruction of the distal seminal ducts:* This abnormality might be accredited to local neuropathy, which is frequently in association with urodynamic dysfunction. There is impairment in transport of sperm which may be idiopathic or due to selective serotonin reuptake inhibitor (SSRI) medication.[150,151]

INFLAMMATION

The effect of any inflammation or infection of the male reproductive tract on fertility relies on many factors, including the chronic versus acute nature of the disease and the type of invading pathogen **(Flowchart 2)**. Nonetheless, noninfectious inflammatory reactions may also affect the male reproductive tract. The key mediators of the inflammatory response in the male reproductive tract are the proinflammatory cytokines, interleukin (IL)-1a, IL-1b, and tumor necrosis factor-alpha (TNF-α).[152,153]

Inflammation of the testicles may cause spermatogenic arrest and a decline in serum levels of testosterone and LH, thus affecting the dual functions of spermatogenesis and steroidogenesis.[154,155]

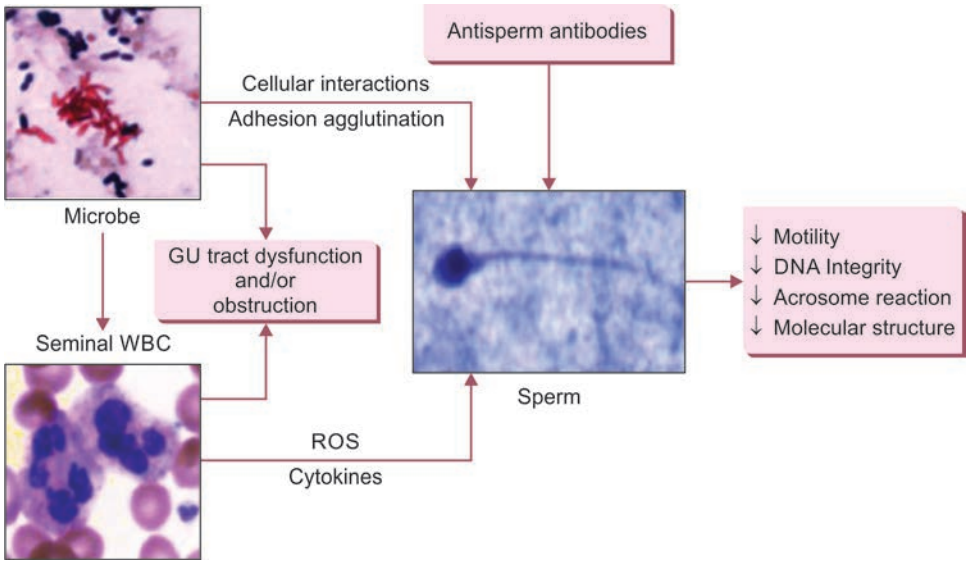
The secretion of both TNF-α and IL-1a during the inflammatory response causes an inhibition of steroidogenesis by Leydig cells.[156,157] In inflammatory states of the male reproductive tract, oxidative stress is generated primarily by the infiltrating leukocytes and the proinflammatory cytokines. Phagocytosis by infiltrating phagocytes causes enhanced oxygen consumption and generation of large amounts of ROS.[158,159]

Inflammatory and infectious conditions of the male reproductive tract may also cause infertility owing to damage of the reproductive tract organs affecting their function (changing the production or release of the secretions required to support sperm function) and due to scarring of the delicate ductal systems and following anatomic obstruction. Nonregenerative epithelial cells lining the epididymis and testis are mainly vulnerable to scarring.[160] The result of such scarring is stricture formation, which may occur in the ejaculatory ducts, thus leading to a reduced ejaculatory volume and impaired fertility.[161]

INFECTIONS—EFFECT ON THE MALE REPRODUCTIVE TRACT

Male genitourinary tract infections are possibly correctable etiologies of male infertility. According to the WHO, urethritis, orchitis, epididymitis, and prostatitis are considered to be male accessory gland infections (MAGIs).[25] Infectious organisms could have a direct negative influence on sperm by directly interacting with sperm cells or potentially have a negative influence on fertility by a secondary effect either through the inflammatory process inherent in the infection or due to the release of toxins. Any infection of the male genital tract causes an inflammatory response whereby the body's immune system tries to fight off this infection. Gram-negative bacteria are one of the main causative infectious agents implicated in the male reproductive tract, which induce an inflammatory response due in part to the release of the endotoxin lipopolysaccharide which is present in the cell wall **(Fig. 3)**.

Flowchart 2: Possible mechanisms of impaired male fertility due to reproductive tract inflammation.



(DNA: deoxyribonucleic acid; GU: genitourinary; ROS: reactive oxygen species; WBC: white blood cells)

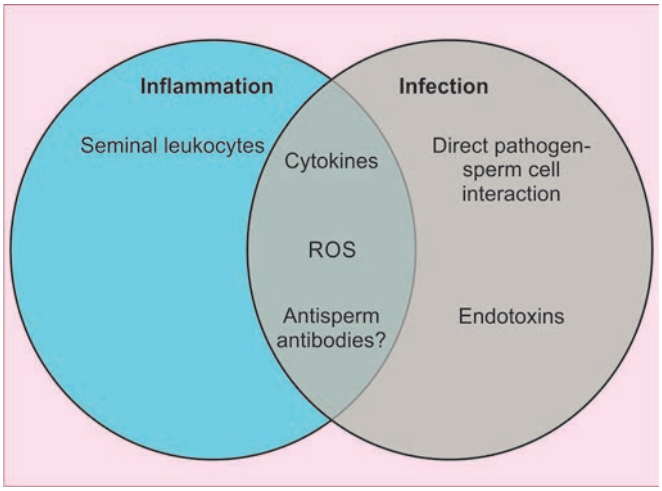


Fig. 3: Synergistic effect of inflammation and infection leading to male reproductive tract dysfunction and/or obstruction. (ROS: reactive oxygen species)

Infections may also impair fertility due to the direct effect of the pathogen on the sperm cell. Several bacterial and viral pathogens are also known to interact with and cause damage to spermatozoa, including *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *E. coli*, and hepatitis B virus (HBV).[162,163] *E. coli* is known to adhere to spermatozoa and can lead to sperm agglutination, while *U. urealyticum* impairs sperm nuclear chromatin integrity. HBV reduces sperm motility by triggering a loss of mitochondrial membrane potential.[164]

The post-testicular type is diagnosed on the basis of physical examination (testicular volume is classically normal, signs of vas deferens or epididymal agenesis or cyst or obstruction), normal FSH values, and sonography of the scrotum with or without transrectal ultrasound (to pinpoint the level of obstruction and better visualize the accessory glands). Additionally, microbiological tests should be done in suspected cases of prostatitis or prostatovesiculitis or epididymitis and in patients with history of recurrent urogenital tract infections (in the patient or in his partner). The pathogens such as Chlamydia and Ureaplasma should be searched for using a urethral swab, while other pathogens can be analyzed in the urine and seminal fluid. Screening for *CFTR* gene mutations in case of CAVD (without kidney malformations) and congenital epididymal malformations is required both in the patient and in his partner.

REACTIVE OXYGEN SPECIES

Presently, almost 50% of men suffering from infertility cannot be diagnosed with a definite cause for their problem. This condition in men is labeled as unexplained infertility and is defined as couples in whom routine semen examination is normal, and the factors accounting for female infertility have been extensively ruled out.[165] There are substantial amounts of data that associate oxidative stress with the etiology of male infertility.[166] ROS production is linked to sperm physiology owing to its role in various sperm processes, including maturation, capacitation, hyperactivation, acrosome reaction, and sperm–oocyte interaction.[167] Pathological ROS levels are similarly implicated in causing significant damage to proteins, lipids, and nucleic acids (both nuclear and mitochondrial genomes) in human spermatozoa.[168]

The key sources of ROS production in seminal fluid include activated leukocytes, mainly neutrophils and macrophages in the seminal plasma. Semen leukocytes produce 1,000 times more ROS than spermatozoa. Immature and morphologically abnormal spermatozoa are other key sources of ROS in semen. However, the main cause of ROS production in human spermatozoa is oxidative phosphorylation reaction in sperm mitochondria.[169] Intrinsic origins of ROS can be attributed to deficient or damaged sperm and several other etiologies, such as infection or inflammation, varicocele, cryptorchidism, testicular torsion, and aging.

A major difference in DNA fragmentation between fertile and general population men could be explained by an environmental attack on the latter. Spermatozoa have limited defense mechanisms against oxidative attack on their DNA, mainly due to the tight packaging of sperm DNA and the absence of a precise DNA repair system. In such cases, the ROS metabolites attack DNA bases (guanine in particular) and phosphodiester bonds, destabilizing these molecules and thus creating the conditions which eventually lead to DNA fragmentation. The essential requirement for accurate transmission of genetic material and the birth of healthy progeny is sperm DNA integrity. It has also been recognized that the male factor is accountable not only for fertilization, but also for correct embryo development.[170,171]

EFFECTS OF CORONAVIRUS DISEASE 2019 ON MALE FERTILITY

The world has faced a major pandemic threat through the outbreak of novel coronavirus disease 2019 (COVID-19). The various studies conducted during this period have concluded that COVID-19 not only affects lungs but also causes functional and histopathological changes in various other organs including male genital tract.

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) enters host cells through a complex process, which starts with the interaction of its spike protein with angiotensin-converting enzyme 2 (ACE2) (receptor) on host cells.[172]

As testis is protected by a BTB, it is partially immune to many microorganisms; however, some viruses, such as the mumps virus, were shown to cross the BTB and cause localized testis inflammation in the form of orchitis.[173,174] It has been shown that ACE2 is strongly expressed at the

protein levels in the testicular cells. This high expression suggests that testes in the COVID-19 infected males may have a significant role in the viral persistence and replication.[175] More specifically, ACE2 is expressed in seminiferous tubules cells along with Leydig and Sertoli cells in testes.[176] It was also observed that ACE2 expression in testes is age-dependent. According to this, the highest and lowest expressions of ACE2 occurs in patients aged 30 and 60, respectively.[177] It was observed that cells which express TMPRSS2 for S protein (which can initiate the viral internalization process) on their surface have enhanced SARS-CoV-2 isolation in them.[178]

The TMPRSS2 expression is prominently found in the epithelial cells of the human prostate gland more specifically in the apical surface of the luminal cells. This high TMPRSS2 expression in the prostate can also be related to COVID infection and can be another point of weakness of the male reproductive system.[179] The SARS-CoV-2 can also have a role in affecting the production of LH, FSH, and testosterone as well.[180] In a study conducted, SARS-CoV-2 was isolated in semen in 26.70% of COVID-19 patients in the acute phase and 8.70% of the patients in the recovery phase.[181] COVID infection also causes inflammatory response in the body, which leads to leukocyte infiltration even in testis. This can interfere with the Leydig cells' normal function and testosterone production and also cause BTB damage and seminiferous epithelium destruction. Additionally, leukocytes can lead to autoantibody development and autoimmune responses in seminiferous tubules via inflammatory cytokines.[182] An increase in levels of serum IgG was reported in both SARS and COVID-19 patients. Therefore, SARS-CoV-2 might trigger secondary autoimmune responses in testis and result in autoimmune orchitis.[183] Most of the viral infections including COVID-19 result in redox homeostasis abnormalities in the body leading to ROS overproduction and developing an ideal situation for replication of the virus further.[184]

The negative effects noticed in the male semen characteristics can also be due to unexpected side effects of unindicated and overuse of COVID-19 medications such as steroids.

Still, at this point of research, the clinical and epidemiological evidence regarding the effects of COVID-19 on reproductive health and future infertility of male patients is scarce to conclude. As COVID-19 is a newly emerged disease with recurring waves, further follow-up studies on reproductive effects and outcomes of affected and recovered patients as well (especially those who are of the reproductive age group) are required.

FACTORS THAT HELP IN PROGNOSTICATING MALE INFERTILITY

Factors that help in prognosticating male infertility are:

- Infertility duration
- Types of infertility—primary or secondary
- Semen analysis parameters
- Partner's age and fertility status.

In infertile couples on follow-up for 2 years with oligozoospermia as the chief cause of infertility, the overall pregnancy rate is around 27%.[185] The age of the female partner is the single most important variable that influences the outcome in assisted reproduction.[186]

KEY POINTS

- Understanding the etiology and pathogenesis of male infertility will help clinicians in achieving the right diagnosis and offering appropriate counseling to the patient about the pathology and treatment options.
- Multidisciplinary input between reproductive medicine specialists, endocrinologists, and surgeons may be required in some cases to optimize treatment.
- As our understanding about etiology and pathogenesis improves, novel treatment options are bound to come, and many conditions might be tackled by medical and lifestyle management rather than opting for assisted reproduction technology (ART).

CHAPTER 25

Clinical and Endocrinological Evaluation of Infertile Male

Radha Pandiyan, S Sowbarnika, D Ramesh Raja, N Pandiyan

INTRODUCTION

Male infertility evades a precise definition. Semen analysis gives a descriptive picture about the spermatozoa and does not necessarily confirm whether the man is fertile or infertile except in extreme situations such as azoospermia, aspermia, total asthenozoospermia, total necrozoospermia, and total teratozoospermia.

World Health Organization (WHO) defines infertility as "A disease affecting the physical, mental, and psychological well-being of the individual." Recent statistics from WHO[1] quote that infertility affects 15% of couples worldwide, while male factor infertility has been acknowledged widely to contribute to 40–50% of the infertile couples.[2]

An unpublished observation for a duration of 2 years, in the Department of Andrology and Reproductive Medicine, Chettinad Academy of Research and Education, Chennai, India, states that the incidence of male factor infertility accounts for about 14% among the total infertile couples.

Sadly, the role of the male partner is diminished to that of a "spermiator" providing semen samples on demand in many infertility clinics. It was also wrongly believed that there is no role for the Andrologist in the present intracytoplasmic sperm injection (ICSI) era.

As the field of human reproduction is ever evolving to reach newer heights, male factor infertility too deserves equal focus, if not more than the female partner. Assisted reproduction is often performed today for male factor infertility. It is needless to say that there is a compelling need to train not only specialists in andrology but also provide working knowledge to the general practitioners in the field of andrology—to identify correctable problems and to refer them to the proper center as early as possible for the correct approach and management.

AIM OF EVALUATION OF THE INFERTILE MALE

This primarily targets the assessment of spermatogenic and endocrine function:

- To identify the probable cause and treat it for achieving spontaneous pregnancy, if possible
- To refer patients with irremediable causes for higher reproductive technologies
- To diagnose and offer concurrent genetic counseling in specific circumstances
- To diagnose testicular malignancies and pituitary lesions, which may be associated with infertility[3] as the leading complaint. This latter may become a cause for sexual dysfunction **(Table 1 and Box 1)**.

TABLE 1: Causes for male infertility.[3]

Causes	*Percentage*
Varicocele (?)	12
Primary idiopathic testicular failure	10
Male accessory gland infection	7
Abnormal sperm morphology	6
Sexual problems	2
Other seminal fluid abnormalities	4
Decreased sperm motility	4
Immunological causes	3
Azoospermia owing to obstruction	1
Endocrine and other causes	4
No demonstrable cause	47

BOX 1: Provocative causes for male infertility.

Provocative causes

Lifestyle factors:[4]
- Smoking
- Alcohol, drug usage
- Obesity

Environmental factors:
- Endocrine-disrupting chemicals[5] (plastics, perfumes, food additives, food storage materials, children's products)
- Environmental toxins[6] (fertilizers, industrial solvents, lubricants, pesticides)

Pharmaceutical drugs[7]

Radiation[8,9]
- Mobile phones, laptops, microwaves, Wi-Fi gadgets, wireless devices, X-rays, nuclear radiation

PRINCIPLES OF MANAGEMENT OF THE MALE PARTNER

Evaluation and management of a male partner should focus on the following:

- Initiating and maintaining spermatozoa production
- Testicular endocrine function
- Treatment of genital tract infections, if any
- Management of retrograde ejaculation
- Decreasing free radicals and enhancing spermatozoa motility
- Correcting sexual dysfunction, if present.

PART I: CLINICAL EVALUATION OF INFERTILE MALE

History

A detailed history brings the significant factors[10] affecting the fertility of the individuals to light and a simple correction of them would restore their fertility. Gametes being the single and specialized cells in the human body are very much liable to be influenced by any disturbances in the health status of the individual. The following sections will help in understanding various factors influencing fertility of the individual.

Prerequisites for History Taking

- The consultation room should offer total privacy, a calm atmosphere, and a comfortable setting for the couple.
- The female partner is encouraged to be present along with the male partner during history taking—at least initially; this is preferable, unless not desired by either or both of them.
- Patients should be allowed to present their history without interrupting their flow of thoughts, at the same time guiding them back to the point, if they go astray. A recent study found that patients are often interrupted within 40 seconds of their narration.[11]
- It is the clinician's duty to provide adequate time to the couple for discussion. Questions should be encouraged from both partners for free discussion and guidance.

Age of the Male Partner

Though the age of the female markedly influences the outcome of treatment to a greater extent, the age of the male partner, especially after 40 years,[12] has a significant impact too. Aneuploidies are more common in the embryos generated by older men leading to increased pregnancy losses.[13,14]

There is a natural decline in testosterone levels in aging men; they may also have other underlying systemic illnesses, both leading to sexual dysfunction as a result of the illnesses per se and/or as side effects of the medications used.[15]

Occupational and Environmental History

Specifically, occupations involving direct handling of chemicals, pesticides, and radiation[9] would certainly impact semen parameters and lead to infertility.[16,17] A pilot study by Benziger et al. clearly brought out the impact of mobile phone irradiation on the motility of semen samples.[8]

Kesari et al. also explain in their review paper that exposure to radiofrequency electromagnetic fields (RF-EMFs) inhibits the cellular metabolism which leads to oxidative stress, which in turn raises the reactive oxygen species (ROS), and is likely to lead to male infertility. They express concerns about "electrosmog" and emphasize the need to restrict the usage of wireless and electronic gadgets, especially by the younger generation, though there is no final word about the impact of their ill effects on health and reproduction.[9]

Similarly, any history of exposure to high heat, disturbed sleep, and nutrition and/or increased stress would also influence semen quality.[10]

Exposure to volatile compounds[18] can result in temporary suppression of gonadotropin secretion and increase in prolactin levels. They have a major impact on spermatozoa production and sexual function.

Substance Abuse: A Truly Reversible Cause

This history is often not considered or ignored by both the patients and physicians. Cigarette smoking, either active or passive, primary, secondary, or tertiary is a well-known cause of deranged seminal parameters—a truly reversible cause for male infertility.[19,20] Similarly, excessive alcohol intake is known to impair sexual function.[21] Hard drugs such as cannabis/marijuana and cocaine hamper the sexual desire and decrease the performance.[21]

Sexual History: The Basic Step in Reproduction

Though it is a very sensitive subject, a detailed sexual history (frequency/week, erection, intravaginal penetration and ejaculation) is mandatory to ensure proper coital practice, which is the basic step in natural reproduction. This can also reveal a correctable cause of infertility such as the use of lubricants during the act. Spermatozoa are known to survive only in the natural vaginal secretions and not in any other artificial solutions/liquid. Most of these lubricants are either spermiostatic or spermicidal. Pregnancies have happened by simply stopping the use of lubricants.[22] Nonconsummation of marriage, infrequent sexual intercourse, and improper techniques are potentially treatable causes for male infertility. Though there is no prescribed norm for sexual frequency, sexual intercourse on at least alternate days optimizes the chances of natural pregnancy.[23]

Fertility History

Duration of marriage; past conception if any, either with the present partner or previous partner, or other partners; and any previous treatment for infertility are all crucial to ascertain the current fertility potential of the male partner.

Sexual Dysfunction

Sexual dysfunction includes both erectile and ejaculatory dysfunction. Many men with normal sexual function start developing sexual dysfunction after the diagnosis of infertility. It could be due to the diagnosis per se or due to the rigmarole of semen collection on demand or performance anxiety (sex on demand).[24] Many a times, couples report to us for only infertility, masking their sexual dysfunction. There are also men who cannot masturbate and situational anejaculation is a common mini-emergency in the infertility clinics. Sexual dysfunction (erectile dysfunction) and infertility can also be due to hyperprolactinemia. This again is another medically treatable cause for male infertility.[25]

Some medical drugs administered for other diseases can also impair sexual dysfunction **(Table 2)**.[7] This is often unnoticed or not paid enough importance. Statins are the most widely used drug. They may cause sexual dysfunction.[26]

A detailed history and guidance by the andrologist would go a long way in alleviating this problem. Retrograde ejaculation should be suspected, if there is no history of antegrade ejaculate or history of passing cloudy urine postcoitally.

Medical History

Past/present medical illnesses such as diabetes mellitus, hypertension, liver and renal failure, urinary tract infections, sexually transmitted infections, and other infections such as chlamydia, gonococcus, and tuberculosis may impair a man's fertility either by the disease per se or due to the long-term use of medications affecting both spermatogenesis and sexual function[7,27] **(Table 3)**.

TABLE 2: Medical drugs impairing sexual dysfunction.[7]

Effect of treatment	***Drugs or group of drugs***
Loss of libido and erectile dysfunction due to increased prolactin concentration	*H2-receptor antagonists:* Cimetidine, ranitidine
Loss of libido and erectile dysfunction (due to increased prolactin concentration), ejaculatory dysfunction (retrograde ejaculation)	*Antipsychotic drugs:* Phenothiazine
Erectile dysfunction	*Antihypertensives:* Clonidine, guanethidine, hydralazine, methyldopa, prazosin, beta-blockers
Erectile dysfunction, ejaculatory dysfunction (retrograde ejaculation) Anticholesterol medication	*Anticonvulsants:* Spironolactone, finasteride, ketoconazole Statins[26]

Gastroesophageal reflux disease (GERD) or acid peptic disease is a common condition often treated by H2-receptor antagonists. These drugs are known to impair sexual function.[28] Agents such as salazopyrin used for the treatment of ulcerative colitis cause changes in semen quality.[29]

Men with azoospermia visit chest clinic repeatedly due to bronchiectasis which could be because of Kartagener's syndrome (immotile cilia syndrome)[30] or cystic fibrosis associated with congenital bilateral absence of the vas deferens (CBAVD).[31]

History of chronic diseases such as bronchiectasis or sinusitis may suggest obstruction of excurrent ducts from testes due to inspissated testicular secretions, in a condition called Young's syndrome.

Another aspect of history is the treatment for malignancies with chemotherapy and/or radiations. If fertility preservation was not done prior to the therapy, it may lead to irremediable infertility.[7]

Surgical History

- Childhood history of inguinal surgeries such as orchidopexy, inguinal hernia repair, correction of hypospadias, and epispadias are to be enquired. Hernia repair surgery can lead to inadvertent damage to the vas deferens. Vas is extremely vulnerable in childhood operations such as herniotomy.
- In adulthood, history of vasectomy, varicocelectomy, hydrocelectomy, torsion correction, bladder neck surgeries, or urethral stricture corrections is to be enquired. Each of these surgical techniques has possible future implications on the fertility of the individual.
- Any history of surgery in para-aortic region including retroperitoneal node dissection and lumbar sympathectomy may lead to sexual dysfunction.

TABLE 3: Medical drugs impairing spermatozoa parameters.[7]

Effect of treatment	***Drugs or group of drugs***
Suppression of spermatogenesis: Reversible	• *Antibiotics:* Gentamicin, neomycin, penicillin G, cephalothin, ampicillin, spiramycin • *Antibacterials:* Nitrofurantoin, sulfasalazine, cotrimoxazole • *Testosterone and its esters*: Injected testosterone
Arrest of spermatogenesis leading to azoospermia: Often irreversible	*Antimitotics/antimetabolites:* Cyclophosphamide, colchicine
Impairment of spermatozoa motility: Reversible	• *Antibiotics:* Tetracyclines, neomycin, erythromycin, lincomycin, tylosin, dicloxacillin • *Antibacterials:* Sulfasalazine, cotrimoxazole, quinolones • *Antiepileptics:* Phenytoin • *Antimalarial:* Quinine
Fertilization failure	*Calcium channel blockers and antihypertensive:* Nifedipine

Developmental/Childhood History

History of mumps, rubella, viral illness, testicular injury, and torsion,[32] any sexual developmental disturbances during puberty, sexual infantilism, and testicular maldescent are to be enquired. Local trauma causes testicular edema and varying degree of ischemia, leading to seminiferous tubular dysfunction.

Family History

It is crucial to ascertain any history of infertility in the family members, especially male siblings. Conditions such as CBAVD, cryptorchidism,[33] and metabolic/endocrine disorders can run in families.

PART II: CLINICAL EVALUATION OF INFERTILE MALE

Nutritional Status and Body Mass Index

- The global pandemic of obesity also has its toll on the fertility of the male as well.[34] Though obesity is more commonly observed in infertile females (many of them having polycystic ovarian syndrome), the males are not exempt from the repercussions of poor lifestyle and diet. Obesity in the reproductive age group men is more likely to impair spermatogenesis[34] sexual function and is often associated with metabolic disorders.[35]
- Associated medical illnesses such as diabetes mellitus, hypertension, and drugs used to treat[23] can also confound the infertility problem by causing sexual dysfunction.

Evidence of Androgenization

This directly reflects the role of testosterone and in turn, the endocrine axis. A hypoandrogenized male exhibits signs of reduced or absence of facial and body hair, female habitus, and gynecomastia. These indicate reduction in testosterone production or malfunctioning of Leydig cells. He needs evaluation for hypogonadotropic hypogonadism.[36] This, if identified, is a potentially curable cause of male infertility with successful medical management.

Eunuchoidal male with gynecomastia and soft small testis may prove to be a case of Klinefelter's syndrome.

Cardiovascular System and Lungs

Blood pressure and routine heart monitoring need to be done to identify any associated abnormal findings. Chest auscultation will pick up pulmonary problems (especially bronchiectasis and tuberculosis) which may be associated with azoospermia;[37] CBAVD in the former and obstructive azoospermia in the later. Chest auscultation will also pick up dextrocardia in situs inversus which is associated with bronchiectasis (immotile cilia syndrome).

Thyroid Disorder

Thyroid disorders are not common[38] in the infertile male unlike infertile women; hypothyroidism if present may be associated with hyperprolactinemia which in turn may result in erectile dysfunction and in turn infertility.

Breast Examination

Besides gynecomastia (as a part of hypogonadism, i.e., Klinefelter's syndrome), rarely one can demonstrate galactorrhea due to increased prolactin; any palpable tumor of the male breast may be revealed in the routine examination. This will lead to early diagnosis and treatment of the pathology detected.

Abdominal Examination

Liver enlargement may indicate chronic hepatitis or tumors. Men with cirrhosis may also present a hypo-androgenized picture. Any visible scar in the lower abdomen/inguinal region may be a telltale evidence of previous varicocelectomy, hernia surgery, or correction of undescended testes.

Genital Examination

This is best done both in the supine and standing position. Penile pathologies such as displaced urinary meatus, leading to hypospadias or epispadias, urethral or meatal strictures, and phimosis are indicative of faulty or no semen deposition into the female genital tract. Simple correction may ameliorate the sexual dysfunction and infertility.

Testes

Well-distended scrotum with rugae is indicative of descended testes into the normal position in the scrotal sac. Size of the testis is assessed by the Prader orchidometer. This can also be assessed by ultrasound, bedside examination, or with a vernier caliper **(Figs. 1 to 3)**.

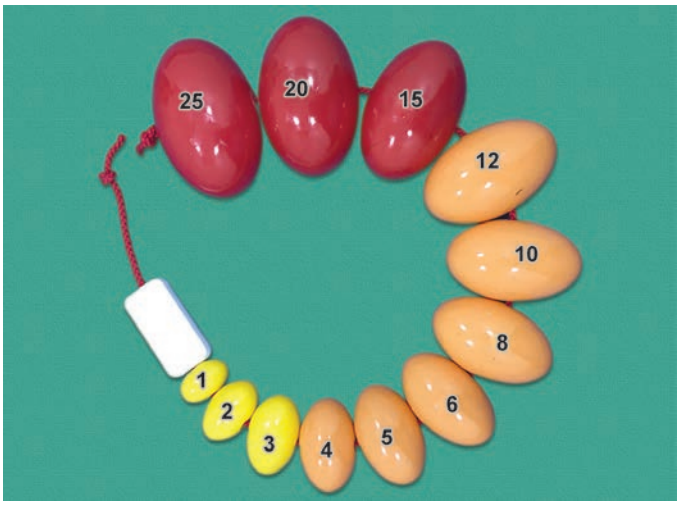

Fig. 1: Prader orchidometer.

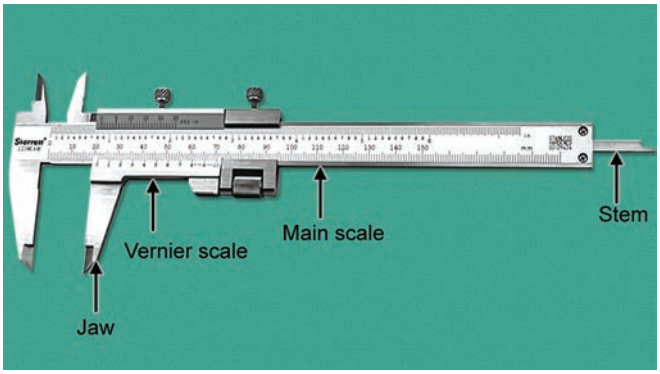

Fig. 2: Vernier caliper.
Idea courtesy: Dr Eswar.
Image courtesy: Dr Ramesh Raja.

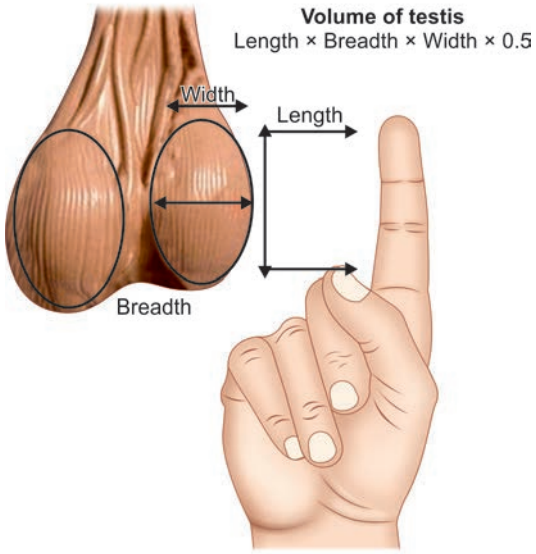

Fig. 3: Bedside clinical assessment of testicular volume.
Idea courtesy: Professor Dr N Pandiyan.
Image courtesy: Dr Ramesh Raja.

Volume of testis:

- Normal volumes (8–15 cm^3)—indicate the presence of a significant amount of the seminiferous tubules. Seminiferous tubules constitute 80% of testicular volume.
- Low volume (<8 cm^3)—soft, shrunken testis is suggestive of hypogonadotropic hypogonadism or seminiferous tubular failure.
- High volume (>20 cm^3)—hydrocele, hematocele (tenderness +), tumors, filariasis.

Testicular sensation:

- Mildly painful sensation to touch—normal male
- Exquisite tenderness—torsion, infection
- Absent or reduced sensation—seminoma testes, leprosy, seminiferous tubular dysfunction.

Epididymis

It is felt on the posterolateral aspects of testes—it is often distended and enlarged in cases of obstructive azoospermia where the obstruction is at the cauda of epididymis, vas, or ejaculatory duct.

Vas Deferens

It is felt as a cord-like structure in the spermatic cord at the root/neck of the scrotum, between thumb and index finger. It snaps when rolled between the fingers. It is absent in cases of CBAVD also called as vasal aplasia.

Varicocele

It is often best felt in the erect standing position; it feels like a bag of worms at the neck of the scrotum. Venous bruit and reversal of blood flow in pampiniform plexus during Valsalva maneuver is often detected with Doppler ultrasound. Cough impulse elicits an inguinal hernia, which may be missed in the lying position.

Rectal Examination

Absence of seminal vesicle by rectal examination adds to the suspicion of vasal aplasia.

INVESTIGATIONS FOR MALE INFERTILITY

Semen Analysis

It is the most important test available for assessing man's fertility, despite its limitations and fluctuations. Various artifacts exist in the assessment of semen analysis—collection artifacts, analysis artifacts, and interpretation artifacts. These have to be addressed/given cognizance while interpreting the seminogram. Spermatological diagnosis is arrived at the overall picture of ejaculate and not the individual parameters. The andrologist correlates the previous and present analyses in conjunction with the clinical and endocrine evaluation and can come to a diagnosis and decide on further management options for the couples.

Semen analysis is performed as per WHO 2021 manual[39] in current day practice **(Table 4)**.

Figure 4 shows the variability of semen picture in the same fertile male over 120 weeks. **Figure 5** depicts the varying spermatozoa concentration and motility from time to time in the same individual. This clearly brings to light the inherent variable nature of spermatogenesis.

Hence, the fertility potential of the individual cannot be assessed with a single semen analysis. Repeated semen tests at 2–3-month intervals are needed to confirm the seminal abnormalities, whereas a normal semen report can be taken as a reassuring step to proceed with further treatment of the couple. However, in most men, the exact cause of the semen abnormalities and infertility remains unknown and could be genetic **(Table 5)**.[40]

Endocrine Workup for Infertile Men

Figure 6 explains the neuroendocrinological control of testicular function. However, routine endocrine workup

is not required in all men presenting with infertility. The common biochemical tests done are: serum follicle-stimulating hormone (S. FSH), luteinizing hormone (LH), total and free testosterone, and prolactin. They indicate seminiferous tubular function, Leydig cell function, and the role of anterior pituitary gland on gonadal function. Rarely seminal fructose estimation is needed as a qualitative test in men with azoospermia as a diagnostic aid to identify obstructive azoospermia due to vasal aplasia or ejaculatory duct obstruction.

TABLE 4: Distribution of semen examination results from men in couples starting a pregnancy within 1 year of unprotected sexual intercourse leading to a natural conception.

	Centiles	
	5th	***(95% CI)***
Semen volume (mL)	1.4	(1.3–1.5)
Sperm concentration (10^6/mL)	16	(15–18)
Total sperm number (10^6 per ejaculate)	39	(35–40)
Total motility (PR + NP, %)	42	(40–43)
Progressive motility (PR, %)	30	(29–31)
Nonprogressive motility (NP, %)	1	(1–1)
Immotile spermatozoa (IM, %)	20	(19–20)
Vitality (%)	54	(50–56)
Normal forms (%)	4	(3.9–4.0)

Source: Campbell et al. Fifth percentile given with variability (95% confidence interval).[39]

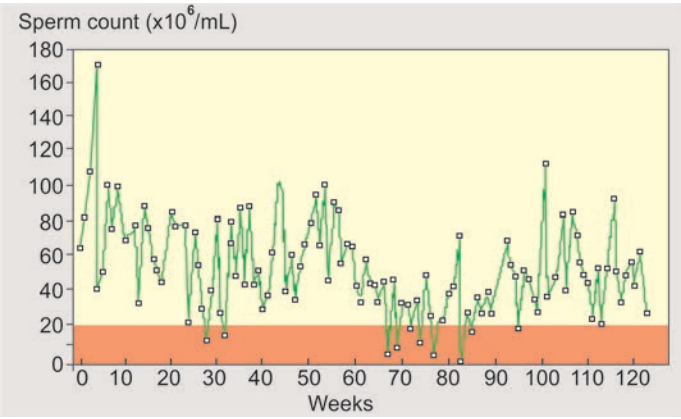

Fig. 4: Variability of spermatozoa concentration of a male over a period of time.[41]

Indications

- More often serum follicle-stimulating hormone (S. FSH) is the only hormonal test required when spermatozoa count is <10 million/mL, men with azoospermia, and in patients with persistent oligozoospermia **(Tables 6 and 7)**. These tables help in the differential diagnosis of azoospermia.

TABLE 5: Nomenclature for seminal abnormalities.

Aspermia	No ejaculate or retrograde ejaculation
Azoospermia	No spermatozoa in the neat sample and centrifuged pellet
Oligozoospermia	Total number (or concentration, depending on outcome reported) of spermatozoa below the lower reference limit[43]
Asthenozoospermia	Percentage of progressively motile (PR) spermatozoa below the lower reference limit[43]
Teratozoospermia	Percentage of morphologically normal spermatozoa below the lower reference limit[43]
Oligoasthenoteratozoospermia	Total number (or concentration, depending on outcome reported) of spermatozoa, and percentages of both PR and morphologically normal spermatozoa, below the lower reference limits[43]
Cryptozoospermia	Spermatozoa absent from fresh preparations but observed in a centrifuged pellet[43]
Normozoospermia	Total number (or concentration, depending on outcome reported) of spermatozoa, and percentages of PR and morphologically normal spermatozoa, equal to or above the lower reference limits[43]
Necrozoospermia	Dead spermatozoa in the ejaculate

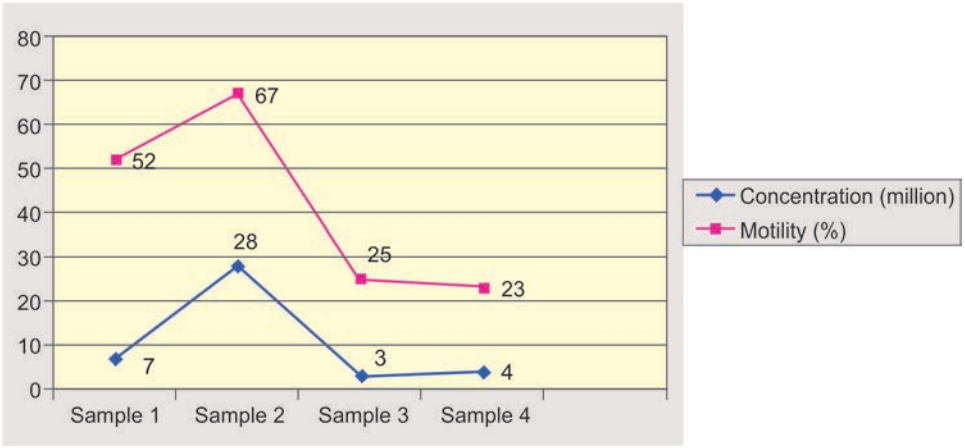

Fig. 5 : Variation in spermatozoa concentration and motility over time.[42]

TABLE 7: Diagnosis of types of nonobstructive azoospermia.

Condition	***Hypogonadotropic hypogonadism***	***Seminiferous tubule failure***	***Borderline azoospermia***
Follicle-stimulating hormone (FSH)	Low or undetectable FSH, low LH, low testosterone, normal prolactin	Raised	Normal range or mild elevation
Testes size	Small	Small	Normal, small
Semen volume	Normal	Normal	Normal
Feature	Hypo/anosmia as in Kallmann's syndrome	–	HPE: Maturation arrest, hypospermatogenesis

(HPE: Histopathological examination; LH: luteinizing hormone)
Source: Adapted from Pandiyan N. Male infertility and its management. Handbook of Andrology. TR Publications; 1999. pp. 21-46.

- Hypogonadal (eunuchoidal) male: S. FSH and serum LH (S. LH), free and total testosterone, prolactin besides karyotyping
- *Sexual dysfunction:* Patients presenting with sexual dysfunction need evaluation of S. FSH, total and free testosterone, S. LH, and serum prolactin.

- *Rarely TSH estimation:* Along with prolactin in the case of sexual dysfunction
- *Anti-Müllerian Hormone (AMH) in male infertility:* Estimating AMH level in female gives an idea of ovarian reserve, whereas it is not of much clinical significance in men.[44]

GENETICS IN MALE INFERTILITY

Genetic analysis is recommended in men with severe oligo-, astheno-, teratozoospermia, and azoospermia. Genetic study requires not only karyotyping but also evaluation of Y-chromosome microdeletions. When diagnosed with Y-chromosome microdeletions, detailed counseling is to be done for the couple regarding possible transmission of deletion to the male offspring.[45] Genetic testing is also indicated when there is clinical suspicion of Klinefelter's or Kallmann's syndrome. Rarely autosomal abnormalities such as translocation[46] can also be the cause for seminal abnormalities.

Cystic fibrosis transmembrane conductance regulator (CFTR) gene mutation evaluation is advised in all cases of vasal aplasia, preferably for both the partners prior to surgical sperm retrieval for assisted reproductive techniques, as the presence of these mutations are indicative of the risk of pulmonary cystic fibrosis and consequent morbidity and mortality in the offspring.[47]

In selective cases of male infertility, genetic testing (especially for Y-chromosome microdeletions) and detailed counseling need to be done regarding possible genetic transmission to the male offspring.

Impact of Severe Acute Respiratory Syndrome Coronavirus 2 on Male Reproduction

COVID-19 is a novel coronavirus affecting humans in late 2019. It has resulted in a pandemic with reports of many systems and organs getting affected in the infected individuals. The reproductive system of the male has been found to have more susceptibility for the viral impact than women due to greater presence of angiotensin-converting enzyme (ACE) 1 and 2 receptors. ACE2 receptor is highly expressed by several cell types in the testes including Leydig cells, Sertoli cells, and the germ line.[48] They are required for viral attachment and propagation.[49]

Research of the impact of COVID-19 on human reproduction is in a very nascent stage. Conclusions are yet to be derived, but still concerns have been raised on COVID-19 virus affecting male fertility. In this continuing pandemic scenario, routine inclusion of reverse transcription-polymerase chain reaction (RT-PCR) test in the initial assessment of the couple and prior to the actual treatment is a good clinical practice.

COVID-19 Vaccination and Male Fertility

Concerns have been raised about the risks to male fertility due to COVID-19 vaccination. Though these fears appear unfounded as the vaccination does not contain the active virus and therefore unlikely to produce active disease or affect testes, yet these fears remained until a recent original article in *JAMA* quelled the fear with its observations of semen parameters before and after vaccination and found no deterioration in semen quality.[50]

CONCLUSION

Diagnosis of Male infertility is devastating to the individuals concerned, their partners and even their families. It has profound emotional, marital, and social issues. It is vital that every practitioner involved in the care of infertile couples is well versed with evaluation of the male partners also. Detailed history remains the pivotal point of examination, strengthened by thorough physical examination and supported by properly done semen analysis and necessary biochemical, radiological, and genetic testing. A clear diagnosis goes a long way in treating the possible causes and directing the couples to undergo the recommended treatment in their journey towards parenthood.

KEY POINTS

- It is explicit from the above detailed narration that it is vital to elicit an exhaustive history, which may give us a clue to the possible cause of infertility and its remedy. This also brings the importance of systemic influence on gonadal functions to light and the need to look at the infertility issue from a holistic point of view.
- A thorough clinical examination is essential to identify features of androgenization and evaluation of genitalia for obvious causes for seminal abnormality.
- Routine endocrine evaluation is not required in all men with infertility. It is indicated in conditions such as severe oligozoospermia, azoospermia, hypogonadal state, and in sexual dysfunction.
- Though the contributions by the male for the couple's infertility problem have been widely acknowledged, sadly there has not been much awareness among public and medical professionals for the need to evaluate the male partner thoroughly.
- The right approach to evaluate male infertility should be a combination of dedicated and detailed history taking and thorough clinical examination with relevant investigations.
- This chapter has attempted to provide a basic understanding of the various clinical and endocrinological methods used to evaluate the issue of male factor infertility and to identify the possible cause and plan appropriate treatment.

CHAPTER 26

Sexual Dysfunction in Male Infertility

Vasan SS, Fahim L Rajwate, Ankur

INTRODUCTION

In recent years, infertility has become the subject of significant media attention and public discussion, particularly in light of new advances in the technology of assisted reproduction. Male factor infertility plays a role in approximately 50% of infertility cases with male factor as a sole cause in about 35%. It has been proposed that a man who fails at fertility is likely to evaluate himself as sexually inadequate and may experience temporary impotence and decreased libido. Constant worry about the problem may arouse inhibitory nerves and interfere with smooth muscle relaxation in the penis, thus causing partial or complete failure of erection.

In India, approximately 15% of couples are unable to initiate a pregnancy without some form of assistance or therapy. These patients are said to be "primarily infertile." In approximately 2% of these couples there are factors other than seminal abnormalities, which prevent conception. It is imperative that these groups of patients are properly diagnosed and treated to enable them to achieve conception.

Some of the uncommon problems seen in males leading to infertility are as follows:

- Nonconsummation of marriage
- Ejaculatory disturbances
- Erectile dysfunction.

Treatment of these problems entails proper understanding of the physiology of erection and ejaculation. The majority of contemporary knowledge on the physiology of erection has been assembled during the past thirty years. It consists of basic biological response and mechanics of pelvic floor muscles and sphincters, during erection, and ejaculation.

BIOLOGICAL BASIS OF MALE SEXUAL RESPONSE

Depending on the situation, a person can be sexually aroused by a variety of factors, both physical and mental. The welcome physical stimulation of an erogenous zone or acts of foreplay can result in arousal, especially if it is accompanied with the anticipation of imminent sexual activity. The potential stimuli for sexual arousal vary from person to person and from one time to another, as does the level of arousal.

Stimuli can be classified according to the sense involved—somatosensory (touch), visual, and olfactory (scent). Auditory stimuli are also possible, though they are generally considered secondary in role to the other three. Erotic stimuli that can result in sexual arousal can include conversation, reading, films, or images or a smell or setting, any of which can generate erotic thoughts and memories in a person.

Five brain areas were found to be more active during the sexual act, they are as follows:

1. The first was the inferior temporal cortex, a region also corresponding to the visual associative zone. The researchers inferred that the subject was assessing and analyzing the visual stimulus when this zone was activated, corresponding to the perceptive cognitive component of sexual arousal.
2. The second region was the right orbitofrontal cortex, which might be related to emotional and motivational phenomena.
3. The third area was the left anterior cingulate cortex, which appears to control primary physiological responses (endocrine and autonomic), but also affective responses, to sexual stimuli. In other words, it would govern physical and psychological preparation for sexual activity.
4. The fourth region was the right insula, which could be involved in subjective perception of physiological modifications associated with arousal (heart rate acceleration, penile erection, etc.).
5. Finally, the right caudate nucleus probably controls whether sexual arousal is followed by sexual activity.

The stimuli from a receptive female and/or sexual act itself leads to the release of dopamine (DA) in at least three integrative hubs.[1] The nigrostriatal system promotes

somatomotor activity; the mesolimbic system subserves numerous types of motivation; and the medial preoptic area (MPOA) focuses the motivation onto specifically sexual targets, increases sexual rate and efficiency, and coordinates genital reflexes. The previous (but not necessarily concurrent) presence of testosterone is permissive for DA release in the MPOA, both during the basal conditions and in response to a female. One means by which testosterone may increase DA release is by upregulating nitric oxide synthase, which produces nitric oxide, which in turn increases DA release. Finally, while DA is facilitative to sexual activity, 5-hydroxy tryptamine (5HT) is generally inhibitory. 5HT is released in the lateral hypothalamic area (LHA), but not in the MPOA, at the time of ejaculation. Thus reciprocal changes in DA and 5HT release in different areas of the brain may promote sexual activity and sexual satiety, respectively. Other factors such as medication, alcohol, and other health problems can modify the biological impact of hormones on libido.

As to the mediators at the cavernosal level, acetylcholine and nitric oxide (NO) released from the endothelium are involved along with noradrenaline, vasoactive intestinal polypeptide (VIP), calcitonin gene related peptide (CGRP) and prostaglandins.[2] Nitric oxide and VIP play the most important roles in the phase of erection. Erection takes the following course (simplified) erotic stimuli—impulses from brain via hypothalamus—stimulation of parasympathetic (PNS) spinal erection center (T11-L2, S2, 3, 4)—release of acetylcholine, no at PNS nerve endings and at cavernous nerve - sinusoids smooth muscle relaxation and rapid filling with blood (tumescence stage)— veno-occlusive mechanism prevents blood egress—full erection phase—erotogenic stimuli lead to the stimulation of the parasympathetic nerve→vasodilating substances are released→the sinusoids are filled with blood (tumescence stage)→the veno-occlusive mechanism starts to work—thus complete erection occurs. Then the contractions of the musculature of the perineum compress the proximal portions of the corpora cavernosa—this leads to rigid erection. Detumescence (which occurs as a rule after ejaculation) is due to released noradrenaline (active stage) and the reduced tonus of the smooth muscles of the blood vessels (released endothelin and neuropeptide Y).

Pelvic Floor Muscles and Sphincters during Erection and Ejaculation

The pelvic floor muscles involved in maintaining an erection[3] consists of puborectalis (PR), levator ani (LA) and, external anal sphincters (EAS) and external urethral sphincters (EUS). The increased PR activity might express the prostatic secretions into the posterior urethra. Levator ani contraction seems to elevate the prostate and partially straightens the prostato membranous urethral kink that might occur during erection. The EAS and EUS contractions are believed to abort the urge to defecate or urinate and prevent leak of feces, flatus, or urine during coitus. The rhythmic EUS contraction at ejaculation might act as a "suction ejection pump," sucking the genital fluid into the posterior urethra while being relaxed, and ejecting it into the bulbous urethra upon contraction.

NONCONSUMMATION OF MARRIAGE

The main factor associated with an unconsummated marriage is the intense social pressure to accomplish hasty sexual activity[4] with an unfamiliar woman (some men having had no social contact with their new bride), and in the presence of relatives waiting nearby for evidence of the bride's virginity and confirmation of sexual act. This initial problem will then be further compounded with resultant erectile failure caused by anxiety about sexual performance. In addition to psychological causes and a lack of sexual education, the social circumstances in which partners are obliged to initiate and complete sexual act are important factors in the etiology of unconsummated marriage.

There may be many reasons for nonconsummation.

- *These may include:*
  - Lack of emotional involvement
  - Fear of sexual act
  - Inappropriate advice or information from friends and family before marriage about first night and sex
  - Vaginismus (terrible cramp at the entrance of the vagina, which makes penetration impossible)
  - Lack of arousal and less lubrication for the female
  - Dyspareunia (painful intercourse)
  - Thick hymen
  - Erection problems or an inability to copulate
  - Fear of pregnancy
  - Sexual abuse in childhood
- *Signs of nonconsummation:*
  - Lack of desire for sex
  - Irritating or painful experience while attempting intercourse
  - Difficulty in insertion of penis into vagina
  - Softening of penis while performing intercourse
  - Ejection of semen before penetration
  - Inability to consummate medically is caused by:
    - Premature ejaculation in 23%
    - Erectile dysfunction in 61%
    - Combination of factors in 16%.

Erectile dysfunction in some form or other may contribute to the problem. It is the clinician's obligation to establish the etiology of impotence, namely end organ vascular failure versus neurologic dysfunction versus psychosexual dysfunction, classify the severity of that dysfunction, and select a therapy that is not only acceptable to the patient but

also addresses his pathology. The most commonly utilized diagnostic tests for erectile dysfunction are mentioned underneath.

Combined Injection and Stimulation Test or CIS Test

They consist of intracavernous injection and visual rating of the subsequent erection. It is simple, minimally invasive, and performed without monitoring equipment. Hemodynamic investigations suggest that a positive injection test is associated with normal veno-occlusion, but not necessarily with normal arterial function. When the penile response to pharmacotesting is suboptimal or equivocal, diagnostic testing with duplex Doppler assessment should be performed.

Nocturnal Penile Tumescence

Nocturnal penile tumescence (NPT) to measure man's nocturnal erections have been measured by each of the following methods—stamp test, snap gauges, strain gauges, NPTR (Rigiscan and Osborn Medical Systems), and sleep laboratory NPTR.[5] Normal nocturnal penile tumescence and rigidity (NPTR) depends on both the integrity of the corticospinal efferents to the penis and vascular responsiveness of the penile tissues to those nerve signals. When nocturnal erections are of appropriate duration and strength, the central and peripheral neuroeffectors and intracorporal regulators of penile hemodynamics are intact. Unfortunately, abnormal NPTR is of little value in determining the etiology or classifying the severity of vascular impotence, the most prevalent kind of end organ failure.

Blood Flow Studies

Insufficient penile blood flow and inefficient corporal veno-occlusion is implicated in up to 30% of patients, and in their evaluation numerous diagnostic tests have been employed to evaluate penile hemodynamics.[6] The more popular ones are color duplex Doppler ultrasound, selective internal pudendal pharmacoangiography and dynamic infusion cavernosometry/cavernosography (DICC). Duplex ultrasound, which measures penile blood flow, provides an objective, minimally invasive evaluation of arterial pattern in a suboptimal/equivocal erectile response.

The diagnosis and demonstration of venous leakage requires complete smooth muscle relaxation. Veno-occlusive dysfunction is associated with poorly sustained erections; this pathology has traditionally been evaluated with dynamic infusion cavernosometry and cavernosography. Dynamic infusion cavernosometry/cavernosography is an invasive test, and is now primarily reserved for patients considering the option of vascular reconstructive procedure.

Neurological Assessment

The sacral reflex arc of erection consists of somatosensory afferents via the dorsal and pudendal nerves and autonomic efferents via the pelvic and cavernous nerves. These afferents have been measured indirectly by somatosensory evoked potentials (SSEP) and bulbocavernosus reflex latency (BCR). These at present are used in research situations, as it does not principally aid in the patient management.

Penile EMGs (CCEMG) have been used to measure corpora cavernosal smooth muscle electrical activity and is far from standardized.[5] Computer-assisted interpretations of penile electrical potentials may eventually differentiate afferent nerve pathologies so long inferred in diabetes, spinal cord injury and following radical pelvic surgery.

Erectile dysfunction evaluation is based on the clinical judgment and not all these tests may be necessary for evaluation. Proper evaluation of nonconsummation will aid in treatment planning. Various options in management are psychotherapy, sexual education, oral medications (sildenafil citrate, tadalafil, vardenafil, udenafil, and uprima), intracavernosal injection and specific treatment directed for organic cause. Most cases respond to medications and counseling with surgical options being reserved for resistant organic causes.

EJACULATORY DISTURBANCES

Diagnosis of Infertility: Psychological Aspects-infertility Investigation

The semen needed for a spermiogram should be collected by masturbation, which can be disturbing to infertility patients. Men may have an erection failure at this time. Masturbation is still often a taboo and the setting is not erotic. Men may fear the judgment of the biologist regarding their semen and this may lead to impotence. Guilt over their felt inadequacy can make impotence persist. In this context, some men suffer scrotal pain, asthenia and depression. They often describe the impression of having a "cold penis."

The use of standard techniques for evaluating medical problems in general such as complete history, physical examination, and laboratory tests which are beyond the scope of this chapter, are essential for this purpose.

A secondary goal of the infertility evaluation is to identify any underlying health conditions that may be contributing to difficulties with conception. This could include any conditions that would contribute to problems with ejaculation such as undiagnosed diabetes, or problems with erection, such as might be caused by a significant smoking history, severe hypercholesterolemia, or hypogonadism. A full discussion of the diagnosis and treatment of erectile dysfunction (ED) is beyond the scope of this article; however, it is not uncommon for men to report some stress-related ED during the course of the infertility evaluation and treatment.

These patients may benefit from a prescription for a phosphodiesterase-5 (PDE5) inhibitor or a dopaminergic drug, apomorphine for enhancing sexual response cycle. Alprostadil (Muse) is not recommended since its potential effect on the ejaculate is not known.

Patients who complain of the difficulty with ejaculation and climax need to be checked for psychotherapeutic agents usage that block dopamine production and consequently blunt the hypothalamic pituitary axis and possibly decrease libido. Other psychotherapeutic agents can decrease vasodilatation and decrease the quality of erections. Tricyclic antidepressants, selective-serotonin reuptake inhibitors, and monoamine oxidase inhibitors can lead to ED, an ejaculation and decreased libido. These patients can have their regimen changed, or may be offered other means of medically managing their complaints, such as a PDE5 inhibitor.

The most widely accepted theory to explain ejaculation consists of two phases:[7]

1. A phase of accumulation of the various constituents of semen inside the prostatic urethra.
2. A phase of expulsion with opening of the striated sphincter, while the smooth sphincter of the bladder neck remains closed.

These events are mediated by the sympathetic nervous system via T10 to L3 level preganglionic fibers. Ejaculation is the forceful antegrade expulsion of semen from the posterior urethra through the urethral meatus. This event is secondary to the rhythmic contraction of periurethral and pelvic floor smooth muscle, mediated by parasympathetic outflow (S2, 3, and 4) and somatic efferents, and occurs in conjunction with closure of the bladder neck, which is sympathetically stimulated.

Ejaculatory Disorders

- Premature ejaculation
- Retrograde ejaculation
- Anejaculation
- Deficient or retarded ejaculation.

On the basis of the history and simple investigations, the various disorders are relatively easy to differentiate. History taking should include information about the ability to ejaculate, including nocturnal emission and the ability to experience an orgasm.

Premature Ejaculation

All men know what it feels like to sometimes want sexual intercourse to last longer. But premature ejaculation (PE; also called early ejaculation, rapid ejaculation or ejaculation praecox or inability to control ejaculation) is much more than just feeling like you want to last longer from time to time. It is a very real condition with real impact on people's life and it is measured by the average intravaginal ejaculation latency time (IELT).

Deficiency in ejaculation appears to be caused by sympathetic, motor pudendal or suprasacral lesion. An altered perception of genital sensations due to a lesion in the afferent pudendal pathway appears to be present in premature ejaculation.[8]

The exact reason why some people have a faster sexual response is not yet fully clear. In the past, PE was thought to be a purely a psychological condition, but Janssen et al.,[9] in their study of IELT in Dutch men with life-long premature ejaculation found serotonin transporter promoter region (*5-HTTLPR*) polymorphism which might explain a genetic basis in some men.

It is proposed that there are two broad causes of premature ejaculation:

1. Biogenic and
2. Psychogenic

There are two different types of premature ejaculation:

1. Primary (lifelong)
2. Secondary (acquired).

The traditional assumption among sex therapists is that premature ejaculation is almost universally caused by psychological features and is easily treated with sex therapy and behavioral techniques. This is questionable, as results from systematic investigations have shown that behavioral treatments for premature ejaculation remain beneficial to only a minority of men three years after treatment ends, suggesting that this male dysfunction is difficult to treat effectively with behavioral techniques.

With proper assessment and identification a specific diagnosis of premature ejaculation can be made and accurate treatment designed to address the particular type of disorder, with long-term benefits, can be achieved.

The commonly used medications in this disorder are fluoxetine, paroxetine, and clomipramine either singly or in combination. Recently, there has been emphasis on pelvic floor rehabilitation as a form of treatment for this disorder.

Retrograde Ejaculation

Retrograde ejaculation is an uncommon cause of male infertility. Antegrade ejaculation requires intact anatomy and innervation of the bladder neck. Retrograde ejaculation can be defined as the escape of seminal fluid from the posterior urethra into the bladder.[10] The etiology may be anatomic, neurogenic, pharmacologic, or idiopathic. *Anatomic causes* include prostatectomy (open or transurethral) or bladder neck surgeries (YV plasty, transurethral incision of the bladder neck). *Neurogenic causes* include spinal cord injury, retroperitoneal surgery, and diabetes mellitus. *Pharmacologic agents* implicated in causing retrograde ejaculation include neuroleptics, tricyclic antidepressants,

α-blockers used in the treatment of prostatism and certain antihypertensives. Also congenital and idiopathic causes have been described.[11]

It should be suspected in any case of persistent low volume ejaculate (<1.5 mL), absent ejaculate or rarely azoospermia. It can easily be differentiated from partial ejaculatory obstruction by transrectal ultrasound. The diagnosis of ejaculatory duct obstruction is suggested by the presence of a cyst posterior to the prostatic urethra, with or without dilatation of the seminal vesicles. The differential diagnosis for a prostatic cyst includes Müllerian duct cysts, utricle cysts, prostatic retention cysts, seminal vesicle cysts, and ejaculatory duct cysts. Such cysts can be classified according to their location and the presence or absence of sperm in the fluid aspirated from them.

Investigations which Aid in the diagnosis

- Demonstration of sperm in the postmasturbation urine.
- Analysis of the ejaculate.
- Determination of the secretion markers of the adnexa.
- Ultrasonographic (abdominal and transrectal) examination of the genital organs.

The patient is instructed to void immediately following ejaculation and the diagnosis of retrograde ejaculation can be confirmed by examination of postejaculate urine (PEU). A sample of the specimen is evaluated microscopically for sperm density and motility. Alternatively, the specimen may be centrifuged and the pellet resuspended in a medium such as human tubular fluid, and then analyzed for sperm density and motility. Presence of >15 sperms/high-pass filter (HPF) is confirmatory of retrograde ejaculation.

Principles of management of retrograde ejaculation (Glander 1998)

- Conversion of retrograde into antegrade ejaculation by drug therapy.
- Harvesting of sperm from postejaculatory urine.

In the treatment of retrograde ejaculation, an initial trial of medical therapy is warranted. Medical management aims to increase the tone of the bladder neck, preventing retrograde flow of semen into the bladder. This can be achieved either by stimulating sympathetic activity (closure of the bladder neck is under sympathetic control) or by blocking parasympathetic input.

The agents commonly utilized are α-adrenergic agonists such as ephedrine, pseudoephedrine, tricyclic antidepressants–imipramine, and antihistamines brompheniramine, and phenylpropanolamine. When pharmacological attempts to restore antegrade ejaculation fail, the spermatozoa should be recovered from postejaculation urine, to be applied in one of the modern techniques of assisted reproduction. The successful recovery of viable spermatozoa from the urine is dependent upon careful regulation of pH and osmolarity of the urine at the time of ejaculation. Careful handling of the retrieved spermatozoa enables isolation of sperm cells with good quality for insemination of ovulated oocytes (in vivo) or retrieved oocytes (in vitro), and is timed to coincide with the wife's ovulation. There are several protocols for urinary alkalinization, however, the protocol outlined below yields the best sperm retrieval rates.

Protocol for urinary alkalinization: Patient is instructed to use sodium bicarbonate tablets 2 g TID and Sudafed 60 mg TID for 3 days prior to anticipated day of ovulation and to monitor his urinary pH with pH strips to assess the efficacy of alkalization.

On the day of sample collection, pH and osmolarity of spontaneous urine is measured. The aim is that the pH should reach 7.3 and the osmolarity should be 280 mOsmol. If not, dissolve 2.0 g sodium bicarbonate in 200 mL of distilled water and administer to the patient. After 30 minutes repeat the measurement and if the desired value has not been attained repeat the procedure by reducing the amount of sodium bicarbonate and measure again in 30 minutes (this is the time the sodium bicarbonate needs to reach the bladder).

It should be remembered that the reducing bicarbonate is dependent on pH level and if the correct pH and osmolarity are reached, the patient is instructed to empty his bladder completely just prior to ejaculation (the closer the better). Then catheterize the bladder, drain it to completion, and administer a small volume of media. The patient then ejaculates and collects his antegrade sample. Then recatheterize, collect the bladder sample and if needed irrigate the bladder with media to collect the rest of the retrograde specimen prior to sending them all off to the laboratory for processing. It is necessary to use media at room temperature and minimal lubrication while catheterizing to enhance sperm recovery.

Most cases of retrograde ejaculation can be managed either by conversion to antegrade by pharmacological manipulation or sperm recovered from the bladder by urinary alkalinization, and surgical treatment is anecdotal in the era of assisted reproduction.

The goal of surgical intervention is restoration of bladder neck integrity. Limited data are available regarding the use of surgical intervention in the treatment of retrograde ejaculation. However, Reynolds, McCall, Kim, and Lipshultz (1998) successfully injected collagen into the bladder neck of a male with retrograde ejaculation, achieving antegrade ejaculation, two subsequent pregnancies, and one live birth. However, this approach is fraught with complications and is currently not recommended as a treatment option.

Anejaculation

Anejaculation and ejaculatory dysfunction are the terms used to describe the inability of a man to have an ejaculation.

The common types are:

- Orgasmic
- Nonorgasmic.

It is a relatively uncommon disorder that can occur as a result of spinal cord injury, retroperitoneal lymph node dissection, or other retroperitoneal surgery, diabetes mellitus, transverse myelitis, or multiple sclerosis.[12] In addition the etiology may be psychogenic or idiopathic. The nerves that are responsible for carrying the signal for ejaculation, exit the spinal cord and course along the aorta, in the posterior part of the abdomen. These nerves are most commonly injured after spinal trauma resulting in paraplegia or quadriplegia, major bowel or vascular surgery, or surgery for testicular cancer. In the past, men with ejaculatory dysfunction were considered infertile because they could not ejaculate but presently there are treatment options available.

Anejaculation, resulting from the damage to the afferent or efferent neural pathways (reflex arc) responsible for emission and/or ejaculation, can be treated with electroejaculation. In cases where the reflex arc is intact or is partially damaged, vibratory stimulation is useful. Some researchers have tried medical therapy in both these types and were generally unsuccessful.

VIBRATORY STIMULATION

Penile vibratory stimulation mimics rapid and repetitive manual/hand stimulation of the penis, which is a natural aspect of human sexual behavior. Vibratory stimulation (VS) employs a custom designed mechanical vibrator (store bought vibrators do not work for many patients) that is applied to the underside of the glans penis and set to vibrate at designated frequency and wave amplitude. This vibration travels along the sensory nerves to the spinal cord and may induce a reflex ejaculation. This technique only works in patients with an intact ejaculatory reflex arc. The results are dependent on the level of spinal cord injury and are most effective in patients with upper cord lesions. This is an office procedure that requires no anesthesia or sedation to perform. However, it is suggested that all the patients, irrespective of the level of injury in the spinal cord, have an initial trial with vibratory therapy, as many a times the lesion may be incomplete. When vibratory stimulation is unsuccessful, electroejaculation often works quite well. After standard bladder preparation (detailed below), a handheld, electrically driven vibrator is applied initially to the dorsum of the glans and then to the frenulum and penoscrotal area. The slow movement of the vibrator often identifies a "trigger" point, which is often reproducible from one cycle to another.[13] The selection of a frequency of 100 Hz and a peak-to-peak amplitude of 2.5 mm may be important for successful ejaculation. Patients who ejaculate using this form of stimulation need to be trained properly in its usage and ejaculatory interval may vary from 10 to 180 minutes depending on the pathology. People who are likely to respond to vibrators develop penile tumescence and pelvic floor contractions. In the absence of these signs electroejaculation is a better option. Most patients who respond to vibratory stimulation will exhibit antegrade ejaculation, but catheterization must be performed because these patients frequently have incomplete closure of the bladder neck, and may also have a significant retrograde component.

The presence of bulbocavernosus and hip flexion reflexes are useful in predicting response of penile vibratory stimulation. When both reflexes were present, 80% of the men ejaculated in response to stimulation, compared to only 8% of men in whom neither reflex was present. Poor prognostic indicators are spinal cord injury within the last 6 months, the absence of reflex hip flexion and lesion below T12 level.

The common types of vibrators available are as follows:

- Ferticare
- Viberect

Electroejaculation

Initially used in veterinary medicine and animal husbandry, electroejaculation produces seminal emission by sinusoidal electrical stimulation of sympathetic efferent fibers and smooth muscle. The best site for inducing seminal emission is in front of the bifurcation of the aorta, between the rectum and obturator nerves, where both preganglionic and postganglionic sympathetic fibers reside. Unfortunately, because electroejaculation does not stimulate the somatically mediated events of ejaculation or coordinate bladder neck closure essential to antegrade emission, pulsatile expulsion of seminal fluid does not occur. Rather, semen either dribbles from the meatus or is deposited retrograde into the bladder.[14,15]

A complete urologic evaluation is required prior to electroejaculation in order to detect and treat any urinary tract infections. Men with spinal cord injuries often have a problem of poor sperm production as well as ejaculatory difficulty. A diagnostic trial of electroejaculation is attempted to obtain and examine the quality of the semen specimen. Good quality samples are frozen for future use as a backup. A fresh specimen is obtained at the time of the women's ovulation. Unlike vibratory stimulation, electroejaculation is uniformly successful, irrespective of the duration and level of the spinal lesion.

Electroejaculation is performed with a device known as an electroejaculator. A specially designed electric probe is inserted into the rectum next to the prostate. A current generated by the machine is applied to stimulate the nerves and produce contraction of the pelvic muscles resulting in ejaculation.[16] The procedure begins by first catheterizing

the patient in supine position and emptying the bladder completely. The use of betadine is to be avoided because of its spermicidal effect. Instead, the urethra is lubricated with glycerin for catheterization. The pH of urine should be assessed to ensure its alkalinity (pH >7.0). Oral sodium bicarbonate may be used if necessary. Because retrograde ejaculation occurs frequently in this procedure, an additional 10 cc of the medium is instilled into the bladder to help preserve any sperm inside the bladder. The catheter is then removed. Although it is possible to perform the procedure in lithotomy position, lateral decubitus position is preferred, as it allows easier access to both the penis and rectum.

Rhythmic delivery of current is performed by manually turning the dial to increase the voltage delivery progressively for a few seconds. After a few initial stimulations, the voltage is reduced to zero. Voltage is then gradually increased until erection/ejaculation has occurred. The voltage at which the first erection/ejaculation occurs is noted and it is then increased to a level 30–50% higher, depending on patient's tolerance and the rectal temperature, which is constantly monitored and displayed. Ejaculation may be entirely retrograde and in such cases, sweating, piloerection, goose bumps on the thighs, buttocks, and partial erection may be the only signs that the patient is adequately stimulated and ejaculated. The number of stimulations, the current, and the voltage necessary to produce a maximum erection are noted, as this information will be useful for subsequent procedure if needed. The ejaculate is collected directly into a cup containing a sperm friendly buffer.

The collected semen specimen is processed in the andrology laboratory and if the specimen is of very good quality,[17] then it can be used for intrauterine insemination (IUI). If there are few sperms, or the sperms have low motility, then the specimen can be used with in vitro fertilization/intracytoplasmic sperm injection (ICSI) to establish a pregnancy. Electroejaculation must be performed under general anesthesia in all patients who have abdominal and perirectal sensation. Anesthesia is not required for spinal cord injured men who have high level injuries and are without sensation. Anyone who has a history of autonomic dysreflexia must have blood pressure and heart rate monitored as electroejaculation may cause a significant increase in blood pressure.

Initial results in terms of the ability to obtain motile sperm were variable, but with refinements in the equipment and techniques, sperm can now be obtained in approximately 90% of anejaculatory patients. These patients have excellent sperm densities averaging 180–300 million/cc. Despite success in the induction of ejaculation, sperm motility has continued to be low, limiting fertility in these patients. Mean sperm motilities of 20% have been reported in several series.[18] This poor motility appears to be secondary to intrinsic factors such as elevated scrotal temperature and recurrent genitourinary tract infection rather than to the electroejaculation procedure. The use of assisted reproductive techniques, especially ICSI, has become increasingly important in this patient population.[19] Because these patients often have supranormal sperm densities with low motility, semen processing with Percoll gradients may be beneficial in removing non motile sperm, white blood cells, and debris before insemination.

Research on persistent low motility in these patients suggests that psychogenic anejaculation is associated with increased incidence of antisperm autoimmunity explaining poor motility.[20] The majority of antibodies were directed against the sperm heads. Surface antibodies were mainly IgA isotype whereas serum antibodies were IgG isotype. Further research on sperm motility and effects of electrical current on sperm behavior in vitro exhibited a significant two fold decrease in motility percentage and viability. Superoxide dismutase (SOD) activity decreased significantly in sperm subjected to direct electric current, in comparison to the control groups.[21] These studies indicate that in vitro and in vivo electrical stimulation generates reactive oxygen species, which affects superoxide dismutase (SOD) activity, which in part is responsible for decreased sperm motion and viability.

Electroejaculation and vibratory stimulation have enabled many men who suffer from ejaculatory failure to conceive children of their own but it is imperative to plan for multiple sittings to maximize benefit.

Patient Preparation

Pretreatment: 24–48 hours alkalinization with sodium bicarbonate, 2 g PO TID.

- Bladder wash + medium optional*
- *They may need*:
  - Prophylactic antibiotics, if there is a history of urinary tract infection
  - Alpha agonist (e.g., Sudafed) to prevent retrograde ejaculation
  - Nifedipine (sublingual), if there is autonomic dysreflexia
  - Several proprietary media are available for sperm preservation
  - Currently, employing this technique, semen can be obtained in >90% of neurologically impaired men. More than 40% of the couples achieve pregnancy with IUI or IVF. Pregnancy rates are slightly better among couples in whom the male partner had spinal cord injury (43%) or idiopathic anejaculation (33%) than in those who had undergone retroperitoneal lymph node dissection (20%) or had diabetes.

Types of electroejaculators:

- Saeger
- Brindley

Retarded Ejaculation

Retarded ejaculation is the persistent difficulty or inability to ejaculate despite the presence of adequate sexual desire, erection, and stimulation (Glander HJ, 1998). Ejaculatory episodes are either partial, without pleasure or with pain. The causes of this dysfunction may be organic, i.e. medical illness or drug induced (particularly medications with antiadrenergic effects), the result of surgical interventions, or secondary to inhibiting psychological factors. With regard to psychological determinants, fear, guilt, and resentment have all been implicated.

Medical therapy is helpful in patients with severe psychological factors, and behavioral therapy or vibratory therapy helps most patients.

Orgasmic Disturbances

- Primary
- Secondary.

Primary absolute anorgasmia is the inability to have an orgasm and ejaculation during any kind of sexual activity while awake, in men with normal erectile function and nocturnal emission.[22] Though some men are occasionally found to have a neurological basis for the problem (occult spinal dysraphism with tethered cord, MS, etc.), primarily it is psychogenic with very few cases reported in literature. Primary modality of treatment of this condition is by:

- Sexual behavioral therapy—where in majority are refractory to treatment.
- Electroejaculation—may require multiple sittings and is usually successful.
- Vasal aspiration and ICSI is used in resistant cases.

Secondary anorgasmia is mainly associated with psychotropic drugs such as sertraline and gabapentin. Clinicians are increasingly faced with the need to identify, treat, and counsel patients regarding psychotropic drug induced sexual dysfunction. Antipsychotic and antidepressant drugs have both rational mechanisms to explain their effects on sexual function and established literature documenting these effects. Sexual dysfunction secondary to the use of antidepressants, especially clomipramine or SSRI's is an adverse effect that is often underestimated. This can affect approximately 60% of the patients. These patients may present with decrease in libido, alterations in the ability to reach orgasm/ejaculation, erectile dysfunction and anorgasmia. These dysfunctions appear to be related to the increase in serotonin, which occurs with the stimulation of serotonin 5 HT receptors. Nefazodone, amantadine, cyproheptadine, sildenafil, and serotonin antagonist mianserin are some of the drugs used in secondary anorgasmia but are ineffective. Failing drug therapy, electroejaculation, or vibratory stimulation is generally successful.

ERECTILE DYSFUNCTION INTRODUCTION

Virtually every male can regain sexual function if he so chooses. The silent suffering experienced by over 50% of males can come to an end with a wide spectrum of treatment forms from well-known means Sildenafil to not so commonly known ones like penile implants.

Sexual dysfunction as a consequence of drug therapy has been reported with a range of drugs, notably antihypertensives, antipsychotics, and antidepressants. The overall incidence of drug-induced sexual dysfunction is difficult to quantify. Patients are often unwilling to raise the issue of sexual health with health professionals leading to under reporting of problems. In addition, many diseases can affect sexual function, making it difficult to establish causality with a drug rather than concurrent illness. Antihypertensive medications are associated with erectile dysfunction and are often prescribed for hypertension in patients with diabetes, which itself may cause impotence. Other factors that can influence sexual function in men and women are age, alcohol consumption, smoking, drugs of abuse, over the counter medicines, and exposure to environmental or occupational toxins. Most of the published literature relates to the adverse effects of drugs on male sexual function. It is more difficult to assess these effects in women and this aspect of drug safety has seldom been considered in clinical studies **(Table 1)**.

The era of safe and effective surgery for the management of erectile dysfunction. The penile implant came to represent the "energizer bunny" approach to male sexual dysfunction, emphasizing the importance of a durable on demand rigid erection. The evaluation and management of male sexual dysfunction switched from the psychiatrist's couch to the urologist office and the operating room. If the "phallocentric approach" was born out of surgical zeal to fix something that was broken, it was also nurtured by industry's correct perception of the financial health market. The chance discovery in 1982 that a vasodilator could produce a normal erection in the absence of sexual stimulation began *the age of physiology and pathophysiology* of erectile dysfunction. This was a decade of directed research that culminated in 1993 with the first National Institutes of Health (NIH) Consensus Conference on impotence where the various aspects of male sexual function (interest, performance, and satisfaction) were addressed and erectile dysfunction was specifically defined.[23-40]

The participants looked at multiple strategies for correctly identifying and evaluating ED; they were most impressed by the statistical associations with increasing age, and the concurrence of distinct medical illnesses—diabetes, atherosclerotic peripheral and coronary artery disease, hypertension, cigarette smoking, and chronic renal insufficiency. In the clinical arena the "goal-directed" was formulated to conserve health care dollars and minimize morbidity to patients from excessive testing. The goal

TABLE 1: The major risk factors for the development of erectile dysfunction (ED).	
Aging	Men who are aged 50–90 are 10 times more likely to develop erectile dysfunction than men younger than 50
Comorbidities	Certain medical conditions can increase the risk of erectile dysfunction, including diabetes and cardiovascular disease. Arteriosclerosis (hardening of arteries), chronic kidney disease, liver failure, Peyronie's disease (bending of the penis caused by scar tissue), endocrine disorders neurological disorders (such as multiple sclerosis, peripheral neuropathy, and stroke), hypertension (high blood pressure), psychiatric disorders (such as anxiety, depression, and schizophrenia)
Traumatic conditions	Vascular surgery, urologic surgery, pelvic surgeries (particularly for prostate cancer), and spinal cord injury
Lifestyle behavior	Certain behaviors increase the risk of erectile dysfunction, including—alcohol use, illegal drug, anabolic steroid use, heavy smoking, interpersonal conflicts with a sexual partner
Medications	Medications increasing the risk of erectile dysfunction, include antihypertensives, antihistamines, antidepressants, tranquilizers, and antipsychotics

directed approach was based on a very limited number of options for ED, and recognition that the main purpose of testing to establish a diagnosis should be to formulate a treatment plan. In an era when there were no cause-specific treatments a good sexual history with assessment of medical risks, permitted most patients to be safely directed to therapy based solely on preference. Without testing efficacy and satisfaction were matters of chance.

Among patients referred to urology clinics for ED, the subgroups having decreased libido, testicular damage/abnormality, arterial disease, insulin resistance, or diabetes were more likely to have hypogonadism. The evidence is less consistent concerning such factors as the severity of ED, duration of ED, or sexual disorders (e.g., premature ejaculation).

Laboratory Testing

Laboratory testing needs tailoring to the patient's complaints and risk factors. Patients may need a fasting blood glucose or HbA1c [preferred over fasting blood sugar (FBS) or random blood sugar (RBS)], and lipid profile, if these are not assessed recently. Hormonal tests include an early morning total testosterone. If indicated, the bio-available or calculated-free testosterone may be needed to corroborate total testosterone measurements. However, the threshold of testosterone required to maintain an erection is low, and ED is usually a symptom of more severe cases of hypogonadism. For levels >8 nmol/L relationship between circulating testosterone and sexual functioning is quite low. Additional laboratory tests may be considered in selected patients [e.g., prostate-specific antigen (PSA), prolactin, and luteinizing hormone]. Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, they present opportunities to identify critical comorbid conditions that should not be missed.

This new age of effective oral pharmacotherapy presents the possibility of cause specific therapy. Currently under clinical evaluation are multiple oral agents with distinct pharmacological mechanisms: central initiators of erection, central conditioners of sexual behavior and peripheral modulators of penile blood flow. Currently, we are compelled to categorize patients simplistically as oral agent responsive or oral agent resistant erectile dysfunction. When available treatments grow into a "laundry list of options" the role of impotence testing will assume a two-fold importance—establishing an etiology specific diagnosis and formulating an effective treatment plan. Patients seeking the expertise of urologists will want to know why a specific agent has failed. We will return to erectile testing to produce vascular profiles, to predict which oral drug or combination of drugs (oral, cutaneous, urethral, and intracavernosal) will effectively restore their erections, or to determine whether patients would best be served by the placement of a penile prosthesis.

How Has Oral Pharmacotherapy Changed ED Practice?

Evidence-based assessments of erectile dysfunction have taken a secondary role in the evaluation process; the introduction of effective oral pharmacotherapy for vascular impotence has dramatically altered my approach to ED testing much like injectable vasoactive agents almost two decades prior. It is clinically pragmatic to begin every evaluation of male sexual dysfunction with a good medical history to determine the patient's relative risks for vascular ED—hypertension, atherosclerotic coronary and peripheral vascular disease, diabetes mellitus, and smoking. Sex questionnaires are a good way of structuring the male sexual history for the novice, but it is unclear whether they accurately distinguish psychogenic from vasculogenic dysfunction or whether they can qualify the severity of erectile dysfunction, no matter what the etiology. It is pragmatic to use an oral agent in a diagnostic role and to characterize the patient as having "oral agent responsive" or "oral agent resistant ED."

Pharmacotherapy: Rationale

The physiology of the smooth muscle cell (SMC) in the trabeculae of the cavernosal sinusoids and in the walls of the cavernosal and helicine arteries is central to the unique erectile function of the penis. The functional state of the

penis is a neurovascular event representing the balance between the degree of relaxation and that of contraction of the SMC.

Nitric oxide (NO), produced by the vascular endothelium and the nonadrenergic noncholinergic parasympathetic nerve endings under the influence of the various isoforms of NO synthase, is the principal chemomediator for SMC relaxation, thus penile erection, through the production of cyclic guanosine monophosphate (cGMP). While neuronal NO initiates erection, endothelial NO maintains the erectile response. Alongside this, through the cyclic adenosine monophosphate (cAMP) pathway, prostanoids and vasoactive intestinal polypeptide also contribute to SMC relaxation.

Smooth muscle cell contraction, on the other hand, is brought about principally by noradrenaline via the $\alpha 1$ sympathetic pathway, and is responsible for penile flaccidity and detumescence. Other chemotransmitters for SMC contraction include endothelin, neuropeptide Y and prostanoids. Currently available pharmacotherapeutic agents for ED act mainly by enhancing SMC relaxation through the selective and nonselective inhibition of the phosphodiesterases.[41,42]

Role of Testosterone in Erectile Dysfunction

Testosterone modulates the expression of NO synthase in the corpus cavernosum and the production of NO, and acts on the cavernosal arterioles enhancing penile rigidity. It influences genital sensitivity and pleasurable enhancement of erectile activity. Testosterone deficiency is an infrequent cause of ED. However, if it is the confirmed cause, treatment with testosterone supplementation is rewarding. Correction of androgen deficiency not only restores erectile function but also improves general well-being and libido. As it influences NO production through hits modulating effect on NO synthase, testosterone enhances the treatment outcome for ED with PDE5 inhibitors.[43-46]

There is no universally accepted method of identifying men with clinically relevant hypogonadism affecting erectile function. The implications of androgen status for erectile dysfunction and its treatments continue to remain controversial. Given the current gaps in knowledge, the most adequate and cost-effective laboratory test for hormonal evaluation is unclear. The two differing guideline statements available reflect this problem.[25]

The American Urological Association recommends testosterone testing based on initial clinical assessment results or failure of prior management with PDE5 inhibitors. However, the European Urological Association mandates testosterone measures (bioavailable or calculated-free testosterone begin preferred over total levels) for all men with ED. These two associations have similar guidelines, which suggest that further laboratory investigations including prolactin, luteinizing hormone (LH), and follicle stimulating hormone (FSH) testing are indicated when low testosterone levels are detected.

Recommendations

Testosterone therapy is not indicated for the treatment of erectile dysfunction in the patient with a normal serum testosterone level.

Combination Pharmacotherapy for the Hard-to-Treat Erectile Dysfunction

Although response to the currently available pharmacotherapy is mostly satisfactory, a significant number of patients with ED are unable to achieve an adequate response. There is, therefore, the need to explore if there may be beneficial outcomes from a rational combination of the therapeutic agents in current use, until newer agents become available. At least three plausible combinations would merit consideration:

- Combination of a centrally acting agent with a peripherally acting agent, e.g., sublingual apomorphine with oral PDE5 inhibitor.
- Combination of an agent acting via the cGMP pathway with one via the cAMP pathway, e.g., oral PDE5 inhibitor with intracavernosal alprostadil.
- Combination of an agent enhancing SMC relaxation with one decreasing SMC contraction, e.g., oral PDE5 inhibitor with α-1 adrenergic blocker.

Further research will be needed to confirm the usefulness of such combinations as intracavernosal alprostadil and oral PDE5 inhibitor and provide rational guidelines for this and other combinations of proven value to be part of the management strategy for ED. The risk of possible side effects may be minimized if the relevant exclusion criteria and prerequisites, based on a sound understanding of the pharmacological properties of the agents used, are strictly observed and treatment protocol meticulously followed.

How Much Testing is Needed in the Era of Effective Oral Pharmacotherapy?

The selection of a treatment for erectile dysfunction (ED) in the 1970s was relatively simple. Sex therapy was the treatment of choice for psychogenic ED, and penile prosthesis implantation was the only reasonable treatment option for organic ED. Today we have a variety of treatment options including: sex therapy, systemic therapy, vacuum erection devices, intraurethral pharmacotherapy, penile injection therapy, penile prosthesis implantation, vascular surgery and the most recent addition penile shock wave therapy. The introduction of the concept of intracavernous vaso active drug injection in 1983 significantly changed both the evaluation and the treatment of ED. Now the following tests based on vasoactive drug injection are available—test injection, cavernosometry, cavernosography, and duplex ultrasonography.

Which of These Tests, If Any, Should be Performed and How Valid are these Tests?

Vasoactive intracorporeal drug injection triggers two responses. The first is increased arterial inflow, which leads to tumescence. The second is corporeal smooth muscle relaxation which if complete leads to corporovenous occlusion and rigidity. Both of the responses can be blunted by anxiety, but this is much more likely to occur with the second response. Psychogenic ED has two subtypes. The man with high performance anxiety remains completely flaccid. The man with a lesser amount of anxiety develops tumescence but either does not obtain full rigidity or cannot maintain it. Responses to diagnostic testing involving vasoactive drug injection often parallel what occurs in men with psychogenic ED; thus these tests are not reliable for differentiating psychogenic from organic ED. Because vasoactive drug injection does not invariably produce complete smooth muscle relaxation, the validity of tests involving these injections comes under question.

In terms of a diagnostic test injection, if a man responds with a full, sustained erection, he may be normal, he may have neurogenic ED, or he may have mild vasculogenic ED. On the other hand, if he fails to respond to a test injection, nothing can be said about the etiology of his ED.

Duplex ultrasonography study of the penile arteries after vasoactive drug injection has two components. The assessment of peak systolic velocities in the cavernous arteries is probably reasonably accurate as this phase of the erection response to these drugs seems less influenced by anxiety than the corporovenous occlusive phase. However, since complete smooth muscle relaxation is quite subject to anxiety, one should be cautious about making the diagnosis of corporal venous occlusive disease/dysfunction (CVOD) if the end diastolic velocity does not return to zero.

There has been a disturbing trend in recent years toward over reliance on tests involving vasoactive drug injections. This is often associated with taking an incomplete sexual history. This is unfortunate because some important elements of the evaluation can only be ascertained by taking a good sexual history. For example, a man with premature ejaculation often presents with the complaint of problems with erections. An incomplete history fails to uncover the fact that his problem is in fact with ejaculatory control. The patient is then subjected to unnecessary testing which often leads to the false diagnosis of CVOD and unnecessary surgery. Another disturbing trend is the abandonment of NPT testing, a diagnostic technique which has been well validated by studies in normal subjects.

Diagnosis and treatment of erectile dysfunction is given in an Analytic framework depicted in the **Figure 1**.

In the Era of Goal Directed Therapy are Any Tests Necessary?

If a man and his partner select a nonsurgical treatment, then a thorough sexual and medical history, physical examination, and laboratory studies to rule out occult systemic disease and hypogonadism should suffice. If a man elects surgical treatment, then further testing is usually desirable.

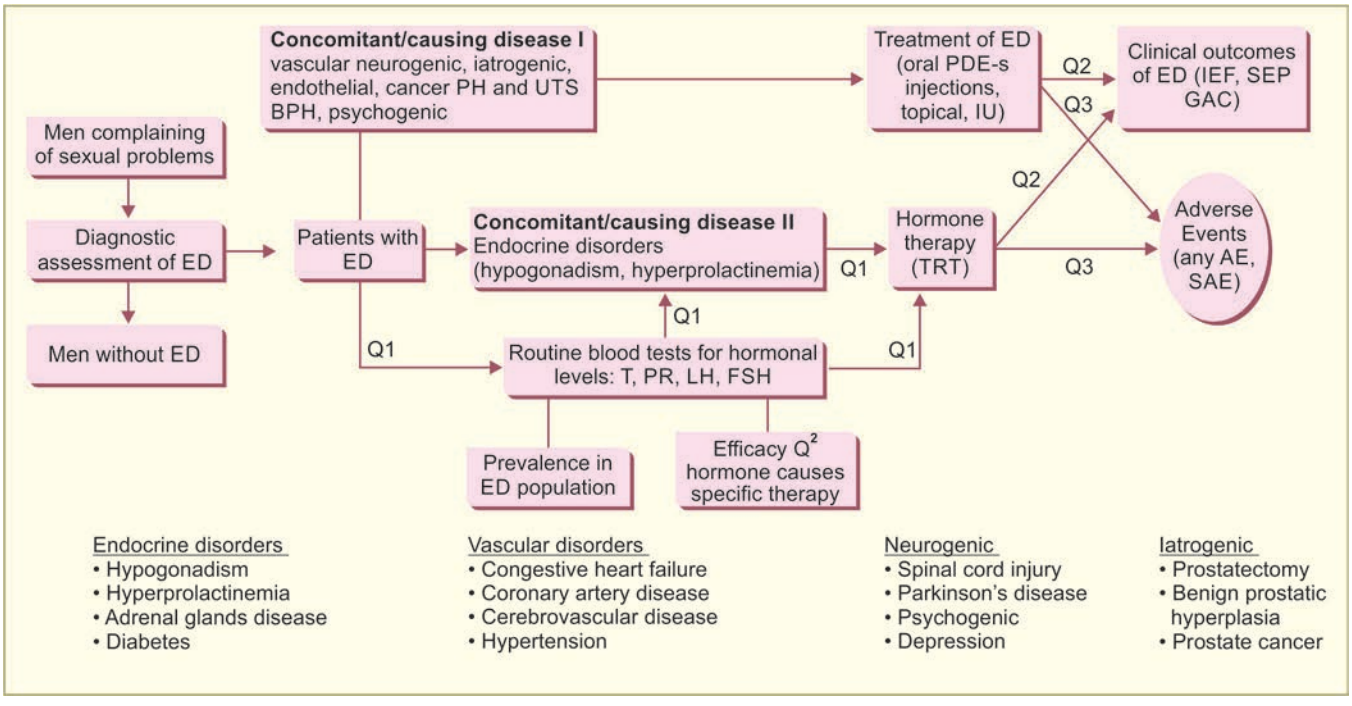

Fig. 1: Analytic framework for the diagnosis and treatment of erectile dysfunction.

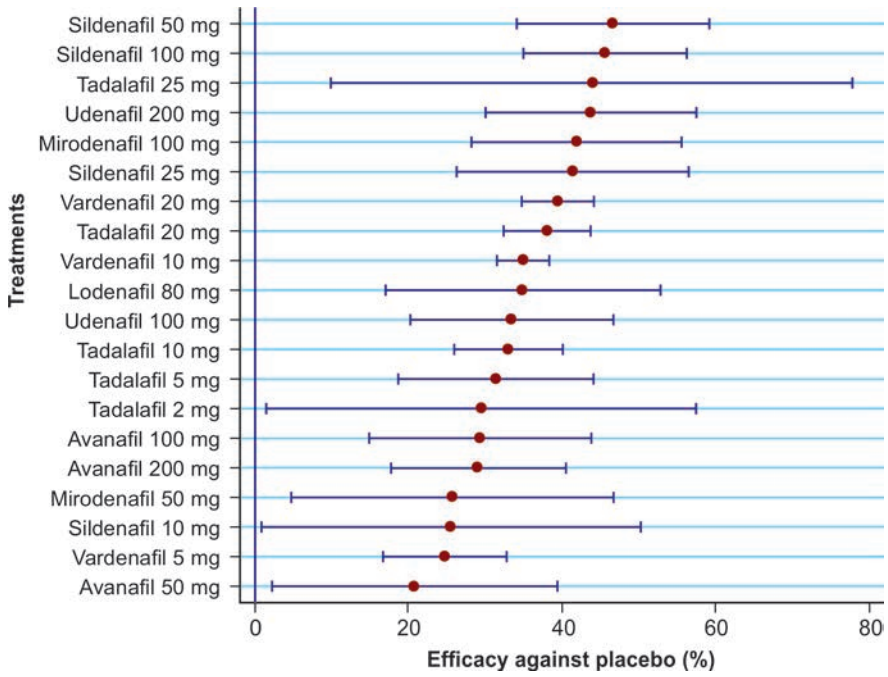

Fig. 2: Efficacy of phosphodiesterase type 5 inhibitor as per trade-off analysis. Sildenafil 50 mg had the greatest efficacy.
Source: Chen L, Staubli SE, Schneider MP, Kessels AG, Ivic S, Bachmann LM, et al. Phosphodiesterase 5 inhibitors for the treatment of erectile dysfunction: a trade-off network meta-analysis. Eur Urol. 2015;68(4):674-80.

Erectile Dysfunction Assessment and Treatment Protocol Evaluation-diagnostic Algorithm for ED (Fig. 1)

- Sexual history (validated questionnaire)
- Psychological profile
- Medical history

Physical Examination Assessment of Cardiac Risks

Investigations:

- Fasting blood sugar
- Lipid profile if indicated
- Serum testosterone if needed

Management/Treatment

- Educate patients regarding treatment options and associated risks and benefits.
- Manage risk factors for erectile dysfunction (e.g., lifestyle modifications to prevent or reverse erectile dysfunction).
- Consider comorbidities when managing patients with ED (e.g., provide appropriate management of patients with ED in the presence of cardiovascular disease).
- *Pharmacologic therapy*:
  - Phosphodiesterase type-5 (PDE5) inhibitors (sildenafil, tadalafil, and vardenafil) **(Figs. 2 and 3) (Table 2)**
  - Alprostadil intraurethral suppositories
  - Intracavernous injection with alprostadil, papaverine, or phentolamine or combinations.
- Vacuum constriction devices:
- *Surgery*:
  - Penile prosthesis implantation with preoperative administration of antibiotics
  - Vascular surgery (penile arterial reconstructive surgery).
- Periodic follow-up of efficacy, side effects, and change in health status.

Primary Interventions

- *Suspicion of predominantly psychogenic impotence*: Psychotherapy
- *Low testosterone and no contraindications*: Testosterone replacement
- *Performance anxiety + mild organic risk factors*: NO donors + mood elevators +/– *sildenafil/tadalafil/vardenafil moderate organic risk factors*: Sildenafil–tadalafil or vardenafil–titrate dosage

Option of intracavernous injection (I/C) therapy for failures or combination therapy of oral drug + I/C injection.

Third Line Therapy—Penile Prosthesis

In **Tables 2 and 3**, we see that penile prosthesis implantation is the only treatment option, which is applicable under all circumstances. VED's (vacuum devices) have the next broadest usage (however this is popular in US but not in India due to cultural reasons and feeling that it is too artificial) but they require reasonably intact corpora, MUSE or ICI require reasonably intact arterial inflow and corpora, and systemic therapy requires that some of all 3 determinants be present.

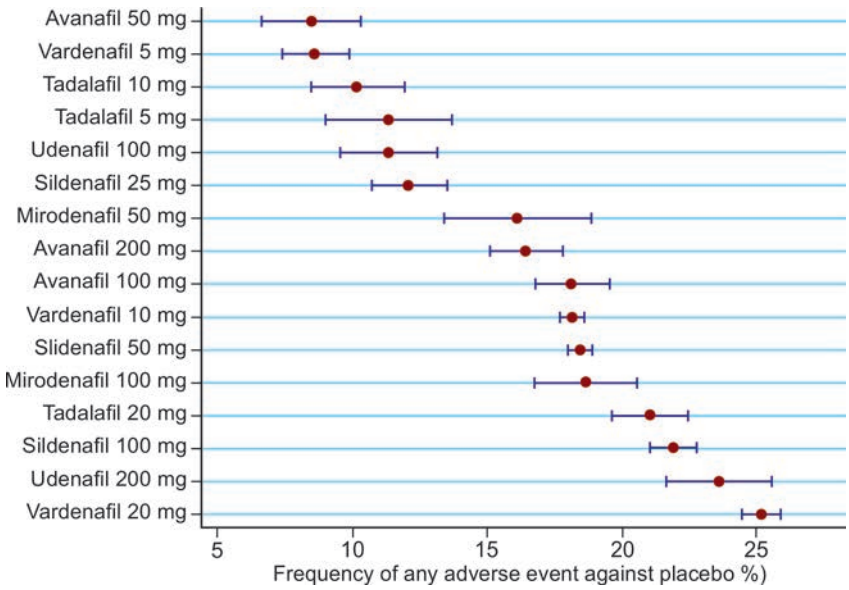

Fig. 3: Safety of phosphodiesterase type 5 inhibitor as per trade-off analysis. Tadalafil 10 mg had the lowest overall rate of all adverse events. *Source:* Chen L, Staubli SE, Schneider MP, Kessels AG, Ivic S, Bachmann LM, et al. Phosphodiesterase 5 inhibitors for the treatment of erectile dysfunction: a trade-off network meta-analysis. Eur Urol. 2015;68(4):674-80.

VED	–	–	+
Implant	–	–	–

When there are significant problems with the corpora in terms of abnormalities of the tunica albuginea and/or the cavernosal smooth muscle, penile prosthesis implantation may be the only reasonable treatment alternative. This includes men with corporeal fibrosis following removal of an infected penile prosthesis or following priapism and men with erectile deformity secondary to Peyronie's disease if they also have significant ED.

Future Therapies in Management of Erectile Dysfunction

Extracorporeal shock wave therapy (ESWT) is currently used in the treatment of urinary stones in orthopedics, cardiology, wound healing, plastic surgery and neurology. Shockwaves are being successfully used around the world since 2005 to treat reversible ischemic tissues in the heart, inducing neovascularization and developing new collaterals which improves the blood supply to tissues.[47] The same modality is used for treatment of vascular based (poor blood flow) erectile dysfunction problems. This therapy aims to provide improvement and possible cure for ED. It allows a man to return to a more normal erection.

With ESWT, it has been possible for the first time to establish a rapid, effective, and cost-effective outpatient therapy that can be used as often as required without any side effects. Short term results are extremely encouraging. Pharmacotherapeutic strategies for ED either promote proerectile mechanisms or suppress antierectile mechanisms, or do both. These objectives are based on the knowledge that the erectile state represents a finely controlled equilibrium between proerectile and antierectile mechanisms that influence corporal smooth muscle tone.

Promoting proerectile action can be achieved by either—(i) inducing smooth muscle relaxation through cell receptor agonists or direct activators of tissue relaxant pathways [e.g., stimulating second messenger cyclic nucleotide (cGMP or cAMP) synthesis] or (ii) inhibiting the deactivation of smooth muscle relaxation pathways. In the latter strategy, for example, inhibition of phosphodiesterases, enzymes that inactivate cAMP or cGMP, results in the accumulation of these nucleotides, which in turn diminishes contractility of smooth muscle tissue and thus maintains the muscle relaxation necessary for erection. Suppressing antierectile action can be achieved by decreasing smooth muscle contraction through receptor antagonists of tissue contractile pathways [e.g., alpha 2 adrenergic (nor epinephrine) inhibitors].

Indications for treatment for ED are enumerated in **Table 3**.

Treatment approaches may also be directed toward the central nervous system (i.e., brain or spinal cord. Similar to peripheral mechanisms, these either promote proerectile pathways (e.g., agonists of dopaminergic receptors in the medial hypothalamus or suppress antierectile pathways [e.g., antagonists of 5(HT.sub.lA/2) serotonergic receptors in the spinal cord] **(Table 4)**.

SUMMARY

Infertility is an emotional crisis and a physical challenge because it interferes with one of the most fundamental human activities. From a list of 87 items of stressful life events, infertility has been ranked as one of the most negative stressful situations—akin to the death of a son or a spouse.

Fertility related concerns are significant for the spinal cord injured male because of his young age and loss of ejaculatory function. Fortunately, using electroejaculation and vibratory stimulation, the successful recovery of sperm has become routine. However, because of the poor quality of the sperm obtained, the assisted reproductive techniques of intrauterine insemination and in vitro fertilization have had only modest pregnancy results. The revolutionary technique of intracytoplasmic sperm injection (ICSI), which involves the injection of a single sperm into an oocyte, is particularly applicable for these patients and has been very successful in initiating pregnancies. The potential for improvement in semen recovery and processing is great and must be considered a challenge for the immediate future. Finally, fertility issues in men may be quite complex and clearly needs a multidisciplinary management approach.

KEY RECOMMENDATIONS

Common Sexual Problem in Clinical Practice and History

As per The Diagnostic and Statistical Manual of Mental Disorders, 2013, all these problems should be present for minimum 6 months and should be associated with personal distress to term as dysfunction. Sexual history taking is very important and crucial first step in arriving to the etiology of sexual dysfunction. Almost 70% cases of sexual problems can be diagnosed by meticulous history taking alone.

Sexual history can be taken by verbal or nonverbal methods including various questionnaires such as Arizona Sexual Experience Scale and The International Index of Erectile Function.

Brief screening questions like "many people have sexual concerns, I wonder what yours might be?" provide high yield of information related to sexual health when it is covered as part of routine history in patients with other health problems.

Almost 64% of men reported some concomitant illness associated with erectile dysfunction; 29% having one comorbidity; 20% having two comorbidities; 11% having three comorbidities, and 5% having four or more comorbid conditions. The common comorbid conditions associated with erectile dysfunction (ED) are angina, hypertension, depression, diabetes, hypercholesterolemia, etc.

Erectile dysfunction and cardiovascular disease have common risk factors, which are dependent on endothelial function all over the body. Smoking, blood pressure, diabetes, and cholesterol all are the common risk factors for both **(Flowcharts 1 and 2)**.

As the diameter of the penile artery is less compared to coronary artery, ED often occurs before other vascular diseases. Hence, it is important to evaluate cardiovascular status as well in young patients presented with ED.

Almost three out of four diabetic patients have reported erectile problems, and as the prevalence of diabetes increases, so the prevalence of ED. Hence, it is important to ask every patient of diabetes coming to the clinic regarding erectile function.

Endothelial dysfunction is a significant marker to predict hypertension and diabetes. As per one study in postmenopausal women, endothelial dysfunction leads to 5.8-fold increase in developing hypertension and sixfold increase in developing diabetes over a period of 3–5 years.

Diagnosis of endothelial dysfunction helps in early diagnosis of cardiovascular and metabolic events.

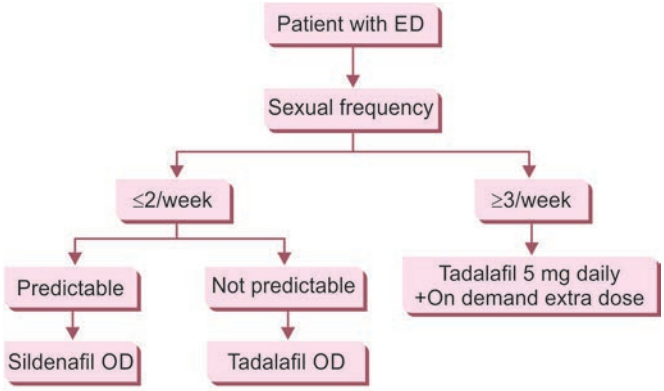
Flowchart 5: Algorithm for erectile dysfunction (ED) medication prescription.



Start with max dose-reduce for side effects

The Erection Hardness Score is a simple measure to diagnose the hardness of penis, which is an old method of ED evaluation.

Assessment of penile endothelial function can help detect early systemic derangement and facilitate ED or vascular risk assessment **(*see* Flowcharts 3 to 5)**. Brachial artery reactivity test is a standardized test to assess the terminal arteriolar health. A reactivity index obtained by this test could indicate penile arteriolar vascular health and endothelial derangement. Tissue perfusion of oxygen is an indirect measure of nitric oxide level, which can be measured by FDA, approved devices. Systemic involvement of endothelial dysfunction can be evaluated by assessment of medium size arteries with pulse wave velocity. Abnormal findings of these tests in ED evaluation suggest that such patients are at high risk of developing future cardiovascular events. Shock wave therapy is one of additional modality of management of arteriogenic ED.

It is hypothesized to increase the nitric oxide level and vascular reactivity as assessed in rat model and cardiac muscle. As per a global study, the effect usually lasts for about 12–14 months with peak effect reported till 6–8 months. Who will benefit? Only those who have the sexual health inventory for men score >8 and mainly arteriogenic ED.

CONCLUSION

In today's era, any patient of sexual dysfunction is treated according to identifying which part of sexual cycle is invovled and keeping his and his partner's goal. The idea is not to be judgmental of patient's preferences but appropriately counsel them about all options, to lead a satisfactory and fulfilling sexual life, which will ultimately enhance their quality of life, which is the main goal of medical practice in this century.

KEY POINTS

In today's era, we can ensure that every patient of ED is treated according to his and his partner's goal. The idea is not to be judgmental of patient's preferences but appropriately

counsel them about all options, to lead a satisfactory and fulfilling sexual life, which will ultimately enhance their quality of life, which is the main goal of medical practice in this century.

CHAPTER 27

Ultrasound in Male Infertility

Kuldeep Jain, Bharti Jain, Maansi Jain

INTRODUCTION

Infertility incidence is increasing and as per estimate, 15% population in the reproductive age group is affected from infertility[1] and a large number of infertile couples opt for treatment because of increasing awareness, availability of infertility-related services, and advancement in all fields of infertility management. Studies have shown that male and female factors coexist in approximately 30% of cases; 30% are because of female problems, while rest are due to male factor. Therefore, it is important to evaluate the male partner concurrently as it may be contributing in as high as 60% of cases.[2]

The primary screening investigation of male infertility is the semen analysis. Male factor can be safely excluded if the semen parameters are normal as per the World Health Organization (WHO) criteria. However, if abnormal, further investigations are required to exclude the causes of infertility and characterize them as testicular, pretesticular, and post-testicular.

ETIOLOGICAL DISTRIBUTION

Table 1 shows the etiological distribution as per a study of 7,057 men.[3]

TABLE 1: Etiological distribution as per a study of 7,057 men.

Factors	*Percentage*
Sexual factor	1.7
Urogenital infection	6.6
Congenital anomalies	2.1
Acquired factors	2.6
Varicocele	12.3
Endocrinal disturbances	0.6
Immunological factors	3.1
Other abnormalities	3.0
Idiopathic oligoasthenoteratozoospermia (OAT)	75.1

As it is evident from the table, >75% of cases do not have any demonstrable cause and usually no investigation is helpful in management.[3]

In the diagnostic protocol, ultrasound (US) has become an integral part of infertility management because it is noninvasive and the entire male genital tract can be imaged easily and accurately. However, ultrasonography (USG) is only indicated for a minority of infertile male patients,[4-7] and the use of USG in male infertility is surrounded by several controversies. This chapter aims to look into the technique of USG and delineate the clinical relevance in male infertility and to evaluate various controversies and recommendations.

Routine USG of male genitalia may not be helpful in diagnostic management of all cases of male infertility and so is not required in all cases. There are certain specific conditions where USG may be helpful in confirming pathology as well as in decision-making. Scrotal USG provides a panoramic view and is very helpful in confirming suspected abnormalities on physical examination, differentiating between testicular and paratesticular pathology, and transrectal ultrasonography (TRUS) is indicated to exclude obstructive azoospermia, mainly the congenital absence of vas deferens (CAVD), seen in 10–20% cases. The aim of the imaging modality is to identify a pathology which can correct a potentially correctable cause and select the best method for retrieving a sperm capable of fertilizing the ova-like sperm aspiration from epididymis and testicular seminiferous tubules which can be used later for intracytoplasmic sperm injection (ICSI).

INDICATIONS OF SCROTAL ULTRASOUND[4,8]

The indications of scrotal ultrasound are as follows:

- *Testicular abnormalities:*
  - Absent testes/cryptorchidism **(Fig. 1)**
  - Atropic/small testes **(Fig. 2)**
  - Ectopic location
  - Enlarged testes/hydrocele **(Figs. 3A and B)**
  - Testicular tumor/neoplasm
  - Abnormalities associated with obstruction
  - Mediastinal cyst

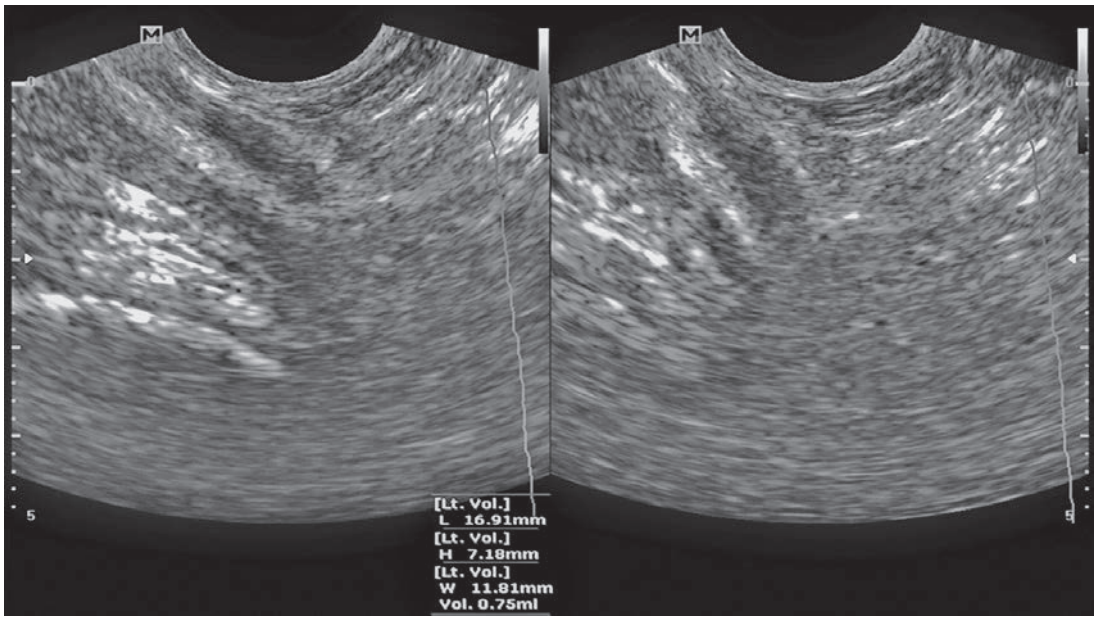

Fig. 1: Absent testis—undescended testis.

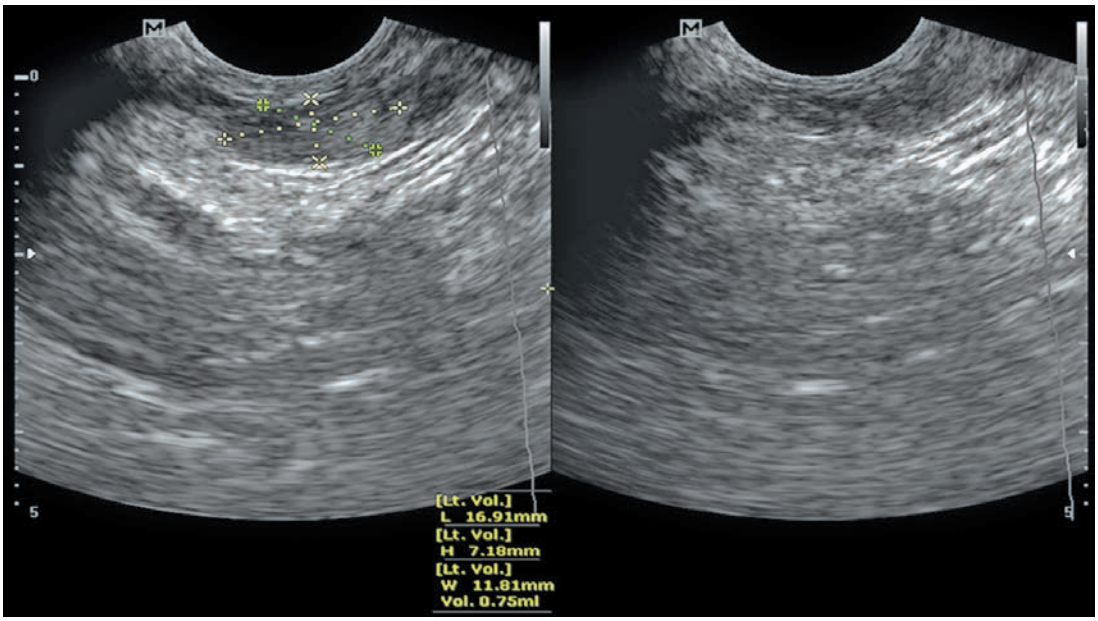

Fig. 2: Atropic testis.

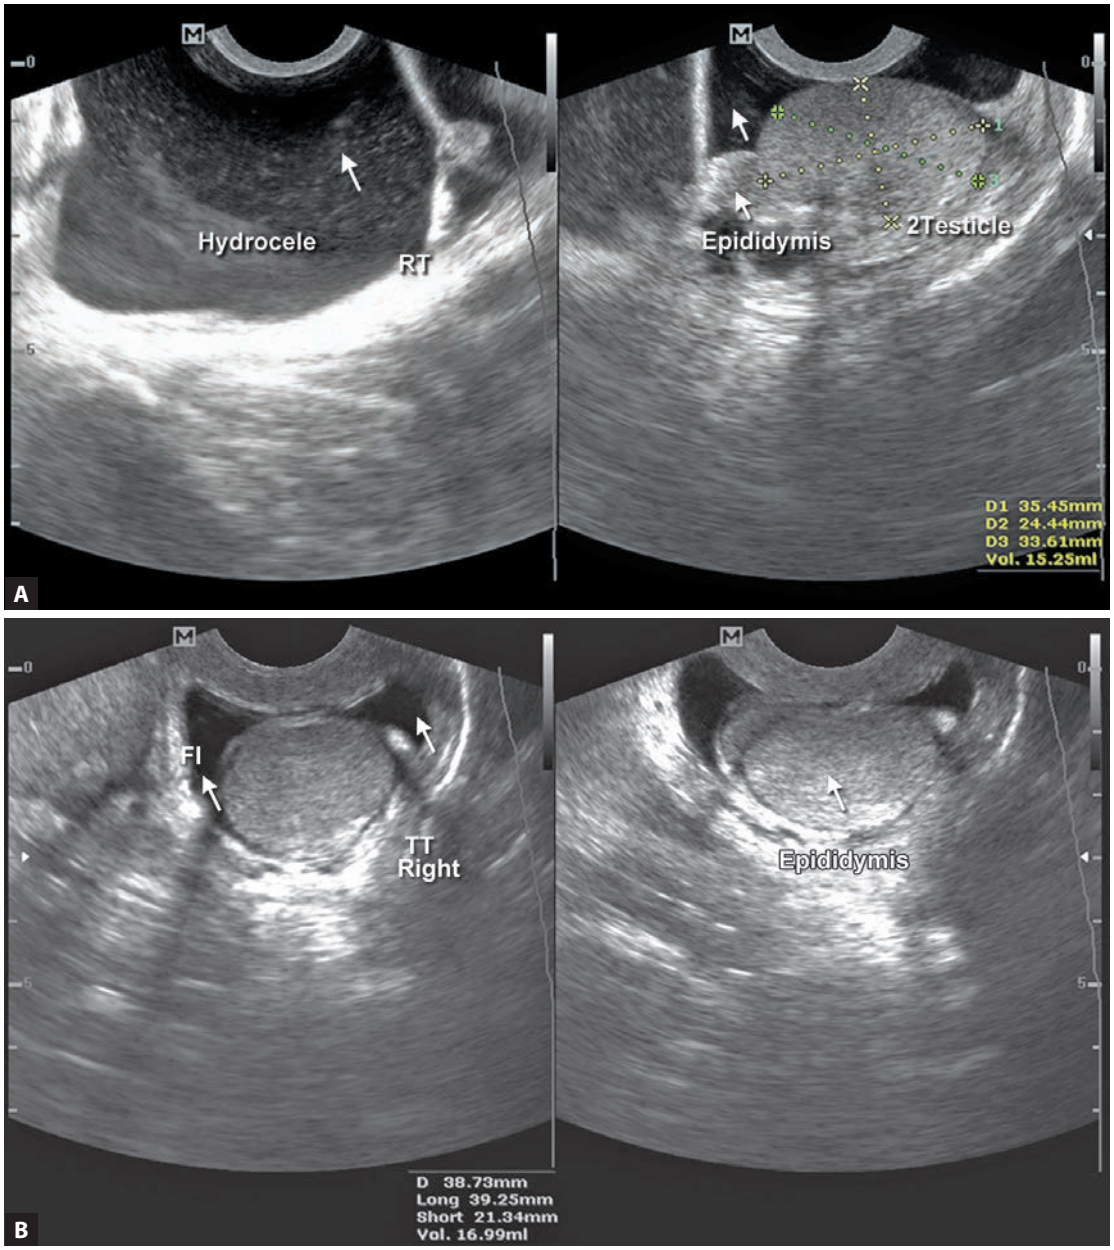
- *Inflammatory disorders:* Acute and chronic orchitis/epididymo-orchitis **(Fig. 4)**
- *Epididymal abnormalities:*
  - Acute and chronic epididymitis
  - Epididymal cyst
  - Spermatocele
  - Tubular ectasia
- *Paratesticular abnormalities:* Varicocele—especially in inconclusive physical examination **(Fig. 5)**
- To differentiate between obstructive and nonobstructive azoospermia.

Technique of Scrotal Sonography

Scrotal US is done using a high-frequency (7–15 MHz) transducer. The patient lies supine with penis resting in the suprapubic region. Scanning is done in transverse, longitudinal, and oblique planes. The size, volume, and echotexture of testes are seen. Testes are ellipsoidal, measuring 3–5 cm (length), 2–4 cm (width), and 3 cm (anteroposterior). Testicular volume (TV) can be estimated by applying the following formula:

Length × width × anteroposterior diameter × 5.2
= Volume (cm^3).[9]



Figs. 3A and B: (A) Gross hydrocele—post-traumatic; (B) Hydrocele with thick wall.
(FL: fluid; RT: right testis; TT: testicular tissue)

Nowadays, almost all machines are equipped with software which can calculate volume by different methods. Normal testicular volume is 15–20 Cu Cms. Normal testes have homogenous granular uniformly distributed echoes with an eccentric hyperechoic line (mediastinum testes).

Epididymis (head, body, and tail) and proximal vas deferens (VD) are evaluated in longitudinal and transverse axes. Epididymis is posterolateral to testes, with head in relation to the upper part and tail related to the lower part of the testes. Head measures 5–12 mm, body 2–4 mm, and tail 2–4 mm. Head is of a higher echotexture, and rest are slightly hypoechoic. In a scrotal scan, proximal VD is seen as a straight duct arising from the tail of epididymis. On TRUS, seminal vesicles look like bow-tie with the deferential ampullas medially placed in transverse scans.

CLINICAL APPLICATIONS

The role of scrotal US is to exclude testicular pathologies in *nonobstructive azoospermia* and indications are:

- Hypergonadotropic hypogonadism
- Cryptorchidism
- Testicular atrophy
- Torsion and infarction
- Mumps
- Neoplasm
- Hydrocele
- Varicocele evaluation.[10]

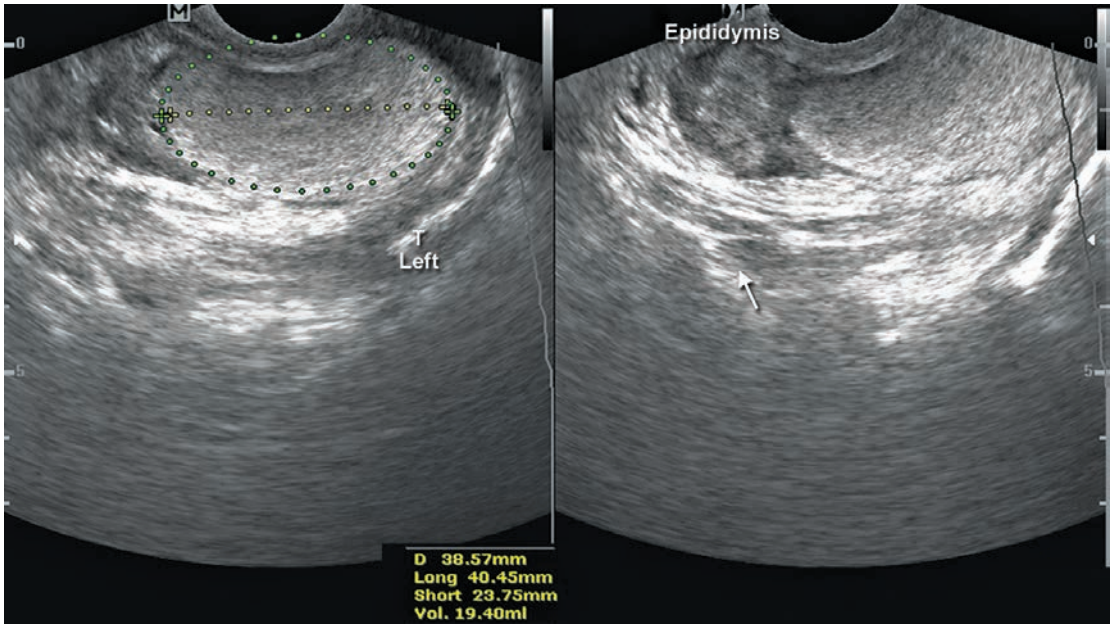


Fig. 4: Chronic epididymitis.

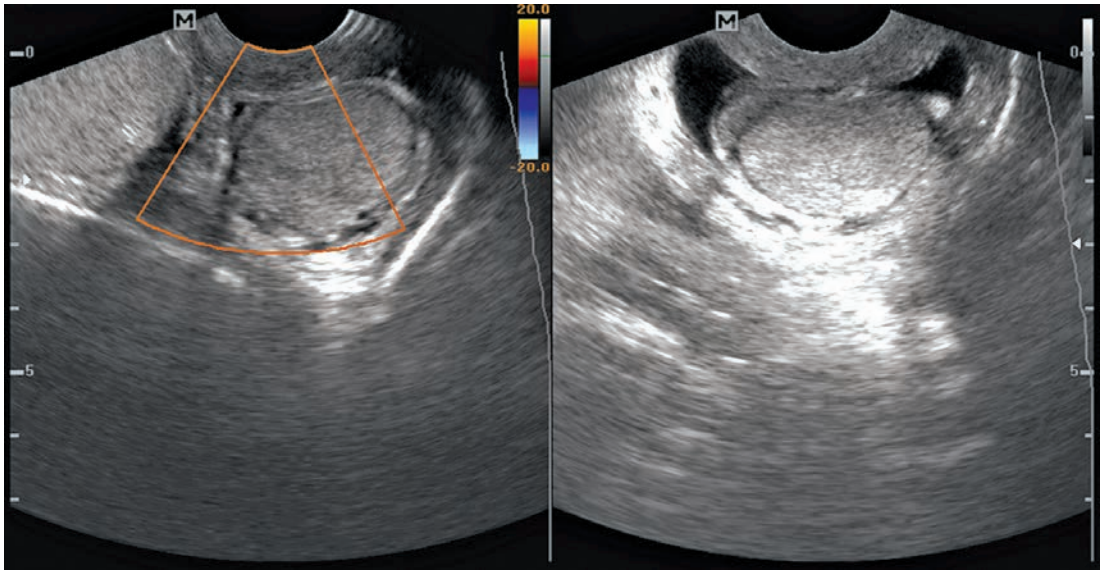

Fig. 5: Absent venous reflux on Valsalva.

Clinically, if testes are not palpable, either there is absence of testis or there are atrophic or undescended testes. US helps in confirming the diagnosis and planning further management. In undescended testes, even though physical examination suffices, USG helps in localizing the testis and seeing the echotexture. Most clinicians believe that there is a limited/doubtful role of USG prior to orchiopexy planning related to infertility management. However, it is useful for general health care follow-up of cryptorchid testis and to exclude risk of malignancy and evaluation contralateral testis.

Testicular volume is significantly higher in obstructive azoospermia (7.7–25.8 cm^3; median 11.6 cm^3) compared to nonobstructive azoospermia (1.2–16.4 cm^3; median 8.3 cm^3) **(Fig. 6)**. Prader orchidometer (PO)-derived TV very well correlates with USG-TV; US scores over PO even though the latter is reliable enough in clinical practice. However, USG is useful when PO has limitations, i.e., when there are testicular pathologies, such as inguinal testis, enlarged epididymis, and large hydrocele. There is a definite positive correlation of TV with the sperm availability and hormonal parameters. Hence, estimating TV should be a part of evaluating the male partner in compromised semen parameters. A volume <50% of the normal is related to suboptimal sperm and hormonal parameters [low testosterone, increased follicle-stimulating hormone (FSH) and luteinizing hormone (LH)]. These cases are less likely to yield sperm recovery

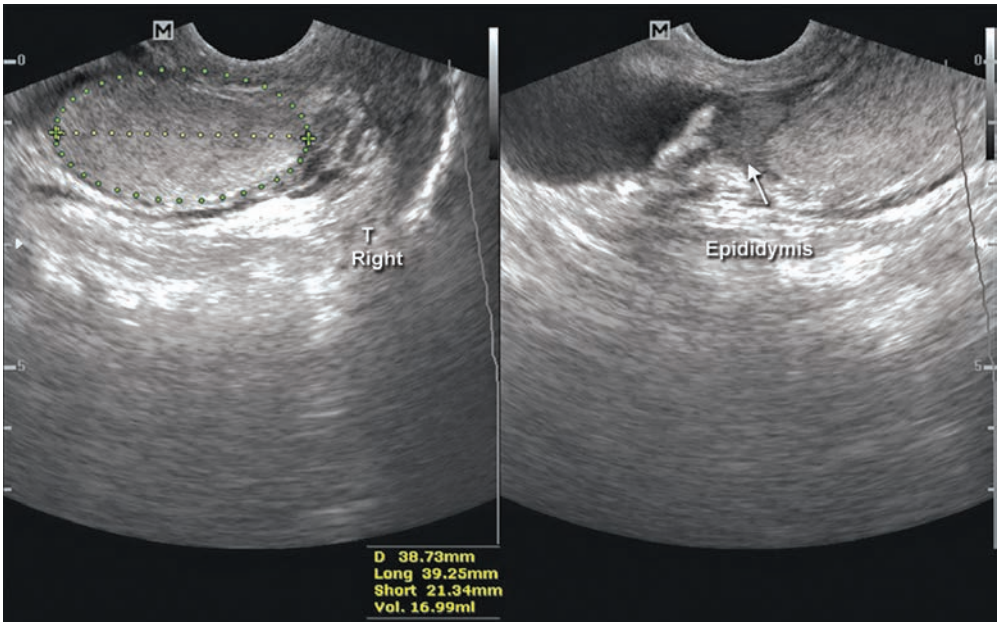

Fig. 6: Normal testis and epididymis.

during percutaneous epididymal sperm aspiration (PESA)/testicular sperm aspiration (TESA). USG determination of TV is not mandatory in fertility as clinical assessment of TV suffices.

Echogenicity of the testis depends on germ cell representation and seminiferous tubules maturation. Echopattern abnormalities such as testicular inhomogeneity are associated with testicular function impairment (reduction of seminiferous tubules and interstitial proliferation).

When gross inhomogeneity or microcalcifications are found, malignancy should be excluded on follow-up scans, especially in the presence of other risk factors in interests of general health care. There is a debatable role of biopsy in the presence of microcalcifications. Doppler adds to the diagnostic confidence by seeing the testicular vascularization—reduced in torsion and infarction and increased in orchiepididymitis or some tumors. Few studies have shown positive correlation of testicular lesions, echotexture, and vascularization with sperm parameters and retrieval by TESE. But as of now, assessing these parameters on USG is not a part of any recommended/standardized protocol for male factor infertility assessment and assessment prior to TESE for probabilities of sperm retrieval.

EPIDIDYMAL DIAMETERS

- US is more accurate than physical examination in evaluating epididymal size. Enlarged epididymis, altered echotexture, and hyperemia may be due to past or present inflammation, which may be associated with oligoasthenospermia. In oligo/azoospermia, if epididymis is absent or dilated, distal obstruction should be excluded by USG evaluation of the prostate–vesicular region.
- Scrotal US is very useful in cases of PESA to identify the position of epididymis, which may yield maximum recovery of sperms as one-third cases of vassal agenesis are associated with hypoplasia of distal two-thirds of epididymis.

SCROTAL ULTRASOUND IN VARICOCELE

Surgical treatment of varicocele is controversial as only few randomized controlled trials (RCTs) evaluating the benefit of varicocelectomy on sperm parameters are available. On the contrary, there is sufficient evidence to suggest harmful effects of varicocele on testicular function and seminal parameters.[11-13] Detrimental effects are reduced TV, slightly increased FSH, LH, and prostatitis-related premature ejaculation due to intrapelvic venous congestion. The effect of varicocele on testosterone levels is debatable. A meta-analysis by Li et al. showed that there is an increase in testosterone after surgical treatment of varicocele. Controversially, it has been seen that 75% of patients with varicocele have normal semen parameters.[14,15]

The current recommendation for varicocele treatment is very clear, and one must take these recommendations into consideration when suggesting varicocelectomy to these infertile men.[16,17] The American Urological Association (AUA)/American Society for Reproductive Medicine (ASRM) recommends treatment for varicocele when in an infertile couple, the female partner is normal or has a potentially treatable cause of infertility, varicocele is palpable on clinical examination, and the semen parameters are deranged. Treatment of varicocele is not indicated in subclinical varicocele or in patients with normal semen parameters.[3] Color Doppler and US (CDUS) is an important and more sensitive modality for diagnosis of varicocele, especially

in cases of clinical doubt such as tight scrotum and obese patients (sensitivity 97% and specificity 94%).[18] The diagnosis of varicocele on USG requires greater than three vessels of size >2–3 mm on Doppler. Varicoceles are seen superior and lateral to testes and extend posteriorly and inferiorly if severe. Varicocele evaluation includes extension, size, and number of vessels. Complete evaluation involves noting the presence of spontaneous flow in upright position and seeing the duration of retrograde flow during Valsalva. There should be a mention of the volume and echotexture of the affected testes and comparison with the contralateral testes.[19] The current recommendations by the ASRM, the AUA (practice committee of ASRM 2008), and the European Association of Urology (EAU) on male infertility suggest that varicocele should be evaluated clinically as only palpable varicoceles have been seen to be associated with infertility.[17] However, the EAU guidelines on male infertility recommend that the diagnosis should be confirmed on Doppler, especially when examination is inconclusive (EAU/ASRM, 2008), and that Doppler is the imaging modality of choice to detect and grade varicocele. Clinical examination has 70% sensitivity, and CDUS has 90% sensitivity in varicocele detection.

Caution: Practice of varicocelectomy only on US finding (subclinical varicocele) should be discouraged as there is no evidence to suggest that varicocele diagnosed on US only required correction.[15,18]

Indication of Ultrasound and Color Doppler for Varicocele Evaluation

- Suspected case of varicocele to confirm (grades II and III).
- Difficult physical evaluation as in cases of tight scrotum, hydrocele, thick skin, and obesity.
- Evaluation of contralateral testes for the presence of subclinical varicocele before varicocele correction.[15]

Scrotal US in obstructive azoospermia: Evaluation of epididymis and testes is important in distinguishing obstructive azoospermia from nonobstructive azoospermia in infertile men with a sensitivity, specificity, and accuracy of 82.1%, 100%, and 87.5%, respectively.[19]

Significant findings are dilatation of proximal seminal duct (mediastinum, testes, epididymis, and intrascrotal portion of VD). Epididymis abnormalities are a significant finding in obstructive azoospermia. Distal genital duct obstruction causes secondary changes—dilated proximal genital tract (terminal vas, ampulla of vas, seminal vesicle, and ejaculatory duct), formation of intratesticular cyst, and epididymal cyst in obstruction of the seminal tract. These obstructive pathologies may be managed by epididymovasostomy or by PESA/TESA and ICSI.[20]

Transrectal ultrasonography and male infertility: The role of TRUS is now firmly established in diagnosing post-testicular causes of infertility. It can clearly visualize the prostrate and distal genital tract (vas ampulla, seminal vesicle, and ejaculatory duct). Low ejaculate volume is one of the most important indications of TRUS. The modality provides complete visualization of the ductal system. TRUS is noninvasive, accepted by most of patients, and provides valuable information, especially in azoospermic patients. It identifies correctable defects and helps in counseling of patients in cases of noncorrectable etiologies for advanced assisted reproductive techniques.

Assessing prostrate volume by USG shows greater accuracy than physical examination. It is not very useful in the management of male infertility; reduced volume may suggest hypogonadism.

Echotexture and vascular abnormalities are suggestive of past or present inflammation and their effect on fertility is not proven. Median cyst of prostrate points toward obstructive azoospermia. Large cysts may cause ejaculatory duct obstruction and aspiration may lead to the improvement of semen parameters.

Seminal vesicles appear as paired saccular structures posterior–superior to prostrate, between the bladder and the rectum. They have bow-tie appearance on transverse scans and are club shaped in longitudinal scans. Seminal vesicles are said to be normal if >25 mm is length, are labeled hypoplastic if <25 mm and >16 mm, and atrophic if found <16 mm in length[21] **(Fig. 7)**. Abnormality of seminal vesicles is significantly higher in the azoospermic group than the nonazoospermic population. The incidence of seminal vesicles anomalies such as atrophy or hypoplasia or vassal agenesis is higher in azoospermic patients and may be found in >75% of patients, while there were no abnormalities in 60% of nonazoospermic patients.[22]

- Evaluation of the ejaculatory duct is useful in defining obstructive azoospermia causes. Ejaculatory duct cyst and seminal vesicle agenesis may indicate *CFTR* gene evaluation. Increased volume of seminal vesicles after ejaculation is suggestive of partial ejaculatory duct obstruction. Giant cyst may indicate genitourinary anomalies. Abnormalities of echotexture may indicate inflammation or stasis.

INDICATIONS OF TRANSRECTAL ULTRASOUND[4,8]

- Low seminal volume
- Suspected distal obstruction
- Seminal vesicle enlargement **(Fig. 8)**
- Midline prostatic obstruction
- Ejaculatory duct obstruction
- CAVD **(Fig. 9)**
- Absent seminal vesicles
- Severe oligospermia
- Anejaculation

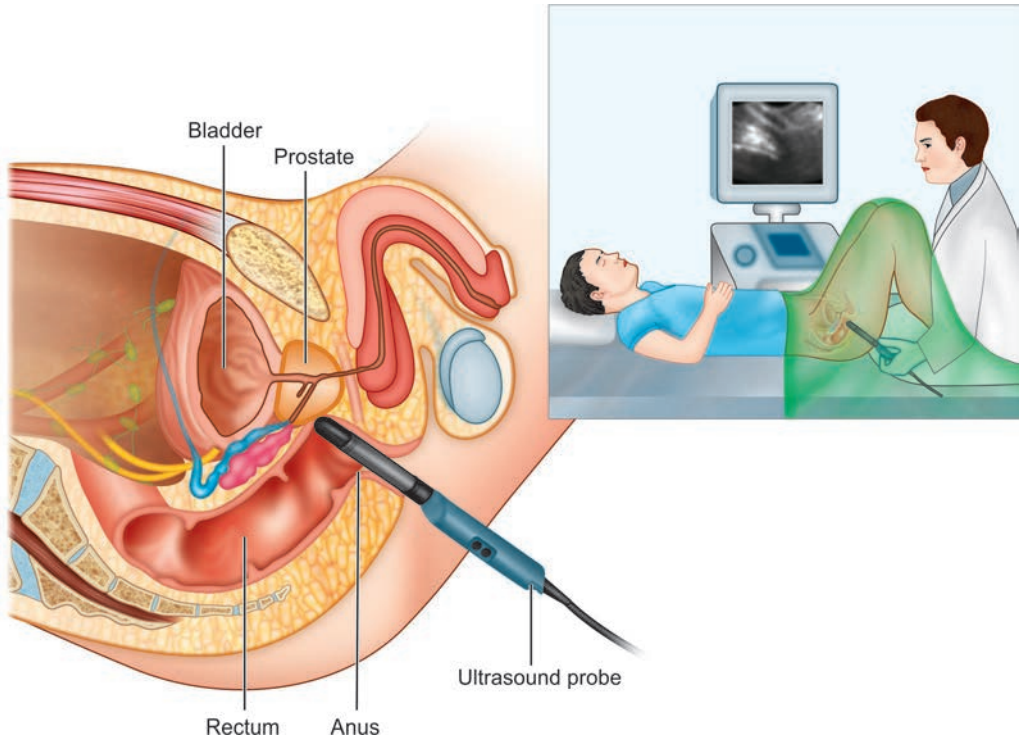

Fig. 7: Technique of transrectal ultrasonography (TRUS).

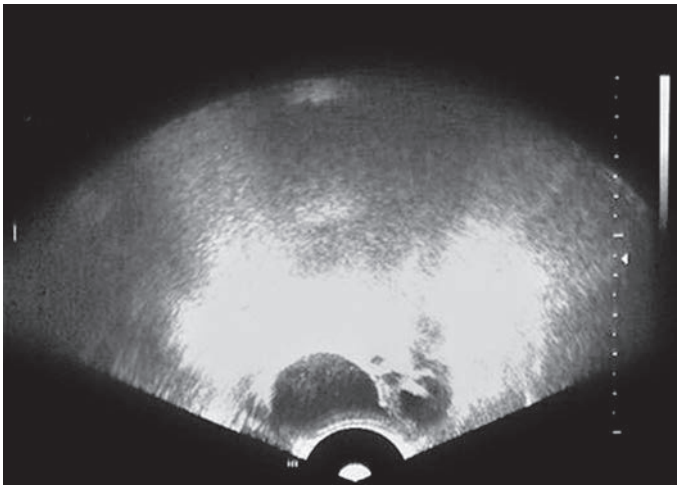

Fig. 8: Seminal vesical cyst—calcification.

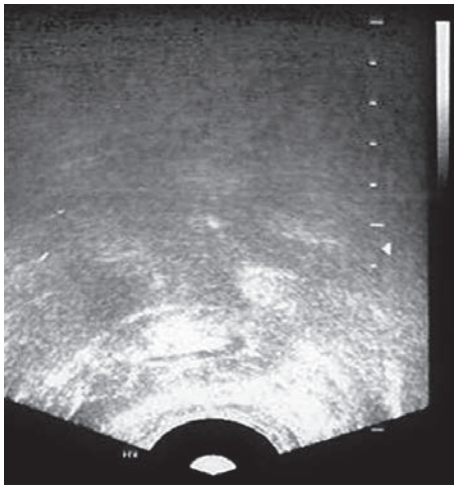

Fig. 9: Absent seminal vesicle/vas.

- Painful ejaculation
- Retrograde ejaculation
- Hematospermia.

Various abnormalities that are seen on TRUS are:

- Vasal agenesis—unilateral or bilateral, partial or complete
- Echogenic vas—calcification
- Cyst of VD or calculi
- Absent seminal vesicle
- Hypoplastic seminal vesicle
- Seminal vesicular cyst
- Ejaculatory duct cyst
- Ejaculatory duct calcification or dilatation **(Fig. 10)**.

Though TRUS is a noninvasive modality, however, it is not enough and reliable tool for diagnosis for ejaculatory duct obstruction and requires an invasive test such as vesiculography and seminal vesicle aspiration to confirm the diagnosis before planning for surgery.

In a study of 70 patients of suspected ejaculatory duct obstruction, 55 patients were diagnosed on TRUS of having ejaculatory duct obstruction; however, only 27 patients were confirmed with seminal vesicle aspiration[22,23] **(Fig. 11)**.

According to recent guidelines published by EAU, scrotal US performed by a high-resolution transducer may be helpful in finding the signs of obstruction, dilatation of rete testes, enlarged epididymis or absent VD, or signs of testicular

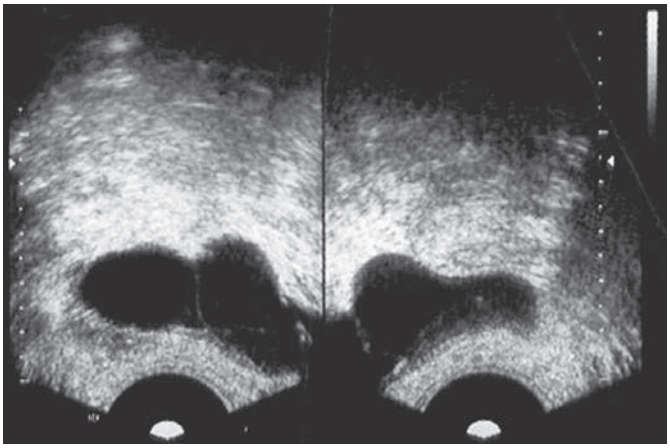

Fig. 10: Bilateral cystic dilatation/ejaculatory duct dilation.

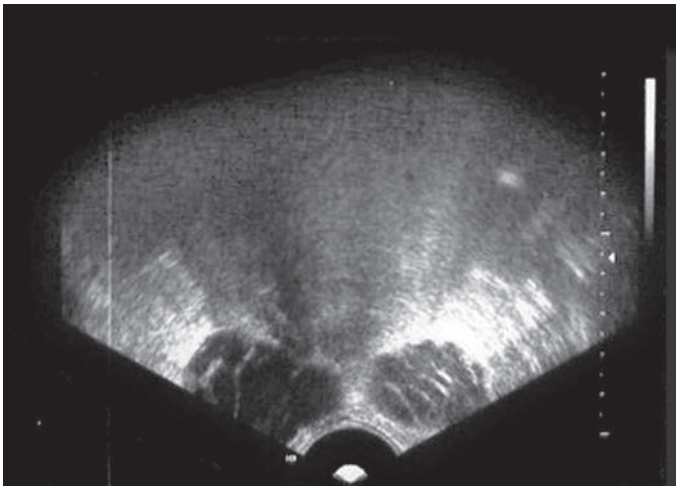

Fig. 11: Midline cyst in periurethral location.

dysgenesis (nonhomogeneous testicular architecture or microcalcification).

It is also indicated in assessment of blood reflex in men with varicocele.

Transrectal ultrasonography is indicated in low seminal volume and suspected ejaculatory duct obstruction. It can also detect testicular microlithiasis, which might indicate carcinoma in situ.

Recently, *TRUS-guided seminal vesiculography* is advocated in a patient with suspected ejaculatory duct obstruction. The seminal vesicles are aspirated using a long needle through a transrectal transducer. It is now preferred over surgical vasography.[24]

CONCLUSION

- Diagnostic and therapeutic measures in treating male infertility have limitations as there is paucity of evidence-based treatment.
- The prime screening modality is semen analysis; hormonal assessment is an adjunct. The role of USG lies in specific decision-making situations.
- Scrotal US is helpful in testicular evaluation and proximal obstruction (e.g., dilatation of rete testis, enlarged epididymis).
- TV can be adequately assessed by either PO or USG, scrotal US is more precise, but PO suffices in clinical practice except when physical examination is unreliable.
- Scrotal US is suggestive of testicular damage, dysgenesis, cryptorchidism, and malignancy in nonobstructive azoospermia, but fails to predict sperm retrieval in nonobstructive azoospermia.
- USG has limitations in surgical sperm extraction decision-making.
- Physical examination is sufficient for diagnosis and decision making in varicocele treatment (AUA/ASRM, 2008); even though EAU guidelines on male infertility require confirmation by Doppler.
- In obstructive azoospermia, USG helps in planning the management, such as TRUS-guided cyst aspiration (large prostatic cyst), surgical treatment (ejaculatory duct abnormalities), or surgical sperm extraction [congenital bilateral absence of the vas deferens (CBAVD)].
- The EAU guidelines on male infertility recommend TRUS to assess distal obstruction, especially when semen volume is <1.5 mL.
- TRUS and scrotal US are useful in diagnosing CBAVD or congenital unilateral absence of the vas deferens (CUAVD) (EAU guidelines on male infertility), followed by *CFTR* gene and urinary tract evaluation by US; surgical sperm extraction is recommended.

To conclude, sonographic imaging of the male genital tract lacks standardization. Multicenter RCTs aimed at defining the indications of USG—scrotal and TRUS—and defining the USG criteria of the pathological abnormalities for standardization of male infertility evaluation and treatment.

KEY POINTS

- Investigations in an infertile male are aimed to find out correctable cause, if any, and to counsel regarding the possibility of further treatment.
- US plays an important role in differentiating obstructive and nonobstructive azoospermia. TRUS further identifies the site of obstruction as well as the cause of obstruction.
- Use of color Doppler for varicocele is though controversial but used to quantify. However, it may not help in management as subclinical varicocele surgery is not recommended and it is clinical varicocele that only requires treatment.[5,25,26]
- Findings suggestive of obstructive azoospermia on scrotal US are to be followed by TRUS to delineate proximal from distal obstruction. This will help plan the management as vasoepididymal anastomosis (VEA) is useful in cases of proximal obstruction.
- In patients with distal obstruction, TRUS or magnetic resonance imaging (MRI) may diagnose the cause and exact site of distal obstruction.

- However, further management is usually based on more invasive tests to confirm or opt for surgical retrieval of sperm and assisted reproductive technique.

CHAPTER 28

Medical Management of Male Infertility

Sonal Agarwal, Vinay Kumar

INTRODUCTION

Since the past two decades, there is an increase in the rate of infertility due to delayed childbearing, late marriages, acquiring sexually transmitted diseases, use of contraception, and higher medical care and assistance for infertility. Male factor is responsible in approximately 50% of infertile couples with 30% of cases having male factor as the sole reason for infertility.[1] Thus along with female partner treatment, male partner management of infertility is equally important. In the past, empirical treatment used to be done in infertile men when surgical treatment was either unavailable or had failed. Recent trend is to identify the cause and then provide a specific treatment for it. Cases where a specific cause **(Fig. 1)** cannot be identified are considered under idiopathic category and given empirical treatment.

This chapter provides an evidence-based overview for medical management of male infertility. Efforts have been done to make this chapter fascinating and interesting to read for reproductive endocrinologists, urologists, fertility specialists, gynecologists, and general practitioners.[2]

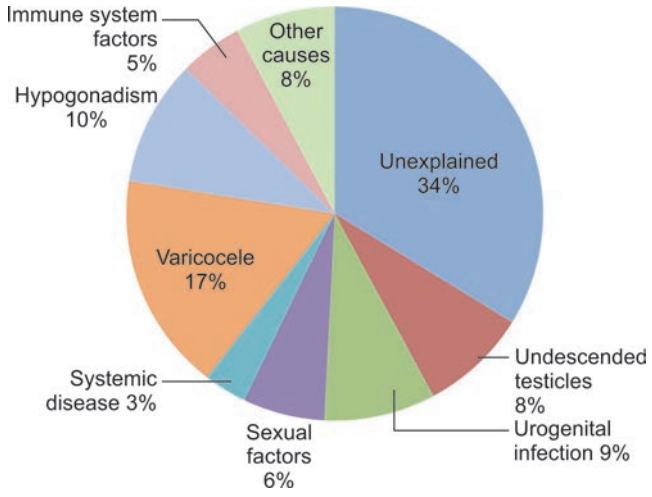

Fig. 1: Causes of male infertility.

MEDICAL THERAPY

Medical therapy is divided into two categories:

1. Specific therapy for endocrine disorders, male accessory gland infections (MAGI), and ejaculatory disorders. It is further divided into subcategories such as:
   a. To enhance sperm production and gonadal function
   b. To prevent and treat genital tract infection
   c. To correct sexual dysfunction [anejaculation, anorgasmic, ejaculatory, and erectile dysfunction (ED)]
   d. To look for free radicals so as to increase sperm motility
   e. To manage infertility related to obesity
2. Nonspecific therapy as empirical treatment for idiopathic causes in the form of antiestrogens, aromatase inhibitors, gonadotropins, and antioxidants.

SPECIFIC THERAPY

To Enhance Sperm Production and Gonadal Function

The classical treatment of infertility can be put under the following points:

- *Lifestyle modifications:* Professional exposure to thermal stress or toxic substances such as pesticides and hot baths should be avoided.[3] Cigarette and alcohol consumption also have a role in infertility.
- *Treatment of systemic illness:* Semen analysis should be done at least after 3 months of febrile illness. Zinc supplementation and improving nutritional status are necessary in renal diseases, cirrhosis, and sickle cell anemia.
- *Treatment of endocrinopathies:* Endocrinopathies dealt with in this chapter are listed in **Box 1**.

Hypogonadotropic Hypogonadism

About 2–5% of male infertility is due to hypothalamic and pituitary causes.[4] Follicle-stimulating hormone (FSH) is

BOX 1: List of endocrinopathies causing male infertility.

- Hemochromatosis
- Hypogonadotropic hypogonadism
- Kallmann syndrome
- Cushing's disease
- Gonadotropin secreting adenoma
- Diabetes mellitus
- Congenital adrenal hyperplasia
- Liver disease
- Thyroid disease
- Androgen resistance
- Acromegaly
- Hyperprolactinemia
- Anabolic steroid abuse

required to initiate spermatogenesis and testosterone, and luteinizing hormone (LH) is needed for processes of spermiogenesis and spermiation. Human chorionic gonadotropin (hCG) is longer acting and is used in place of LH as no commercial preparations of LH are available. Advantage of giving gonadotropins is that initiation of spermatogenesis and secondary sexual development occur simultaneously. Replacement with gonadotropin injections is accepted for effective management of associated infertility.[5]

Gonadotropin replacement therapy can be by any of the following methods:

- hCG
- Human menopausal gonadotropin (hMG) (mimics LH and FSH)
- Purified FSH
- Pulsatile GnRH in Kallmann syndrome.

Gonadotropin replacement for hypogonadotropic hypogonadism with only a few pubertal signs is as follows:

- Initially, hCG has to be given intramuscularly (IM) or subcutaneously (SC) 2,000 IU/thrice a week until adequate serum testosterone levels are detected in 6 weeks followed by addition of FSH 75 or 100 IU 3 times/week.[6]
- Human menopausal gonadotropin 75 or 150 IU 3 times/week restores serum testosterone levels and normal spermatogenesis after 6–9 months of treatment. If satisfactory, FSH can be suspended, and spermatogenesis may be maintained with hCG alone.[7] The dose has to be doubled if no response in fertility is seen in 3–6 months or no increase in gonadal size within 3 months of the start of treatment.[8] If spermatogenic cells are nonfunctioning even after 6 months of treatment, recombinant follicle-stimulating hormone (rFSH) injections have to be added.[9]

Treatment of prepubertal adult:

- hCG 2,000 IU thrice weekly IM for 6 weeks
- At the end of 6 weeks, 37.5 IU FSH thrice a week is added.[10]

Treatment with FSH can be started when adequate serum testosterone levels are detected with hCG. hCG combined with FSH has shown results in 94% of men.[11]

In resistant cases, therapy may be for a longer duration of 1–2 years. In cryptorchid patients, even after testicular descent, prognosis for fertility is poor.[12]

Treatment of a postpubertal adult: In patients with incomplete hypogonadism or adult with hypogonadotropic hypogonadism, only hCG is sufficient for both androgenization and fertility.[13]

Disadvantages of hCG injection:

- Cost
- Increasing resistance to hCG is because of frequent injections due to induced downregulation of receptors. With adequate spacing of injections, it can be prevented
- Antibody formation blocking action of hCG may also occur but it is rare.

In such men, once fertility is achieved, cryopreservation of sample should be done for future fertility issues. One study by Esteves et al.[14] worked on clinical efficacy and safety of recombinant hCG to restore spermatogenesis and androgen production of hypogonadotropic hypogonadal men and found that 10 out of 11 patients had restoration of spermatogenesis and improvement in virilization, libido, and erectile function.

Positive predictive factors of gonadotropin replacement response are:

- Larger volume of testis
- Prior intake of gonadotropin therapy
- Postpubertal status
- Absence of bilateral maldescended testes.

Negative prognostic factors for treatment with gonadotropins are:

- Extreme gonadotropin insufficiency
- Obesity
- Cryptorchidism
- Small testicles.

Gonadotropin-releasing Hormone Therapy

Gonadotropin-releasing hormone is a more physiologic drug in increasing the production of FSH and LH when administered in a pulsatile manner and normalizing the LH–Leydig cell–testosterone axis. Substitution with GnRH is most pivotal in patients with hypothalamo-pituitary insufficiency as it is necessary for induction of proliferation of Sertoli cells and spermatogonia.[15] GnRH induces spermatogenesis in up to 85% as early as 4 months after the start of treatment. Achievement of normal levels of inhibin B, testosterone, and gonadotropins along with increase in testicular volume are predictors of successful treatment with GnRH.[16]

Dosage: 100 or 500 mg of gonadorelin is given in a pulsatile form through the SC/intravenous (IV) route with the help of

an electric-driven pump at a rate of 90 minutes apart with doses around 25 ng/kg body weight. It provides 1–2 mg/pulse. In cases of profound suppression of hypothalamus, doses can reach up to 300 ng/kg body weight. This should result in a rise in gonadotropin and testosterone levels after about 7 days of treatment.

Disadvantages:

- High cost
- Anaphylactic reaction
- Pump is visible through clothes
- Hindrance in swimming and other outdoor recreational activities.

Causes of failure of GnRH therapy:

- Patients who develop GnRH antibodies during the course of therapy resulting in deterioration of testosterone and gonadotropin levels
- Mutation of the GnRH receptor gene.

Androgen Therapy

Testosterone replacement therapy (TRT) (androgen therapy) causes pubertal development in the form of increased muscle mass, pubic hair, beard growth, penile growth, normal sexual behavior, and cognitive function in men.[17] Pituitary hormones may be needed to stimulate testicle growth. Starting with an initial low dose and then gradually increasing, it causes less adverse effects and mimics hormonal status during physiological puberty. It is a useful means to restore sexual functionality and in a person with hypogonadotropic hypogonadism who is not desirous of fertility at that point of time. It has the advantage of cost over gonadotropins and can be used for inducing puberty.[18] Natural testosterone can be taken orally and undergoes rapid degradation by hepatic metabolism. Chemical changes such as 17-alpha alkylation and modified ring are done to lessen enterohepatic circulation.[19]

Mechanisms of testosterone action: Testosterone in a way acts as three hormones due to different biologic effects. It directly binds to androgen receptors, can act via dihydrotestosterone (more avidity than testosterone) which acts after conversion by enzyme 5-alpha reductase, and acts as estrogen after conversion through the aromatase enzyme.

Routes of administration: The particular route of administration depends on preference, side effects, compliance, and cost of that method.

- *Injection:* Testosterone enanthate or testosterone propionate or decanoate 100–250 mg IM injection every 3–4 weeks. This will result in attaining steady levels of androgen in the majority of patients. In prepubertal patients, start with lesser doses and increase as pubertal maturation ensues. Testosterone undecanoate (Aveed) was recently approved by the Food and Drug Administration (FDA).
- *Crystalline pellet form (testosterone implant):* 100 and 200 mg doses. A special introducer helps in the insertion of pellet every 3–6 months. Though it is expensive, it will save patients from monthly injections.
- *Oral preparation of testosterone undecanoate (Andriol):* 120–160 mg/day
- *Modified androgen mesterolone (Proviron):* 50–75 mg daily doses
- *Transdermal preparation in patch or cream form:* Recently developed Androderm patch is applied each night to the back, abdomen, upper arm, or thigh. The site of application should be rotated in order to maintain at least a 7-day interval between the same site application so as to lessen skin reactions. Adverse effects of patch include pruritus, erythema, vesicle formation, induration, headache, depression, rash, and gastrointestinal bleeding.
- *Gel:* Different gel preparations are available. Gel is either rubbed into your skin on the upper arm or shoulder (AndroGel, Testim, Vogelxo) or applied in each armpit with an applicator (Axiron) or a pump on the front and inner thigh (Fortesta). No bath should be taken for 4–5 hours after application for complete absorption. Gel causes lesser skin reactions as compared to patches. Avoid skin-to-skin contact until it gets dried, otherwise the risk of transferring medication to another person is there. Nasal route gel is also available. It avoids the risk of transfer of medicine through skin contact. It should be applied twice in each nostril three times a day, but this method does not have better compliance due to inconvenience.
- *Gum and cheek testosterone replacement (Striant)* in the form of a putty-like substance delivers testosterone through the natural depression above your top teeth at the junction of the gum and upper lip. Quick absorption is there.

Long-term use of alkylated preparations can lead to liver damage and thus precautions should be kept in mind. All patients should be carefully monitored for changes in hematocrit, liver function, lipid parameters, and prostate-specific antigen (PSA). The dose should be increased gradually to full adult dosage over 18–24 months to prevent abrupt virilization and bone maturation. Maintain serum sex steroid concentration in mid-normal adult range. The Institute of Medicine recommends 1 g of calcium and 600 IU vitamin D per day for men aged between 19 and 70 years along with hormone therapy. In men of >70 years of age, 1200 mg of calcium and 800 IU of vitamin D are needed.

A multicenter trial has demonstrated restoration of serum testosterone levels and increased desire and libido, mood, and bone markers after testosterone administration. It showed that the earliest improvement in androgenic features is seen with TRT.[20]

Debate between urologists and infertility specialists: Urologists and general practitioners generally use TRT in patients with hypogonadism due to testicular failure with intentions of improving muscle strength and bone loss prevention.[21] Men receiving such replacement usually experience increase in energy, sex drive, erectile function, and a sense of well-being.

Fertility specialists believe that in pituitary causes, gonadotropin therapy should be given to stimulate sperm production. Testosterone therapy should be reserved for those whose concern is not fertility. Androgen in the form of exogenous testosterone is detrimental for spermatogenesis to occur and has a contraceptive effect due to negative feedback on the hypothalamus and pituitary.

Guidelines

Recent ED consensus guidelines have recommended evaluation of bioavailable testosterone and free testosterone in patients of suspected hypogonadism and sexual dysfunction. These guidelines have titled gonadotropin therapy as first line of management and TRT as second line of management.[22]

Thyroid Disease

Hypothyroidism: Prevalence of hypothyroidism is 0.6% in males. There is loss of libido and reduced potency. It is often associated with hyperprolactinemia but its contribution toward male infertility is unknown. Young males are at increased risk. Sperm quality is also severely affected.[23]

Treatment of hypothyroidism: Aim is to resolve hypothyroidism.

Hyperthyroidism: Prevalence of hyperthyroidism is 0.9% in males. It causes weight loss and varying degrees of hypogonadotropic hypogonadism. Excessive thyroxine production sensitizes pituitary gonadotrophs to GnRH, as such response is enhanced but despite it, gonadotropins and testosterone levels remain the same.

Treatment of hyperthyroidism: Hyperthyroidism can be managed by antithyroid medication and treatment of underlying cause.

Hyperprolactinemia

Presentation of hyperprolactinemia in men as compared to women is subtle and may take years to get diagnosed. Its prevalence in males is 11%. Tumors of pituitary tend to be large, often causing loss of peripheral vision and invading cavernous sinuses causing ophthalmoplegia. Excess prolactin secretion results in decrease in frequency of LH pulses. It causes overall reduction in testosterone secretion,[24] although more effect on sexual dysfunction such as loss of libido, retrograde ejaculation, and impotence is seen in such men.

Treatment of hyperprolactinemia: Medical treatment is appropriate. Dopamine agonist cabergoline (Dostinex) 0.5–2 mg/wk and bromocriptine are also used for this purpose. In large tumors, treatment may be needed lifelong. Gonadotropin therapy is also required in patients having hypospermatogenesis.

Cushing's Disease

Prevalence of Cushing's disease is between 1.2 and 2.4 cases per million. Usually, due to high adrenocorticotropic hormone (ACTH), adrenal gland produces high levels of cortisol; there is reduction in serum levels of LH and FSH, causing hypogonadism.[25] Prolactinemia may be associated with it. Loss of libido and reduced potency are there in more than half of the men.

Treatment of Cushing's disease: Surgery results in rise in LH and testosterone. Ablation of pituitary tumor can be done by irradiation therapy too. Normal adrenal function will soon ensue resulting in recovery in sexual function and semen quality. If no adenoma is present, ketoconazole medical therapy can be given to block steroid synthesis.

Gonadotropin-secreting Adenoma

Clinical presentation of gonadotropin-secreting tumors in males is rare because excess FSH secretion produces fewer symptoms, which remain undetectable for a longer time. Tumors take time to reach a considerable size. Serum FSH levels are elevated.[26]

Treatment of gonadotropin-secreting tumors: They can be removed by surgery or irradiation. Reduction in size can occur following bromocriptine therapy.

Diabetes Mellitus

Diabetes mellitus is one of the most common endocrine diseases. It interferes with normal sexual function. Both neurological and vascular factors cause erectile failure in diabetics and autonomic neuropathy causes ejaculatory disturbances in patients. Impotence is a very common complication of diabetes and occurs in almost 50% of all. Nocturnal penile tumescence is reduced because of an organic lesion. Retrograde ejaculation progresses to ejaculatory failure. Testicular biopsies from impotent diabetic patients show a huge range of changes varying from minimal reduction in spermatogenesis to completely hyalinized and nonfunctional seminiferous tubules.

Treatment of infertility due to diabetes mellitus: It depends on the severity of dysfunction and infertility. If testes are reduced in size with FSH raised, primary testicular disease is suspected and significant damage to sperm production will be there. Thus, diabetic patients are susceptible to developing sperm maturation disorders. If a patient is able

to produce good fertile ejaculate, it is wise to cryopreserve semen for future insemination because primary testicular disease or ejaculatory failure may occur any time.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia is a genetically inherited autosomal recessive disease due to deficiency of enzymes needed for production of steroid precursors of cortisol.[27] This results in enhanced pituitary ACTH secretion. Only nonclassical nonsalt losing congenital adrenal hyperplasia (NCAH) is diagnosed in men late in life. It is not a very common disease with an incidence of 1 in 2,500 adults. The patient will present with a history of precocious puberty. Nonclassical CAH has normal androgenic features but testes are reduced in size. Semen analysis may show severe oligozoospermia or azoospermia. Testicular biopsy shows hyalinization in seminiferous tubules and spermatogenic arrest along with reduced number of Leydig cells.

Treatment: Dexamethasone may improve Leydig cell hypoplasia.

Liver Disease

In relation with alcoholic cirrhosis, liver disease may be seen associated with infertility. Hepatocellular damage affects gonadotropin secretion and spermatogenesis.

Treatment of liver disease: Liver disease can be treated by abstinence from alcohol and treatment of underlying pathology of liver.

Acromegaly

Occasionally, men suffer from infertility and sexual dysfunction due to it. There is acidophilic adenoma of pituitary causing overproduction of growth hormone. Rise in prolactin causes relative LH deficiency.

Treatment of acromegaly: Acromegaly can be treated by surgical removal of pituitary adenomas or radiotherapy. Treatment with bromocriptine can also result in shrinkage in size of tumor.

Androgen Resistance

Androgen resistance is also known as androgen insensitivity syndrome or testicular feminizing syndrome. It is genetically determined. Depending on severity, four types of phenotypic and endocrine abnormalities have been determined. Androgen receptor resistance is present. In typical syndrome, male pseudohermaphroditism is there. Patients are thus hypogonadal with LH and testosterone levels increased. Genital abnormalities such as hypospadias, cryptorchidism, and bifid scrotum are associated.

Excess androgens are converted to estrogens resulting in gynecomastia. Penile size is reduced and prostate is markedly reduced in size. Histology may reveal maturation arrest.

Treatment: Reduced chances of improving semen quality as this disease is genetically predetermined. Thus, some form of assisted reproduction is required in such cases.

Kallmann Syndrome

Kallmann syndrome is an X-linked disease with hypogonadotropic hypogonadism resulting in absent pubertal maturation and maldevelopment of midline structures such as hypothalamus. Anosmia is associated with aplasia of the olfactory tract. Severe hypogonadism is associated.

Treatment of Kallmann syndrome: Gonadotropin-replacement therapy can be used to treat Kallman syndrome.

Hemochromatosis

In anterior pituitary cells, there is deposition of iron causing decreased secretion of FSH and LH. Sexual dysfunction may be associated along with it. Males usually present with complaints of impotence, loss of libido, hypoandrogenization, and reduced testes size. Gonadotropin levels decrease causing reduced testosterone levels. Histological section of testis shows hypospermatogenesis and absent or reduced Leydig cells with no iron deposition.

Treatment: Depletion of iron from tissues is important for attaining normal testicular and sexual function. Phlebotomy can be done to achieve this. The main cause is pituitary insufficiency, so treatment with gonadotropin therapy is of utmost importance.

Anabolic Steroid Abuse

Anabolic steroid abuse is seen in sports persons, athletes, and weightlifters so as to increase their muscle mass. This in turn causes profound suppression of gonadotropins. Due to illegal transactions of such agents, patients hide this while history-taking. Such men present with impotence and azoospermia. At first, these patients may have few signs visible along with loss of libido. Serum hormones have negligible levels with hypospermatogenesis.[28]

Treatment: Gonadotropin therapy can be used to treat anabolic steroid abuse.

Treatment of Antisperm Antibodies and Infection

Incidence varies between 8 and 21% among infertile men.[29] Antisperm antibodies affect fertilization by inhibiting cervical mucus penetration and facilitate destruction of coated sperm by uterine leukocytes, inhibiting capacitation, binding to zona, and acrosome reaction. In cases of

antisperm antibodies, treatment with prednisone at a dose of 40–60 mg/day for 10 days corresponding to the female partner's first 10 days of menstrual cycle has been tried. Ejaculation into Tyrode's buffer solution has been tried too, to dilute antibodies secreted by the prostate. Intrauterine insemination (IUI) and in vitro fertilization (IVF) can be tried but due to high rates of fertilization failure, intracytoplasmic sperm injection (ICSI) is more successful.

One of the potentially correctable causes of male infertility is symptomatic and asymptomatic infection of the male urogenital tract. Etiology is given in **Table 1**.

Infection causes male infertility in the following ways:[30]

- Affects normal functioning of the male reproductive system
- Disrupts blood–testis barrier
- Semen parameter changes occur
- Disrupts normal morphology, biochemistry, and sperm function
- Reactive oxygen species (ROS) production increases
- Impairs sperm–oocyte interaction
- Accessory glands' normal functioning is impaired
- Duct system is occluded.

Basic ejaculate analysis does not reveal a link between accessory gland infection and impaired sperm characteristics. Antibiotic treatment gives symptomatic relief, eradicates microorganisms, and no positive effect is there on inflammatory alterations. It cannot reverse functional deficits and anatomical dysfunctions and cannot always enhance the probability of conception.[31]

Comhaire et al.[32] suggested that the presence of any two of the following parameters indicates diagnosis of abnormal semen samples:

- History of genitourinary infection and/or abnormal rectal examination
- Abnormally expressed prostatic secretion and/or urinary sediment after prostatic massage
- $\geq 10^3$ bacteria/mL or $\geq 10^4$ nonpathogenic bacteria/mL in a dilution of 1:2 of seminal plasma
- $\geq 10^6$ leukocytes/mL of ejaculate.

TABLE 1: Etiology and distribution (%) of male infertility among 7,057 men.

No demonstrable cause	48.5
Sexual factors	1.7
Urogenital infection	6.6
Congenital anomalies	2.1
Acquired factors	2.6
Varicocele	12.3
Endocrine disturbances	0.6
Immunological factors	3.1
Idiopathic abnormal semen (oligoasthenoteratozoospermia syndrome)	26.4
Other abnormalities	3.0

Source: Dohle GR, Colpi GM, Hargreave TB, Papp GK, Jungwirth A, Weidner W, et al. EAU guidelines on male infertility. Eur Urol. 2005;48(5):703-11.

Guidelines and Recommendations

The World Health Organization (WHO) guidelines (2010) for seminal tract infections:

- Significant bacteriospermia—$\geq 10^3$ bacteria/mL ejaculate
- Detection of *Neisseria gonorrhea* or *Chlamydia trachomatis* or *Ureaplasma urealyticum*
- Significant leukocytospermia—$\geq 10^6$ peroxidase-positive leukocytes/mL of ejaculate.

Treatment according to Centers for Disease Control and Prevention (CDC) guidelines for uncomplicated genital chlamydial infection is given in **Box 2**.

Partner management: Male accessory glands are reservoirs for organisms (*C. trachomatis* and *Mycoplasma genitalium*); hence, they increase transmission to the partners.[34] Sex partners of the infected person should be evaluated and tested. They have to be treated if sexual contact was done within 60 days preceding the onset of symptoms or diagnosed with *Chlamydia*. The most recent sexual partner has to be evaluated and treated even if the time of last sexual contact was >60 days from the time of the start of patient's symptoms and diagnosis.

For *M. genitalium*, azithromycin 1 g single dose has been considered superior to doxycycline 100 mg BD for 7 days. Moxifloxacin (400 mg daily × 7, 10, or 14 days) has been successfully used to treat *M. genitalium* in men and women with previous treatment failures or persistent nongonococcal urethritis (NGU) Centers for Disease Control and Prevention (CDC 2015). Unlike female sterility, the significance of genital infections for male infertility is still in debate. Leukocytospermia does not always indicate infection.[35] Instead of classical parameters, for example, the determination of microorganisms and/or counting leukocytes, functional parameters such as cytokines, ROS, or other indicators of inflammation should be estimated if available. Proper antibiotic treatment directed against the specific organism in symptomatic men and not empirical treatment is important

BOX 2: Treatment of uncomplicated genital chlamydial infections in adults.[33]

Recommended regimens:
- Azithromycin 1 g orally single dose or
- Doxycycline 100 mg orally twice a day for 7 days

Alternative regimens:
- Erythromycin base 500 mg orally four times a day for 7 days or
- Erythromycin ethylsuccinate 800 mg orally four times a day for 7 days or
- Ofloxacin 300 mg orally twice a day for 7 days or
- Levofloxacin 500 mg orally once a day for 7 days

for eradicating microorganism, improvement of symptom, prevention of transmission to others, and decrease of potential complications, for example, stricture, obstruction, or atrophy, and improvement of semen quality.

To Correct Sexual Dysfunction

The aim is to retrieve spermatozoa for use in assisted reproductive technology (ART).[36] Psychotherapy is of not much use. For anejaculation, vibratory or electroejaculation can be tried. Retrograde ejaculation can be either medically or surgically treated.

- *Medical treatment of retrograde ejaculation:*[37] It is directed to control the internal sphincter by use of sympathomimetics **(Table 2)**. Alkalization of urine has to be done before collection of urine post ejaculation to recover spermatozoa.
- *Surgical:* To restore bladder neck integrity. Recently, collagen injection in the bladder neck has been tried to allow antegrade ejaculation who has a history of previous V-Y plasty. This is for people in whom medical therapy and IUI have failed.

For detailed etiology, diagnosis, and management of sexual dysfunction.[38]

TABLE 2: Medication for retrograde ejaculation.

Medication	*Dose*
Pseudoephedrine (sympathomimetic)	60 mg orally four times per day
Imipramine (tricyclic antidepressants)	25 mg orally two times per day
Ephedrine (sympathomimetic)	25–50 mg orally four times per day
Phenylpropanolamine (sympathomimetic)	75 mg po bid
Brompheniramine maleate (antihistamine)	8 mg bid
Desipramine (tricyclic antidepressants)	50 mg every alternate day

To Decrease Free Radicals and Enhance Sperm Motility

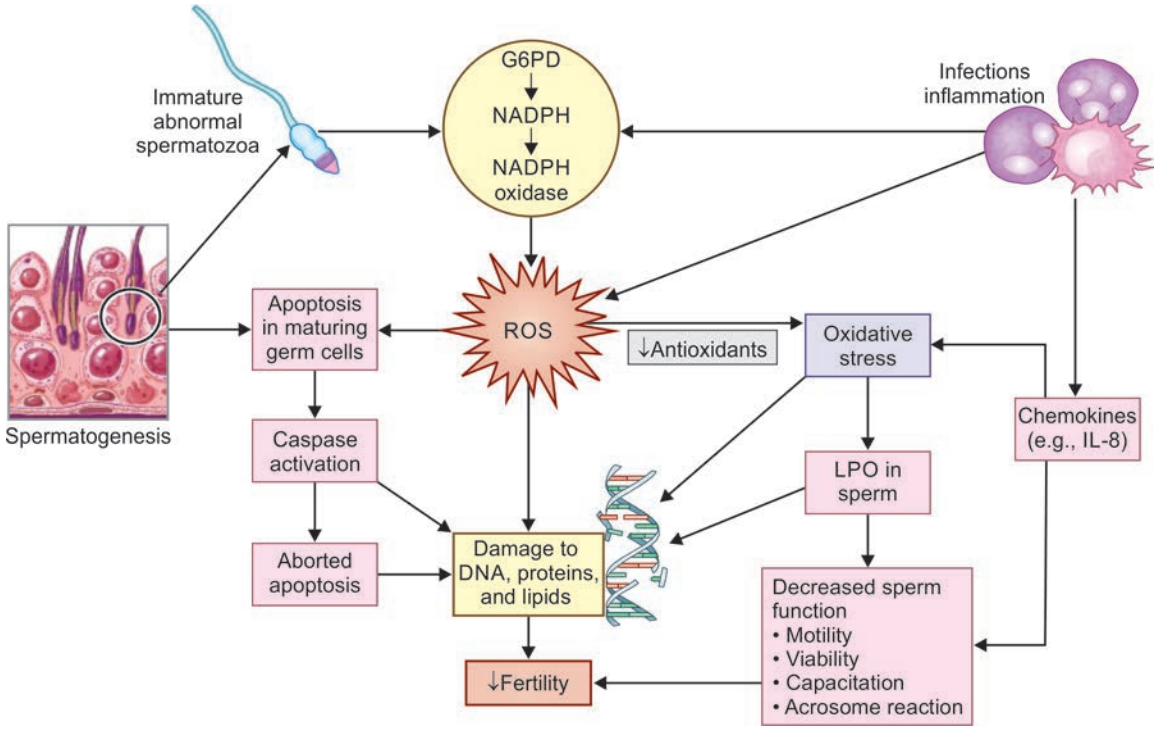
Antioxidants

Reactive oxygen species such as hydroxyl radicals and superoxide anions are released out of leukocytes and abnormal immature forms. Seminal plasma has antioxidant activity. ROS is associated with dysfunction of sperm and deoxyribonucleic acid (DNA) damage resulting in impaired motility of sperm and sperm membrane damage and lipid peroxidation **(Flowchart 1)**.

Classification:

- *Enzymatic:* Superoxide dismutase, catalase, and glutathione peroxidase. These inactivate ROS. These are metal-containing enzymes, which catalyze superoxide in O_2 and H_2O_2 which are less toxic.
- *Nonenzymatic:* Ascorbic acid, alpha-tocopherol, and carnitine. These neutralize ROS.

Flowchart 1: Depiction of balance between oxidative stress and antioxidants.



(DNA: deoxyribonucleic acid; G6PD: glucose-6-phosphate dehydrogenase; IL-8: Interleukin-8; LPO: lipid peroxidation; NADPH: nicotinamide adenine dinucleotide phosphate; ROS: reactive oxygen species)

About 30–80% of male infertility is due to the damaging and harmful effect of oxidative stress. Oral antioxidants may improve sperm quality by causing reduction in oxidative stress. Cochrane (2014) analysis concluded that antioxidants cause statistically significant increase in pregnancy and live birth rate.[39] There is no protocol as such to take over-the-counter antioxidant supplementation for improving semen parameters and pregnancy outcomes.[40] There are many confounding factors such as duration of treatment, control for dietary intake, and lack of standardized dose regimens.[41] No conclusive results have been obtained yet. A systemic analysis of 17 randomized studies evaluated the effect of antioxidants (carnitine, carotenoids, zinc, selenium, folate, vitamin C and E) on sperm parameters and pregnancy rates in 1,655 infertile men. 82% of trials showed either improved sperm quality or pregnancy rate after therapy.[42]

Overtreatment with antioxidants should not be done as it causes asynchronous chromosomal condensation and cytoplasmic fragments in embryo, resulting in decreasing pregnancy rates.[42] In a study, 47 normogonadotropic men with idiopathic asthenozoospermic were divided randomly and given 1,200 mg of pentoxifylline/day for 6 months. Sperm motility increased following pentoxifylline treatment after 3 and 6 months from 25.5 (21.0–30.0) to 35.5 (31.5–39.0) ($p < 0.00001$) and to 42.0 (38.0–46.0) ($p < 0.00001$), respectively.[43] **Table 3** depicts various antioxidants and their role with

TABLE 3: Various antioxidants and their role and rationale behind use.

Antioxidant	*Rationale*	*Parameter improved*	*Evidence*
N-Acetylcysteine	Lowers ROS and protects from xanthine oxidase-induced damage	Motility	Oeda et al.[44]
Vitamin E	Lowers LPO and protects sperm from loss of motility	Motility	Verma and Kanwar[45]
Dithiothreitol, catalase, SOD, and GSH		Motility	Griveau and Le Lannou[46]
Ferulic acid	Increases sperm cAMP and cGMP	Motility	Zheng and Zhang[47]
EDTA/Catalase	Reduces centrifugation-induced ROS and protects from xanthine/xanthine oxidase-induced loss of motility	Motility and DNA integrity	de Lamirande and Gagnon[48]
GSH/Hypotaurine	Protects from xanthine/xanthine oxidase-induced loss of motility	Lessen DNA damage	Lopes et al.[49]
Isoflavones (genistein, equol) or vitamin C/E	Protects from H_2O_2-induced DNA damage		Sierens et al.[50]
Vitamins C, E, zinc, and β-carotene	Vitamin C expresses genes involved in intracellular redox pathways. Its concentration in seminal plasma is 10 times more than in blood plasma *Dosage:* 1,000 µg *Dose <200 µg:* no benefit	DNA damage decreased from 22 to 9% after 2 months of vitamins C and E 1 g each Six out of nine couples got pregnant after 3 months of vitamins C and E, 1 g each	Greco et al.[51] and Gil-Villa et al.[52]
Vitamins C and E (400 mg), zinc, selenium, and β-carotene	Vitamin E protects integrity of phospholipid bilayer of cell membrane and mitochondrial sheath by preventing lipid peroxidation. Enhances production of antioxidant enzymes and decreases MDA concentrations (a marker for lipid peroxidation)	Rx (90 days): ↓ Sperm% DFI (32→26%: By 19%)	Menezo et al.[53]
Menevit (lycopene, vitamins C, E, zinc, selenium, folate, and garlic)	Decrease in ROS production and increased sperm protamination	Rx (3 months): 39% ICSI pregnancy rate, but no ↑ in embryo quality	Tremellen et al.[54]
		Rx (3 months): ↓ Differential diagnosis (22→18%)	Tunc et al.[55]
Vitamins C, E, β-glucan, papaya, and lactoferrin		Rx (90 days): ↑ motility and morphology	Piomboni et al.[56]
Vitamin C, E, and glutathione (400 mg)		Rx (2 months)	Kodama et al.[57]

Contd…

Contd…

Antioxidant	***Rationale***	***Parameter improved***	***Evidence***
Astaxanthin 16 mg for 3 months	Acts like vitamin E	Motility	Comhaire et al.[58]
Vitamin E 300 mg: 6 months		Asthenospermia	Suleiman et al.[59]
Glutathione 600 mg alternate days for 2 months	Glutathione protects plasma membrane from lipid peroxidation, scavenges superoxide, and prevents O_2 formation	Motility and morphology increased in men with varicocele and infection	Lenzi et al.[60]
Vitamin E + selenium		Motility	Keskes-Ammar et al.[61]
L-carnitine + L-acetyl carnitine	• Carnitine increases expression of antioxidant enzymes (heme oxygenase and endothelial nitric oxide synthetase) • Helps in membrane stability and in sperm development and maturation	6 months: Motility	Balercia et al.[62]
Selenium 100 mg or/with vitamin A 1 mg, vitamin C 10 mg, and vitamin E 15 mg	Selenium increases glutathione peroxidase expression, which destroys H_2O_2 molecules	3 months: Motility	Scott et al.[63]
LC ± LAC ± cinnoxicam		Improved concentration, motility, and morphology in men with varicocele except in high-grade varicocele men	Cavallini et al.[64]
NAC 600 mg for 3 months	NAC increases availability of glutathione Acts as ROS scavenger	Improved volume, motility, and viscosity	Ciftci et al.[65]
Folic acid 5 mg and zinc 66 mg	Folic acid reduces homocysteine levels	Improves concentration	Ebisch et al.[66]
LC 2 mg 6 months		Improves concentration and motility	Lenzi et al.[67]
Zinc 400 mg ± vitamin E 20 mg—3 months	• Zinc has membrane-stabilizing activity by inhibiting membrane-bound oxidative enzymes • Immunological function		Omu et al.[68]
β-Glucan 20 mg, papaya 50 mg, lactoferrin 97 mg, vitamin C 30 mg, and vitamin E 5 mg for 3 months		Motility and morphology	Piomboni et al.[56]
Selenium 200 mg ± NAC 600 mg 300 mg coenzyme Q10 for 26 weeks	Coenzyme Q10 inhibits lipid peroxidation	• Motility, morphology, and concentration • Acrosome reaction had increased from 14 ± 8% and 15 ± 8% to 31 ± 11% and 16 ± 10% in the coenzyme Q10 and placebo groups, respectively ($p = 0.01$)	Safarinejad and Safarinejad[69]
Folic acid 5 mg and zinc 66 mg		Concentration	Wong et al.[70]
NAC 600 mg + vitamins—minerals		Concentration	Paradiso et al.[71]
Pentoxifylline	Methylxanthine increases intracellular cAMP levels, which improves sperm motility hyperactivation and acrosome reaction	Curvilinear velocity, path velocity, straight-line velocity, lateral head displacement, beat cross frequency, and sperm hyperactivation	Tesariki et al.[72]

(cAMP: cyclic adenosine monophosphate; cGMP: cyclic guanosine monophosphate; DNA: deoxyribonucleic acid; DFI: DNA fragmentation index; EDTA: ethylenediaminetetraacetic acid; GSH: glutathione; ICSI: intracytoplasmic sperm injection; LC: L-carnitine; LAC: L-acetyl carnitine; LPO: lipid peroxidation; MDA: malondialdehyde; NAC: N-Acetylcysteine; ROS: reactive oxygen species; SOD: superoxide dismutase)

TABLE 4: Recommended daily allowance (RDA) of antioxidants.[76]

Vitamins/Minerals	*RDA*
A (carotenoids)	800 µg
E (tocopherols)	12 mg
C (ascorbic acid)	80 mg
B1 (thiamine)	1.1 mg
B2 (riboflavin)	1.4 mg
B3 (niacin)	16 mg
B5 (pantothenic acid)	6 mg
B6 (pyridoxine)	1.4 mg
B7 (biotin)	50 µg
B12 (cobalamin)	2.5 µg
Zinc	10 mg
Selenium	55 µg
Copper	1 mg
Chrome	40 µg
Magnesium	2 mg
Iron	14 mg

evidence supporting it. Candidates for oral antioxidant therapy are infertile men with ROS after indirect or direct assessment of it.

Indirect assessment methods are lipid peroxidation (malondialdehyde), protein oxidation products (8-OHdG), and sperm DNA integrity. Direct assessment methods are measuring total antioxidant capacity, seminal ROS levels, and detection of superoxide anion.[73] A quick way to detect sperm DNA fragmentation is sperm chromatin dispersion test in which sperms detected with absent halos are the ones with DNA strand breaks. It is a quantitative assay. Once the oxygen species is diagnosed, our focus should be on identifying the source and controlling it. Conditions such as genital infection, varicocele, smoking, medication, drug abuse, systemic diseases, pollution, and radiation are some of the attributable causes, which can be corrected. Differentiation between leukocytes and sperm should be done to know the source of ROS. Antioxidants should be selected according to their formulation and dosage. Recommendations for daily allowance of antioxidants are given in **Table 4**. Earlier, it was believed that antioxidant therapy should be given for 80 days at least[74] but now the latest concept of 60 days has come up depending on the time taken for sperm to undergo the process of differentiation and maturation.[75]

To Treat Obesity-related Infertility

Obesity is a risk factor for male infertility in various ways.[77] Effects of obesity on fertility are depicted in **Box 3**.

Treatment Modalities

- *Lifestyle and nutritional changes:* Diet and exercise should be included. Patients should be counseled about negative effects of smoking cigarettes and marijuana and alcohol.[78]
  Exposure to harmful substances should be avoided. Psychological counseling and stress-relief therapy can be done.[79]
- *Pharmacological intervention:*
  - Appetite suppressants such as sibutramine
  - Weight loss drugs such as orlistat: It is the only FDA drug approved for this purpose.
  - Aromatase inhibitors such as anastrozole and letrozole.[80] Peripheral androgen aromatization is enhanced in men with increased body mass index (BMI). Obese men have increased plasma estradiol and low testosterone levels. Aromatase inhibitors lower estradiol levels and thus there is increase in LH and FSH, in turn increasing testosterone levels. This indirectly stimulates spermatogenesis.
- *Surgical:* Morbid obese men can go through bariatric surgery or scrotal lipectomy can also be tried.
- *ART:* It is the last modality if all fails.

BOX 3: Effects of obesity.

Physical effects:
- Increased erectile dysfunction
- Increased scrotal temperature
- Increased sleep apnea

Seminal effects:
- Oligozoospermia[80]
- Increased DFI
- Decreased seminal volume

Hormonal:
- Increased estrogen, insulin, and leptin
- Decreased testosterone

Erectile dysfunction or disorders

(DFI: DNA fragmentation index)

NONSPECIFIC TREATMENT (EMPIRICAL THERAPY)

According to WHO 2010 analysis, oligospermia is defined as less than 15 million sperms/mL, asthenospermia as less than 40% motility, and teratospermia as less than 4% normal sperms (Tygerberg criteria). Such healthy men present with infertility but are eugonadotropic with normal androgenic features and virilization with subnormal seminal characteristics. No specific etiology is known for such people.

Nonspecific or Empirical Drug Treatment

Indications:
- Patient with oligospermia, asthenospermia, or teratospermia of unknown origin
- Other specific treatments have failed.

In such cases, empirical treatment can be tried to improve sperm count and motility only if FSH levels are normal. These are:

- Antiestrogens
- AIs
- Gonadotropins
- Adjuvants.

Antiestrogens

Antiestrogens such as clomiphene and tamoxifen act on estrogen receptors of hypothalamus to prevent negative feedback by estrogens.[81] It results in increased secretion of FSH and LH, which act on Leydig cells to secrete testosterone and possibly spermatogenesis. Clomiphene citrate is most commonly used in treating idiopathic oligospermia by binding to estrogen receptors. It decreases peripheral conversion of testosterone.[82] It is less likely to be efficacious in men with elevated levels of gonadotropins with markedly abnormal semen analysis or testicular biopsy.[83] Studies have shown conflicting results in sperm counts, morphology, motility, and pregnancy rates. A meta-analysis of 10 controlled studies involving 738 men when treated with clomiphene or tamoxifen for idiopathic oligo- or asthenospermia had positive hormonal effect, but no improvement in pregnancy rate was seen.[84] One randomized controlled trial (RCT) assessed the effect of treatment with clomiphene and vitamin E on the incidence of pregnancy and sperm variables in men with idiopathic oligoasthenozoospermia and infertility. Patients were randomly assigned in two groups with one group getting 25 mg/day of clomiphene and 400 mg/day of vitamin E and the other group placebo for 6 months. Significant higher pregnancy rates were found in the treatment group with increase in sperm count and progressive sperm motility. Nonsignificant changes in total sperm motility, percentage of abnormal forms, and volume were present.[85] A number of meta-analyses have shown a significant elevation in FSH, LH, and testosterone levels on treatment with selective estrogen receptor modulators (SERMs).[86]

Aromatase Inhibitors

Aromatase enzyme belongs to the cytochrome P450 group of enzymes, which is involved in synthesis of aldosterone, cortisol, and androgens.

Mechanism of action:

- Aromatase inhibitors block the conversion of androgens to estrogens and thus increase testosterone levels.
- Aromatase inhibitors block inhibitory feedback of testosterone on the hypothalamic–pituitary–gonadal (HPG) axis and convert into more potent estrogen without any increase in circulating estrogens and E2 receptor modulators.[87]

The most commonly used are letrozole and anastrozole. For AIs to work, the HPG axis should be functional. Altered estrogen-to-testosterone ratio impairs spermatogenesis. Aromatase inhibition is dose-dependent, thus as a result of which aromatase is less suppressed in testis than in adipose tissue and muscle tissue. This is beneficial as it prevents excess reduction of estradiol levels. Semen parameters and testosterone/estradiol ratios improved in a study of nonobstructive azoospermic and cryptozoospermic patients.[88] Treatment of infertile males with the aromatase inhibitors testolactone, anastrozole (1 mg/day), and letrozole (2.5 mg/day) have been associated with increased sperm production and return of sperm to the ejaculate in men with excess aromatase activity [abnormal testosterone/estradiol (T/E) ratios].[89]

Adverse effects: There may be detrimental effects on mineralization. Decrease in high-density lipoprotein (HDL) and increase in hemoglobin level may be present.

Contraindications:

- Elevated liver enzymes and liver diseases
- Estrogen deficiency—osteopenia or osteoporosis
- High blood pressure
- Alopecia, peripheral edema, rashes, and acne.

Gonadotropins

Follicle-stimulating hormone is beneficial in a subset group with normal levels of inhibin B and FSH with hypospermatogenesis but without maturation defects.[90] Four RCTs in a Cochrane analysis of 278 participants had better pregnancy rate per couple with idiopathic subfertility after completing 3 months of treatment [odds ratio (OR) 3.03, 95% confidence interval (CI) 1.30–7.09]. Pregnancy rate was 13.4% (19/142) in the gonadotropin group and 4.4% (6/136) in the control group.[91] The number of participants and trials was small and thus evidence is insufficient to decipher any conclusion. Large multicenter trials with more participants are needed.

Adjuvants

Products such as arginine, pentoxifylline, growth hormone, testolactone, GnRH, kallikrein, prostaglandin inhibitors, and antioxidants have not shown any beneficial effect in controlled studies in normogonadotropic patients. In one controlled study by indomethacin (50–75 mg/day for 60 days) was found to significantly improve both semen parameters and pregnancy rates compared with no improvement in the placebo group. More studies are needed to add this in daily practice.

EFFECT ON MALE INFERTILITY IN COVID-19 ERA

Angiotensin-converting enzyme 2 (ACE2) is expressed in spermatogonia, Sertoli, and Leydig cells of testes, which might lead to testicular dysfunction in patients infected

with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). This damage to testes may be allocated to inflammatory response and fever-associated inflammation. Testicular inflammation caused by viral infection causes increase in interleukins and tumor necrosis factor-α resulting in defective spermatogenesis. Testicular dysfunction may also be caused by disease-related medications, glucocorticoids, and disease-related stress.[92] This may affect semen parameters such as motility and concentration for 72–90 days post-COVID-19 infection. Changes in semen quality are either a direct impact on spermatogenesis caused by viruses or an indirect effect of cytokine excess due to disease and oxidative stress. Achua et al.[93] performed immunofluorescence analysis of testicular biopsy samples of six patients to exhibit association between spermatogenesis dysfunction and increased ACE2 levels, thus stipulating the mechanism of testicular infection by SARS-CoV-2.

Ma et al.[94] detected an increase in circulating LH levels and reduced testosterone: LH ratio in COVID-19 patients, suggesting a negative impact on Leydig cell function. Damage affects not only fertility but mental and psychological well-being also. These effects may subside with time, though further studies are required to validate the point.

Gonzalez et al.[95] studied semen parameters before and after two doses of COVID-19 messenger ribonucleic acid (mRNA) vaccine (Pfizer and Moderna) and found no significant decrease in semen parameters. This may be due to the fact that the vaccines contain mRNA and not the live virus and thus it is highly unlikely that the vaccine would affect sperm parameters. This cannot be predicted for the long-term future due to limitations of the study. Abdel-Moneim[96] has affirmed that precautions should be taken to minimize the risk of transmitting infection via sexual intercourse as also advised by American Society for Reproductive Medicine (ASRM). Miller et al.[97] have demonstrated the importance of telemedicine in the COVID-19 era. Agarwal et al.[98] have recently developed a novel test for oxidative stress measurement called MiOXSYS, which can be used in this COVID-19 era.

Follow-up studies are needed to identify the actual effect on reproductive functions of male patients before any definitive statement can be issued in public as limitations are present in all aforementioned studies.[99] Recently, a project PROTEGGIMI is developed for making an international collaborated registry to fill gaps within the association of SARS-CoV-2 and male fertility.[100]

KEY POINTS

- When a clinician faces male factor infertility, an affirmative and diligent search has to be done to reach up to proper and correct diagnosis. Early diagnosis and intervention along the correct line of management is the key to success.
- A fully functioning basic andrology laboratory along with embryology laboratory should be mandatory in a tertiary-level infertility clinic.
- Understanding of basic HPG axis with basics of endocrinology is of utmost importance.
- Majority of male infertility causes are idiopathic.
- Gonadotropin replacement therapy results in improving androgenic and seminal parameters.
- Primary focus is on optimizing testosterone production through Leydig cells and FSH production to stimulate Sertoli cells and spermatogenesis.
- Despite the fact that testosterone is necessary for virilization and spermatogenesis, exogenous androgens in the form of testosterone should be avoided as they have contraceptive effects by inhibiting LH stimulation on intratesticular testosterone and FSH stimulation of Sertoli cells.
- Aromatase inhibitors play a significant role in men with abnormal testosterone-to-estrogen ratio.

CHAPTER 29

Azoospermia: Evaluation and Management

Ameya Rangnath Sangle, Tarun Dilip Javali

INTRODUCTION

Infertility affects nearly 10–15% of couples who are unable to conceive after 1 year of unprotected intercourse. Male factor infertility accounts for nearly 20–50% of these couples.[1] Of these men, azoospermia is diagnosed in nearly 10–15%.[2] Aspermia is distinct pathology where no ejaculate is produced.

TERMINOLOGY

As per the 2010 World Health Organization (WHO) standards (5th edition) for the evaluation of human semen,[3] the terminologies that are most used in andrology practice are given in **Table 1**.

DEFINITION

The diagnosis of azoospermia requires the absence of sperm from at least two separate centrifuged semen samples. The WHO Laboratory Manual for the Examination of Human Semen and Semen-Cervical Mucus Interaction recommends that the seminal fluid be centrifuged for 15 minutes at a centrifugation speed of, preferably, 3,000 × *g* or greater.[4]

CLASSIFICATION OF AZOOSPERMIA

The classification of azoospermia has been shown in **Flowchart 1**.

CLINICAL CLASSIFICATION OF AZOOSPERMIA

The clinical classification of azoospermia has been shown in **Flowchart 2**.

TABLE 1: Terminology.

Aspermia	No ejaculate (0 mL)
Asthenospermia	<40% total motility
Azoospermia	0 sperm on two centrifuged specimens
Normospermia	>39 million sperm/ejaculate
Oligospermia	<39 million sperm/ejaculate
Teratospermia	<4% normal morphology

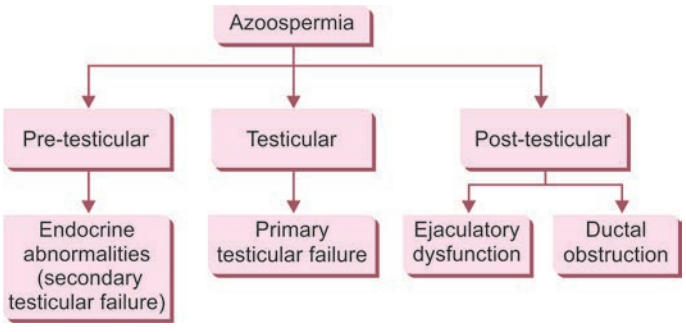
EVALUATION OF A MALE PATIENT WITH AZOOSPERMIA

The initial evaluation of the azoospermic male should begin with a standard reproductive history and physical examination.

History should include:[5]

- *Fertility history:*
  - Duration of infertility
  - Whether the infertility is primary or secondary
  - Any treatments to date
  - Libido
  - Sexual function
  - Sexual activity.
- *General health:*
  - *Diabetes:* Long-standing diabetes may lead to ejaculatory dysfunction and erectile dysfunction.

Flowchart 1: Classification of azoospermia.



Flowchart 2: Clinical classification of azoospermia.

  - *Respiratory illness:* Recurrent respiratory tract infections may be due to cystic fibrosis, Young's syndrome, and Prune belly syndrome.
  - *Recent illness:* Acute viral fever may cause temporary suppression of testicular function but is usually reversible within 3 months.
  - *Smoking:* It causes oxidative stress and deoxyribonucleic acid (DNA) damage of spermatozoa.
- *Genitourinary infections:*
  - Mumps-orchitis
  - Epididymo-orchitis
  - Sexually transmitted infections.
- *Prior surgeries:*
  - Testis cancer
  - Undescended testis
  - Hydrocelectomies
  - Spermatocelectomies
  - Varicocelectomies
  - Vasectomies
  - Testicular torsion.
- *Medication history:*
  - *Hormone or steroid therapy:* Anabolic steroids have a negative impact on the hypothalamic–pituitary–gonadal axis.
  - *Antibiotics:* High dose of nitrofurantoin may affect sperm maturation. Erythromycin and tetracycline may impair sperm motility. Sulfasalazine decreases sperm density, motility, and morphology.
  - *α-blockers:* They cause retrograde ejaculation.
  - 5-α-reductase inhibitors
  - *Chemotherapeutic agents and radiation:* Almost all chemotherapeutic agents are gonadotoxic. Chances of recovery are poor with agents such as bleomycin, etoposide, cisplatin, procarbazine, and vincristine. Cryopreservation should be considered in young patients prior to initiation of chemotherapy.
  - Narcotics
  - Recreational drugs and alcohol.
- History of genetic abnormalities in the family or patient himself
- *Environmental/occupational hazards:*
  - Pesticides
  - Excessive heat on testicles
  - *Occupation:* Welders/coal miners, etc.

Physical examination should focus on evaluating:

- *State of virilization:* Development of secondary sexual characters
  - *Facial, truncal, axillary, and pubic hair:* Sparse in primary and secondary hypogonadism
  - *Voice:* High pitched in hypogonadism
  - Presence of gynecomastia.
- *Scrotal examination:*
  - Presence of testis in scrotum
  - Size of the testis
  - Consistency of the testis
  - Presence and grade of varicocele
  - Palpation of vas deferens
  - Presence of testicular mass.
- *Abdominal examination:*
  - Presence of abdominal mass
  - Presence of scars over abdomen indicative of previous surgeries.

Laboratory Investigations

- *Semen analysis:* Azoospermia in men, by definition, is the absence of sperms in the ejaculate. For further evaluation, the following semen parameters are of importance:
  - *Volume:* Threshold volume is 1.5 mL.
  - *Liquefaction:* Semen is aspirated into a pipette and length of the drop which forms is measured. Length should be no longer than 2 cm.
  - *Semen pH:* Semen pH is generally alkaline. Acidic pH may indicate obstruction or infection.
  - *Fructose:* Patients with obstructive azoospermia tend to have absent fructose whereas those with nonobstructive azoospermia generally have fructose-positive semen.
- *Endocrine evaluation:* Hormonal abnormalities of the hypothalamic–pituitary–testicular axis are well-recognized, though not common causes of male infertility; they form an important component in the evaluation of an azoospermic male **(Tables 2 and 3)**. An endocrine evaluation should include:
  - Serum follicle-stimulating hormone (FSH)
  - Total testosterone
  - Luteinizing hormone (LH)
  - Estradiol
  - Prolactin
  - Free testosterone levels
  - Inhibin B.
- *Urine analysis:* In males with low ejaculate volume (<1.5 mL) and normal hormone levels, postejaculate urine analysis is an important initial test to evaluate for retrograde ejaculation.

TABLE 2: Endocrine parameters in various types of azoospermia.

	FSH	*LH*	*Testosterone*	*Inhibin B*
Obstructive azoospermia	Normal	Normal	Normal	Normal
Hypogonadotropic hypogonadism	Low	Low	Low	Low
Hypergonadotropic hypogonadism	High	High	Low	Low

(FSH: follicle-stimulating hormone; LH: luteinizing hormone)

TABLE 3: Endocrine and semen parameters in azoospermia based on etiology.

Etiology		*Semen volume*	*Total testosterone*	*Serum FSH*
Pre-testicular	Hypogonadotropic hypogonadism	Normal	Low	Low
	Exogenous androgens	Normal	Elevated/normal/low	Low
Testicular	Primary testicular failure	Normal	Low	Elevated
Post-testicular	Epididymal obstruction, vasectomy	Normal	Normal	Normal
	Ejaculatory duct obstruction	Low	Normal	Normal/elevated

(FSH: follicle-stimulating hormone)

Radiological Evaluation

Imaging in a case of infertility is not indicated for routine evaluation or as a part of initial workup. However, it plays an important role in aiding the diagnosis and imaging modalities should be chosen as per clinical indication.

- *Scrotal ultrasound:*
  - To assess testicular size and volume
  - Color Doppler can be used to assess varicocele.
- *Transrectal ultrasound (TRUS):*
  - TRUS is recommended when semen analysis is suggestive of obstructive azoospermia (i.e., acidic, fructose negative, azoospermic, semen volume <1.5 mL, with normal serum testosterone, palpable vas deferens). TRUS evidence of ejaculatory duct obstruction includes:[6]
    - Seminal vesicle anteroposterior (AP) diameter >1.5 cm
    - Seminal vesicle cyst may or may not be present.
  - TRUS can also be used for chromotubation, wherein seminal vesicles can be aspirated to check for sperms and a dilute dye (methylene blue or indigo carmine) can be injected, and cystoscopy can be done to see if the dye flows from the ductal orifice.[7]
- *Vasography:* It is currently rarely performed. It is usually done at the time of vasal reconstructive procedures, wherein contrast is injected in the vasal lumen toward the abdominal end to assess the site of obstruction. Indications for vasography:
  - Hernia or pelvic surgery
  - Semen volume <1 mL
  - Fructose-negative azoospermia with palpable vas.

Testicular Biopsy

The current role of testicular biopsy in patients with male factor infertility is:

- To differentiate between obstructive and nonobstructive azoospermia in case of uncertainty in diagnosis
- To assess the presence or absence of focal spermatogenesis in nonobstructive azoospermia **(Fig. 1)**. The biopsy or aspirate is performed with the additional ability to examine the tissue for sperm and to cryopreserve it, potentially avoiding the need for a second procedure.

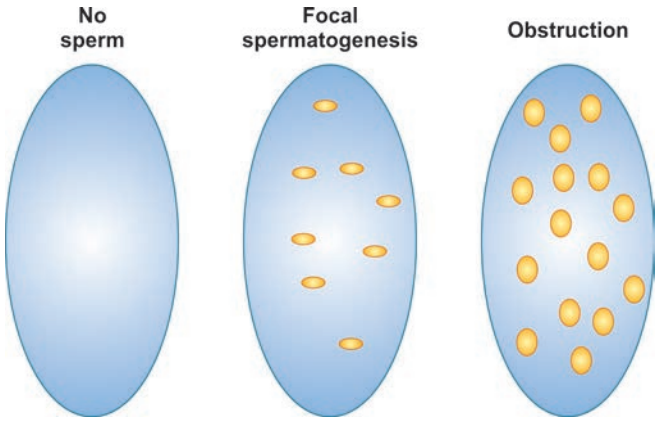


Fig. 1: New interpretation of testicular biopsy.

ETIOLOGY OF AZOOSPERMIA

The etiology of azoospermia is given in **Table 4**.

Obstructive Azoospermia

Congenital Bilateral Absence of the Vas Deferens

The most common cause of congenital bilateral absence of the vas deferens (CBAVD) is the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene mutation. Diagnosis can be easily made by physical examination. Imaging studies and surgical exploration are generally not necessary to confirm the diagnosis but may be useful for diagnosing abnormalities associated with vasal agenesis such as seminal vesicle aplasia. The American Urological Association (AUA) recommends genetic counseling and testing for *CFTR* mutation for both partners. However, failure to identify a CFTR abnormality in a man with CBAVD does not rule out the presence of a mutation as many are undetectable by routine testing methods. In patients with unilateral absence of vas, contralateral segmental atresia of the vas deferens or seminal vesicle and ipsilateral renal anomalies may be present.[8] Treatment options include:

- Intrauterine insemination using epididymal sperm (3–5% pregnancy rate)
- Percutaneous epididymal sperm aspiration (PESA)–intracytoplasmic sperm injection (ICSI) (30–40% pregnancy rate).

TABLE 4: Etiology of azoospermia.

	Nonobstructive		
	Testicular failure	***Hypogonadotropic hypogonadism (HH)***	***Obstructive***
Most common etiology	• Y chromosome microdeletions • Klinefelter syndrome • Cryptorchidism • Postinfectious (mumps) • Radiotherapy • Chemotherapy • Testicular trauma/torsion • Idiopathic	• Congenital [e.g., Kallmann syndrome, normosmic HH), Prader–Willi] • Acquired (e.g., pituitary tumor, steroid abuse)	• Postsurgical (e.g., vasectomy, epididymal cysts removal, hernia repair, scrotal surgery, prostatectomy) • CBAVD • Postinfectious • Ejaculatory duct obstruction • Idiopathic
Physical examination	• Either small-sized (long axis <6.6 cm) or normal testis • Normal epididymis • Palpable vas	• Small-sized testes (volume <15 mL and long axis <4.6 cm) • Small epididymis • Palpable vas	• Either normal or enlarged epididymis • Palpable or nonpalpable vasa (e.g., CBAVD) • Normal-sized testes (volume ≥15 mL and long axis >4.6 cm)
Semen analysis	• Normal (>1.5 mL) ejaculate volume • pH (>7.2) • Hypospermia (<1.5 mL) may be found with hypogonadism	Low ejaculate volume (<1.5 mL) and normal pH	Either normal or low pH and ejaculate volume (e.g., CBAVD and EDO)
Endocrine profile	• Either elevated (>7.6 mIU/mL) or normal FSH levels • Either elevated or normal LH levels • Either low (<300 ng/dL) or normal testosterone	• Low FSH and LH levels (<1.2 mIU/mL) • Low testosterone (<300 ng/dL)	• Normal FSH (300 ng/dL) • Normal LH • Normal testosterone
Genetic testing	• Nonmosaic (47,XXY) and mosaic (46,XY/47,XXY) Klinefelter syndrome • AZF Yq microdeletions seen in about 15% of cases	*KAL1, FGFR1, PROK2, PROKR2, CHD7,* and *FGF8* gene mutations can be found in congenital HH	Cystic fibrosis transmembrane conductance regulator gene mutations usually found in males with CBAVD
Testicular biopsy	• Hypospermatogenesis • Maturation arrest • Sertoli cell-only • Tubular atrophy • Mixed pattern	Not applicable	Normal spermatogenesis

(AZF: azoospermia factor; CBAVD: congenital bilateral absence of the vas deferens; EDO: ejaculatory duct obstruction; FSH: follicle-stimulating hormone; LH: luteinizing hormone)

Treatment of Obstructive Azoospermia

Treatment options for men with obstructive azoospermia include **(Flowchart 3)**:

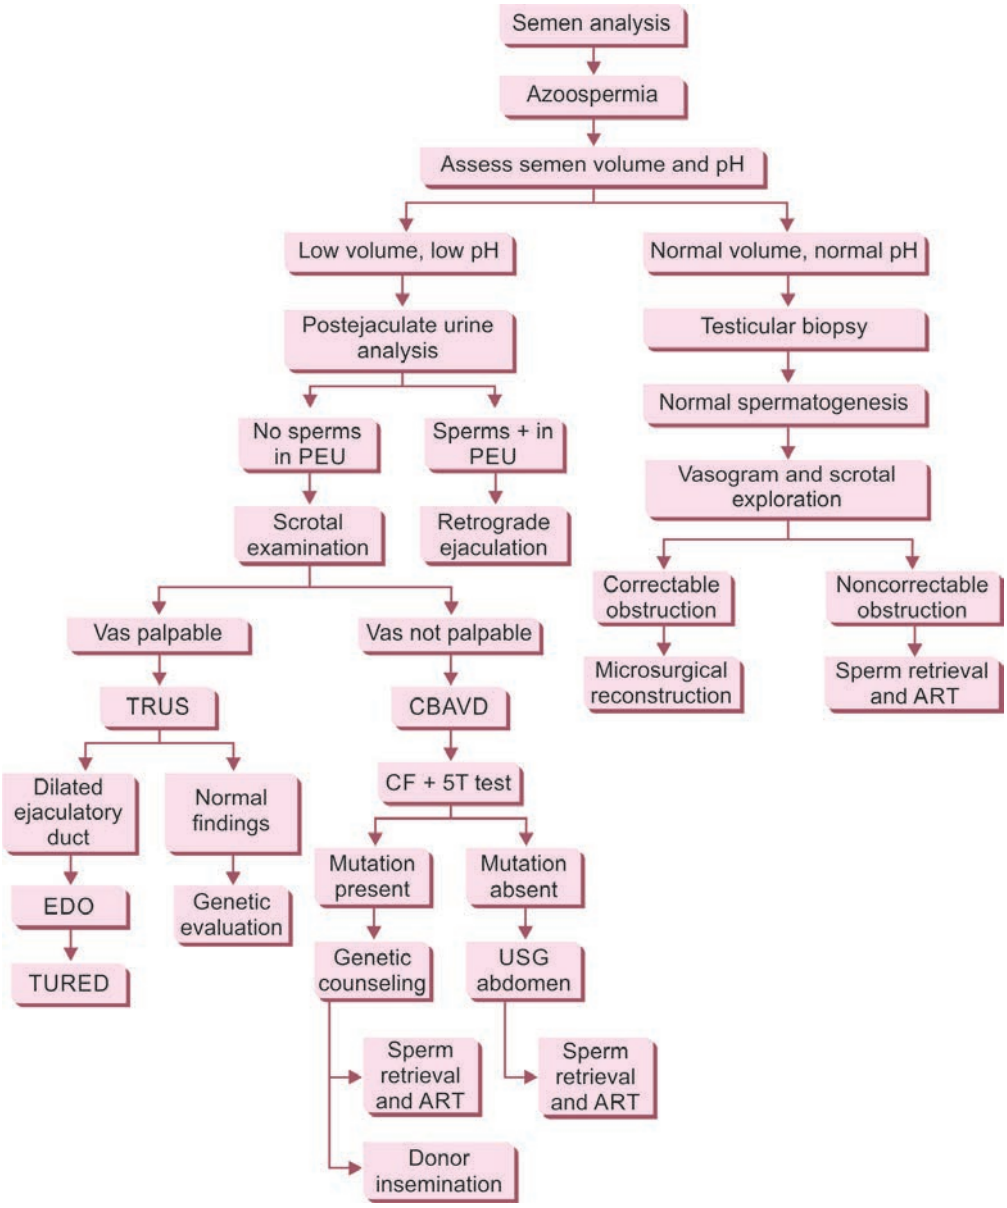
- Surgical correction of the obstruction which obviates the need for assisted reproductive technology (ART)
- Retrieval of sperm from the male reproductive system for in vitro fertilization or ICSI.

Surgical treatment: Surgical options include microsurgical reconstruction of vas and/or epididymis, and transurethral resection of ejaculatory duct (TURED) in case of ejaculatory duct obstruction. The AUA recommends evaluation of female factor infertility prior to microsurgical reconstruction of vas and/or epididymis.

Ejaculatory duct obstruction: Ejaculatory duct may be obstructed in patients with previous genital infection, calcification, stones in ampulla, tuberculosis, Müllerian or Wolffian duct abnormality, and previous surgical trauma. Ejaculatory duct obstruction may be of two types: (1) Fibrous (associated with normal TRUS) and (2) cystic (associated with dilated seminal vesicles). Patients usually present with infertility, anejaculation or scanty ejaculate, hematospermia, pyospermia, and pain or dysuria. Diagnosis can be confirmed with TRUS, which shows dilated ejaculatory duct, seminal vesicles, calcification, and/or stones in ejaculatory duct. Treatment is by TURED at the point where the duct enters the distal prostatic urethra near the verumontanum. TURED results in the appearance of sperm in the ejaculate in about 50–75% of cases. A 25% pregnancy rate can be expected following TURED (AUA Guidelines).

Microsurgical reconstruction: Microsurgical reconstruction, introduced by Silber and Owen, is considered the gold standard for reconstructive surgery for treatment of men with obstructive azoospermia. Vasovasostomy or vasovasal

Flowchart 3: Management of obstructive azoospermia.



(ART: assisted reproductive techniques; CBAVD: congenital bilateral absence of the vas deferens; CF: cystic fibrosis; EDO: ejaculatory duct obstruction; PEU: postejaculate urinalysis; TRUS: transrectal ultrasound; TURED: transurethral resection of ejaculatory duct; USG: ultrasonography)

anastomosis (VVA) and vasoepididymostomy (VEA) are the microsurgeries commonly performed. Microsurgical reconstruction is preferred in younger couples, and the advantage is that it is less expensive and conception can be achieved by natural means. However, the disadvantage is the high failure rate and the need for special expertise.

Vasovasal anastomosis is usually performed following vasectomy (2–6%) or following injury to the vas during hernia surgery (6%). VVA is usually performed under general anesthesia or spinal anesthesia with an epidural using a high scrotal approach for vasectomy reversal or an inguinal approach in case of vasal injuries following hernia surgeries. Initial vasography is performed to assess the length and site of obstruction. Fluid from the proximal end of vas is analyzed prior to VVA **(Table 5)**. Testicular vasal fluid may be watery and copious or thick and creamy in consistency and have one of the following microscopic characteristics:

TABLE 5: Fluid analysis prior to vasovasal anastomosis (VVA).

Clear fluid, sperm +ve	VVA
Thick copious fluid, no sperm	Barbotage with 0.1 mL saline and reanalyze; sperm present: VVA; sperm absent: VEA (secondary epididymal obstruction)
Vas dry, no sperm	Vasoepididymostomy

(VEA: vasoepididymostomy)

- *Grade 1:* Mainly normal motile sperm
- *Grade 2:* Mainly normal nonmotile sperm
- *Grade 3:* Mainly sperm heads
- *Grade 4:* Only sperm heads
- *Grade 5:* No sperm.

Vasovasostomy should be performed for grades 1–4. For grade 5 vasal fluid, vasovasostomy should be performed if the fluid is watery and copious. Vasoepididymostomy should be performed in other cases.[9,10]

Vasovasal anastomosis is performed by multilayer microdot technique with 10-0 monofilament nylon suture in a mucosa-to-mucosa, watertight, tension-free interrupted fashion followed by a seromuscular and adventitial suture. Following VVA, the return of sperm to the ejaculate occurs in 70–95% of the patients and spontaneous pregnancy in 10–75% of the couples. The Canadian Urological Association (CUA) recommends that all men be offered the option to cryobank sperm retrieved during the course of the operation in case the surgery is not successful (level of evidence: 3; grade of recommendation: C) **(Fig. 2)**.[5]

Vasoepididymostomy: This is indicated in patients with secondary epididymal obstruction, wherein no sperm is aspirated from the vasal lumen with normal spermatogenesis on testicular biopsy. Conventional VEA is an approximation rather than an anastomosis, wherein the adjoining vas is anastomosed to the epididymal tunica with the hope that a fistula would form. This technique was associated with poor results. Newer techniques of VEA include:

- Vasoepididymal ductal end-to-side anastomosis (VEDSA) **(Fig. 3A)**
- Triangulation technique **(Fig. 3B)**
- Longitudinal intussusception vasoepididymostomy (LIVE) **(Fig. 3C)**.

Following VEA, sperm is present in ejaculate in 85% of the patients with spontaneous pregnancy seen in over 50% of the couples.[11]

Sperm retrieval techniques: Sperm retrieval may be used in patients with postvasectomy obstruction as a primary therapy for obstructive and nonobstructive azoospermia or as an adjunct to microsurgical reconstructive procedures in cases of obstructive azoospermia. It is indicated in patients with obstructive azoospermia with CBAVD, failed VEA, unreconstructable causes of OA, and older males. Types of sperm retrieval technique are given in **Table 6**.

*Sperm Retrieval techniques **(Flowchart 4)**:*

- *Microsurgical epididymal sperm aspiration (MESA):*[12,13] The epididymis is exposed through a scrotal incision. Under microscope magnification, the epididymal tunica is incised and an epididymal ductule is mobilized. The ductule is opened and spermatic fluid is aspirated. The aspirated fluid is evaluated for the presence of sperm. If an adequate sample is aspirated, the ductule is sutured. If no sperms are retrieved, another ductule is opened.
- *Open fine needle aspiration (OFNA):*[14] It is an open technique of sperm retrieval in which the epididymis is exposed and a ductule is directly punctured through the tunica without dissection. A 26G needle is used for aspiration of the epididymal fluid. The epididymal fluid continues to flow out after withdrawing the needle. This fluid, too, is aspirated from the epididymal surface.
- *PESA:*[15] The head of epididymis is stabilized between the thumb and index finger. A 26G needle is used to puncture the epididymis through the skin. Sperms are aspirated using a tuberculin syringe. The syringe is filled with 0.1 mL of sperm washing medium. A small amount of air is kept between the rubber and this

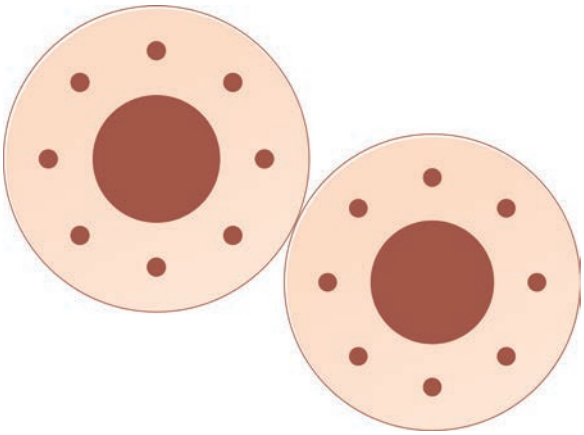


Fig. 2: Microdot technique.

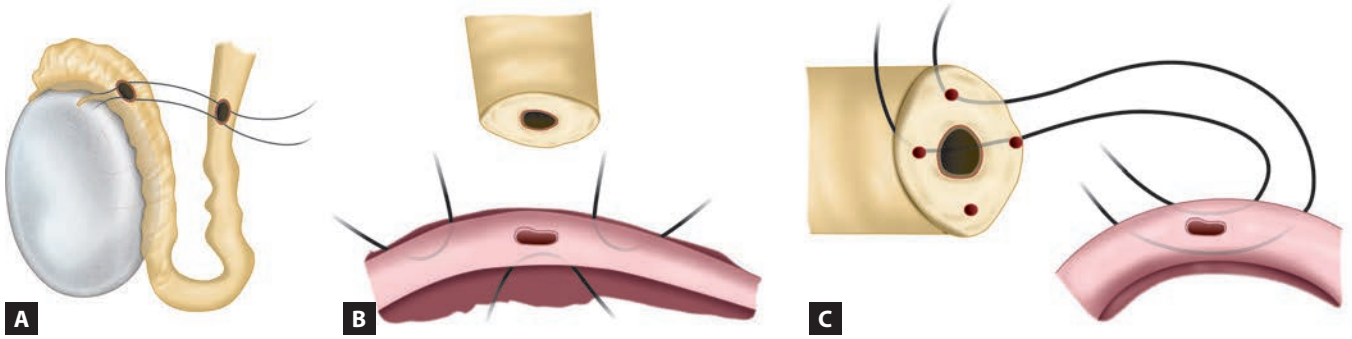


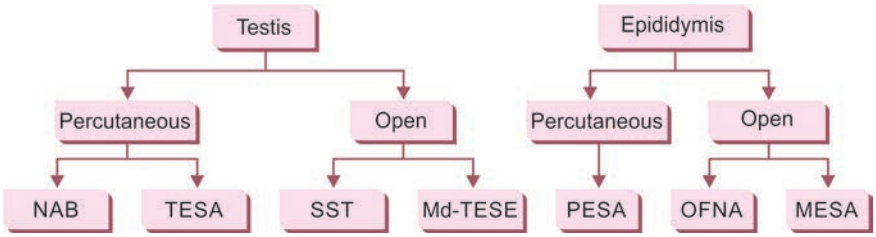
Figs. 3A to C: (A) Conventional vasoepididymostomy; (B) Triangulation technique; (C) Longitudinal intussusception vasoepididymostomy.

TABLE 6: Types of sperm retrieval technique.

	Advantages	*Disadvantages*
Microsurgical epididymal sperm aspiration (MESA)	• Large quantities of sperm obtained suitable for several in vitro fertilization/intracytoplasmic sperm injection cycles in one procedure • Individual epididymal tubes identified and aspirated under microscopic vision • Best pregnancy rates • Minimum complications	• Requires microsurgical skills • Incision with postoperative discomfort • Higher cost compared to percutaneous procedures • Requires anesthesia (GA/sedation)
Percutaneous epididymal sperm aspiration (PESA)	• No microsurgical skills required • Fast and repeatable • Minimum postoperative discomfort • OPD procedure • Done under LA • Can be repeated if needed	• Fewer sperm retrieved • Risk of epididymal damage • Risk of hematoma
Testicular sperm extraction (TESE) and micro-TESE	No microsurgical skills required except when micro-TESE performed	• Risk of testicular damage with multiple biopsies • Incision with postoperative discomfort • Higher cost compared to percutaneous procedures
Percutaneous testicular sperm aspiration (TESA)	• No microsurgical skills required • Fast and easy • Minimum postoperative discomfort • Minimally invasive	Fewer sperm retrieved
Open testicular biopsy	• No microsurgical skills required • Done under LA • Sperm yield comparable to MESA • Tissue diagnosis to determine cause of infertility is possible	• Possible testicular damage • Lower live birth rates as compared to MESA
Percutaneous testicular biopsy (PercBiopsy)	• No microsurgical skills required • Done under LA • Tissue diagnosis to determine cause of infertility is possible • Multiple pass can be performed • Minimum postprocedure discomfort	• Same as open biopsy • Sperm yield is lower

(GA: general anesthesia; LA: local anesthesia; OPD: outpatient department)

Flowchart 4: Sperm retrieval techniques.



(MESA: micro epididymal sperm aspiration; Md-TESE: micro dissection testicular sperm aspiration; NAB: needle aspiration biopsy; OFNA: open fine needle aspiration; PESA: percutaneous epididymal sperm aspiration; SST: single seminiferous tubule biopsy; TESA: testicular sperm aspiration)

medium. The needle is manipulated within the epididymis in different directions while maintaining continuous suction.

- *Testicular sperm aspiration (TESA):*[16] This is similar to fine needle aspiration cytology (FNAC). A 22G needle is used to puncture testicular substance through the scrotal skin. A continuous suction is applied using a 20cc syringe, and the aspirate is examined for the presence of sperm.
- *Single seminiferous tubule (SST) biopsy:*[14,17] Scrotum is incised and testis is exposed. Testis is punctured with a 26G needle through an avascular area in the tunica. The puncture is dilated with microscopic forceps till a seminiferous tubule is exposed. The tubule is then examined under an operating microscope and biopsy is done and evaluated for the presence of sperm.
- *Needle aspiration biopsy:*[14] An 18G needle is pushed into the testicular substance and under continuous suction with a 10cc syringe, the needle is moved to and fro in the testicular parenchyma till aspirate is noted. The needle is then withdrawn from the testis. Along with the needle,

a loop of seminiferous tubule is pulled out and biopsy is done. The aspirate and the tissue are examined for sperms. The procedure is repeated until an adequate sample is obtained.

- *Microdissection testicular sperm extraction (Md-TESE):*[18] Testis is incised to expose the parenchyma. The seminiferous tubules are separated gently and examined under an operating microscope. Healthy tubules are biopsied and examined for sperms. Dissection and biopsy are done till an adequate sample is obtained.

Microsurgical testicular sperm extraction is the preferred sperm retrieval technique in patients with nonobstructive azoospermia and failed MESA (AUA recommendation). In obstructive azoospermia, MESA or PESA is the preferred technique. AUA recommends that the timing of sperm retrieval in relation to oocyte retrieval should be based upon local preference and expertise because there is no evidence that either fertilization or pregnancy rates are different using either fresh or thawed cryopreserved sperm from patients with either obstructive or nonobstructive azoospermia.[19,20]

Some of the recent advances in sperm retrieval techniques are as follows:

- *Multiphoton microscopy (MPM):* It is a technique which helps to identify the presence of sperm within the tubules without the need for extraction of testicular tissue. MPM uses a low-energy infrared femtosecond pulse laser which excites photons and produces autofluorescence which in turn can be translated to produce detailed images of underlying tissue.[21] The MPM technique has shown promising results that can enhance the ability of the surgeon to improve sperm retrieval by correctly identifying seminiferous tubules and also decrease operative time.[22]
- *Full-field optical coherence tomography (FFOCT):* It uses the principle of white light interference microscopy to produce high-resolution images of unstained tissue.[23] The high-resolution images obtained demarcate the seminiferous tubules, the layers of germ cells that line the tubule, and the distinct tubule lumen with intraluminal sperm. This technique is helpful in reducing the number of biopsies and the operating time. The one disadvantage of FFOCT is its inability to identify cellular and nuclear details.[22]
- *Raman spectroscopy:* It utilizes laser-based optics to determine the biochemical structures of living tissue. The advantage of this technique is that it is nondestructive, and the sperms extracted can be used for ICSI.
- *Sperm antibody detection:* This technique utilizes fluorescent microscopy to identify antibody-labeled sperm in seminiferous tubules during micro-TESE. Sperm-specific monoclonal antibodies are injected into the rete testis prior to surgery and thus help the surgeon in identifying sperms during extraction.

BOX 1: Etiology of primary testicular failure.

Genetic abnormalities
- Klinefelter syndrome
- Y chromosome microdeletion

Acquired
- Torsion testis/trauma
- Postinflammatory (mumps)
- Exogenous factors (Chemo-/radiotherapy)
- Testicular cancer
- Systemic diseases (CKD/CLD)
- Varicocele

Idiopathic

(CKD: chronic kidney disease; CLD: chronic liver disease)

Nonobstructive Azoospermia

Primary Testicular Failure

Etiology of primary testicular failure (PTF) is discussed in **Box 1**.

Genetic Abnormalities

Klinefelter syndrome: The most common identified genetic cause of male infertility is the presence of a supernumerary X chromosome yielding 47,XXY or Klinefelter syndrome.[24] This syndrome affects 1 in 500–1,000 live births, and over 95% of the affected adults have azoospermia.[24] Body morphology features such as increased height and sparse secondary sexual characters are seen in 30% of the affected patients.[24] A nonmosaic 47,XXY karyotype is seen in 80–90% of men with Klinefelter syndrome.[25]

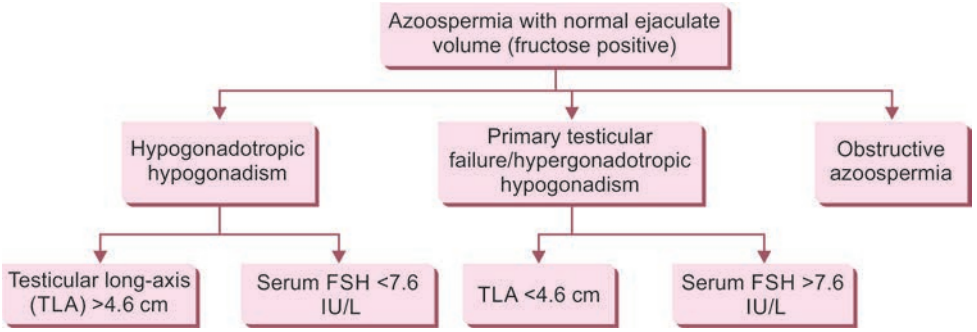
Only about 8% of the patients with Klinefelter syndrome have sperm in ejaculate, while the remainders are azoospermic. Many of these patients are prescribed exogenous testosterone, which suppresses native spermatogenesis if present. Patients with Klinefelter syndrome are managed by surgical extraction of sperm at early or mid-puberty before initiation of testosterone therapy or donor insemination.[26]

Structural chromosomal anomalies: Y chromosome microdeletions are associated with azoospermia or oligospermia. Investigators researched three regions of the Y chromosome which may be responsible and designated them as:

1. Azoospermia factor a (AZFa)
2. Azoospermia factor b (AZFb)
3. Azoospermia factor c (AZFc).

Microdeletions of AZFa and AZFb are almost always associated with the absence of retrievable sperm from the testis. Deletion of the entire AZFa region is associated with the severe testicular phenotype, Sertoli cell-only syndrome. Complete removal of the AZFb region is associated with spermatogenic arrest at meiosis.[25] AZFc is the most frequent deletion of the Y chromosome and is associated with a wide range of phenotypes, including complete absence

Flowchart 5: Evaluation of nonobstructive azoospermia.



(FSH: follicle-stimulating hormone)

of germ cells in the testes, reduction in germ cells—hypospermatogenesis, and maturation arrest.[27] Patients with AZFc microdeletions have nearly 70% sperm retrieval rate.

Acquired Causes: The various acquired causes of testicular failure include torsion testis, trauma, mumps, testicular neoplasm, chemotherapy and radiotherapy, and varicocele. The first step in the management of these patients is to rule out reversible causes of testicular failures such as varicocele. Approximately 20% of men with nonobstructive azoospermia and large varicocele will show appearance of sperm after varicocele ligation. However, sperm counts may still remain low and most patients may still require ICSI.[5]

Management of Patients with Primary Testicular Failure: Patients with a clinical diagnosis of PTF typically have azoospermia, small testis, raised FSH and LH, and low testosterone. Reversible causes such as large varicocele have to be diagnosed and treated. Patients with irreversible PTF should undergo genetic testing to rule out Klinefelter syndrome and Y chromosome microdeletion. Patients with AZFa and AZFb are best treated with donor insemination or adoption. Patients who are eligible for sperm retrieval can undergo mapping microsurgical testicular biopsies to assess the presence or absence of focal spermatogenesis. Patients with focal spermatogenesis can undergo micro-TESE-ICSI. Sperm retrieval rates in patients with nonobstructive azoospermia are around 40%, and live birth rates after micro-TESE-ICSI are around 20% and 40% with donor sperm-ICSI **(Flowchart 5)**.[28]

Nonobstructive Azoospermia Due to Hypogonadotropic Hypogonadism

Patients with hypogonadotropic hypogonadism typically have azoospermia, small testis, and low FSH, LH, and testosterone. Both congenital and acquired causes are described in **Box 2**.

Congenital Causes

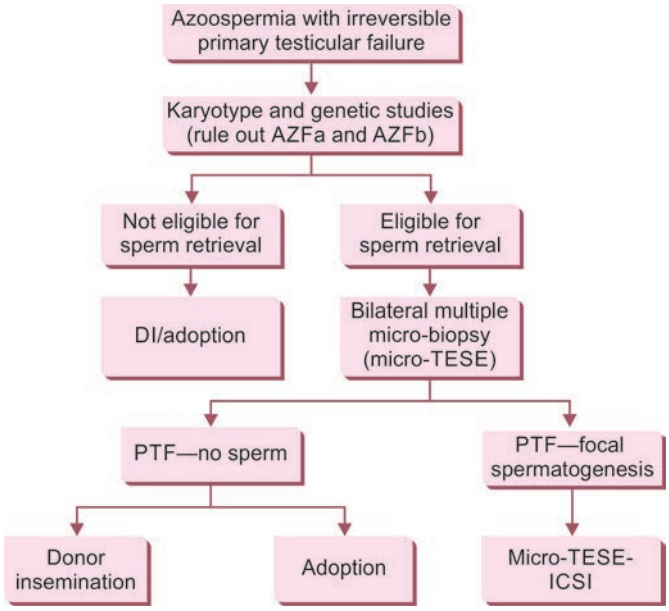
Kallmann syndrome: It is a syndrome associated with pituitary dysfunction and anosmia. Various genes have been found to be responsible, including *KAL1* which codes for anosmin-1

BOX 2: Etiology of hypogonadotropic hypogonadism.

Congenital
- Kallmann syndrome
- Prader–Willi syndrome

Acquired
- Pituitary tumor
- Steroid abuse
- Testosterone replacement therapy

Flowchart 6: Management of primary testicular failure (PTF).



(AZFa: azoospermia factor a; DI: donor insemination; ICSI: intracytoplasmic sperm injection; Micro-TESE: microsurgical testicular sperm extraction)

and is responsible for neurotropic growth factors during embryogenesis, genes coding for gonadotropin releasing hormone (GnRH) receptor, *PIT1*, Kisspeptin receptor, and homeobox genes. Treatment includes replacement of LH with human chorionic gonadotropin (hCG) and replacement of FSH with recombinant FSH (rFSH) or human menopausal gonadotropin. Treatment with hCG alone may initiate spermatogenesis. A typical dose of hCG is 1,500–5,000 IU two/three times per week **(Flowchart 6)**.

Prader–Willi syndrome: It is a syndrome characterized by failure to thrive in infancy associated with poor suck reflex followed by loss of satiety which may lead to early onset obesity. Other features include hypogonadism, small testis, growth hormone deficiency, and dysmorphic facies. The precise pathophysiology of this syndrome is still uncertain, but it is believed to be due to hypothalamic dysfunction with growth hormone deficiency and hypogonadism. Genetic malformation in Prader–Willi syndrome is loss of expression of genes located on chromosome 15q11-q13. In Prader–Willi syndrome, genes located on maternal chromosome 15q11-q13 are active, and those on the paternal ones are inactive, whereas in healthy individuals, the paternal genes are active.

Acquired Causes

Pituitary tumors and diseases: Space-occupying lesions in sella turcica and such as micro- and macroadenomas and craniopharyngiomas may compress pituitary resulting in FSH and LH suppression. Most pituitary tumors secrete prolactin and are associated with erectile dysfunction. Patients with raised prolactin of >50 μg/L should undergo a cranial magnetic resonance imaging (MRI). Functioning microadenomas may be treated with dopamine agonists such as bromocriptine and cabergoline whereas macroadenomas are treated with surgery.

CONCLUSION

- Azoospermia is a encountered in 10–15% of males during evaluation of infertility.
- Algorithmic approach to azoospermia is essential for proper management of infertility.
- Multiple options are available for treatment of obstructive azoospermia with high success rates.
- Micro TESE is the method of choice for surgical sperm retrieval in nonobstructive azoospermia.

KEY POINTS

- Management of azoospermia has evolved with advances in ART and microsurgical techniques.
- Management of azoospermia today is complex, challenging, but rewarding.

CHAPTER 30

Varicocele and Infertility

Ameya Rangnath Sangle, Varun Huilgol, Tarun Dilip Javali

INTRODUCTION

Varicocele is a vascular abnormality due to the enlargement and elongation of the veins of the pampiniform plexus within the spermatic cord. It is considered as the most common cause of male infertility. The overall prevalence of varicocele in different studies ranges from 4.4 to 22.6% in general population.[1,2] Left-sided varicoceles are more frequent than right ones due to venous reflux because the perpendicular termination compromises flow from the left spermatic vein in the presence of elevated left renal venous pressure. With a bilateral incidence of 10% of patients and an isolated right varicocele in <1%, the left side is more prevalent than the right.[3] Varicoceles, in majority, are clinically insignificant. A small number of varicoceles can cause pain, infertility, and/or impairment in testicular growth.[4] The temperature in the testis is usually 2–4° lower than the core body temperature for the sperm to mature and function. The pampiniform plexus causes this by acting as a heat exchanger with a countercurrent flow, thereby reducing the temperature of the blood in the testicular artery before it enters the testicles.[5] Increased temperature due to varicocele causes impairment in the function of testis further leading to infertility.[6] There have been theories that hypoxia, oxidative stress (OS), and food deprivation are a combination of genetic and other molecular variables that together induce varicocele-mediated infertility (VMI) rather than being the sole cause.[7] However, even after receiving surgery, antioxidant therapy, or other treatments, some patients never restore their fertility. It was reported that this condition affects between 15 and 20% of adult males. Further, almost 40% of men who are being tested for infertility have varicocele.[3]

ETIOLOGY OF VARICOCELE

In majority, the left internal spermatic vein drains into the left renal vein lateral to the vertebral column.[8] The right internal spermatic vein usually drains into the inferior vena cava (IVC) just below the right renal vein. Variations in these findings are found quite frequently in studies examining cadaver specimens.[9] Most commonly, this classic anatomic configuration is seen on the right in 78% and on the left in 79% of patients. Anomalous drainage patterns described on the right include termination of the testicular vein in the renal vein in 8% and multiple veins terminating in the IVC and the renal vein in 16%. Anomalous drainage patterns described on the left include multiple veins terminating in the renal vein in 20%. Infrequently, one of the multiple branches may terminate in the infrarenal IVC.[8,10] The exact etiology of varicocele is not fully explained; however, multiple factors have been postulated for the origin of varicocele, one of the factors being hydrostatic pressure. Due to the anatomical structure of the veins, there is higher hydrostatic pressure in the left spermatic vein in comparison with the right side, which is said to predispose the left side to varicocele formation.[11] Another factor for varicocele formation is said to be incompetent or absent valves in the spermatic veins that predispose to varicose information. Based on these, two types of varicocele have been described: Stop type and shunt type.[12] However, this concept is controversial as the absence of valves has been noted in men without varicoceles on autopsy. Ahlberg et al.[13] identified absent valves in approximately 40% of left spermatic veins and 23% of right spermatic veins. The third mechanism that may result in varicocele formation is the nutcracker effect. It is also known as the left renal vein entrapment syndrome. Compression of the left renal vein by the abdominal aorta and the superior mesenteric artery or common iliac artery causes pressure elevation in the renal vein, which is transferred to the left internal spermatic vein and pampiniform plexus.[14] Nevertheless, the adverse effects of varicocele on spermatogenesis are multifactorial.

PATHOGENESIS

The presence of a varicocele has a detrimental effect on the processes of spermatogenesis, testicular volume, standard semen parameters, sperm function, fertilization, implantation, and the outcomes of embryos. The effects of varicocele on the male reproductive system are potentially

mediated through elevated scrotal temperature, reflux of toxic metabolites into the internal spermatic vein, hypoxia, antisperm antibodies, hormonal dysfunction, and OS. However, despite the clear evidence of the adverse effects, the underlying pathophysiological mechanisms have not yet been completely elucidated.[15,16]

OXIDATIVE STRESS

In mitochondrial respiration, highly reactive oxygen-containing species are released as unavoidable by-products.[17] The primary sources of seminal reactive oxygen species (ROS) are believed to be immature sperm cells and leukocytes.[18] ROS are vital products for optimal sperm function by regulating capacitation processes—hyperactivation and acrosomal reaction—and, consequently, fertilization. Despite such important physiologic effects, excessive amounts of ROS can be harmful as they can exacerbate sperm deoxyribonucleic acid (DNA) damage, lipid peroxidation, and abortive apoptosis.[19] Patients with varicocele are associated to have higher OS in their semen leading to infertility. There is evidence that says varicocelectomy is associated with decreased sperm DNA fragmentation and increase in fertility.[20,21]

IMPAIRMENT OF SPERMATOGENESIS BY SCROTAL HYPERTHERMIA

The ideal temperature range for spermatogenesis, which is temperature-sensitive and operates best between 35 and 36°C, is maintained. Varicoceles cause the temperature of the scrotum to increase by 2.6°C, which leads to impaired spermatogenesis.[22] A rise in scrotal and intratesticular temperature in males with varicoceles can be produced by retrograde blood flow into the pampiniform plexus, which abnormally encourages spermatozoa and leukocytes to generate more ROS.[23] A decrease in the quantities of antioxidants as well as a downregulation in the expression of antioxidant enzymes can both be caused by heat stress. In cryptorchidism in which chronic elevation in testicular temperature is a primary factor for the impairment of testicular function, a similar increase in ROS has been seen. This is because cryptorchidism affects the testicles. In addition, some animal models have shown that scrotal hyperthermia can inhibit the production of androgen, increase the rate of death in germ cells, and decrease the expression of heat shock proteins.[24,25]

Molecular mechanisms of heat stress causing impaired spermatogenesis are decreased production of proteins and key enzymes such as topoisomerase 1, DNA polymerase, and heat shock proteins.[26-28]

Impairment of Blood Flow in Testis

Venous blood flow is decreased in varicocele and may result in localized testicular hypoxia. Research suggests that there is increase in the expression of hypoxia-inducible factor-1 (HIF-1) in the testicular tissues of rats with varicoceles. HIF-1 regulates numerous genes' transcription and translation in hypoxia to improve cellular survival rates. HIF-1 may, paradoxically, restrict stem cell proliferation in the presence of decompensated or persistent hypoxia.[29] Numerous authors have proposed that elevated HIF-1 expression causes elevated p53 expression, which in turn speeds up the apoptotic process in testicular tissue.[17] Recent proteomic studies have revealed that HIF-1 is responsible for the lower expression of heat shock proteins in individuals who have unilateral varicocele. This study also revealed an increase in reduced nicotinamide adenine dinucleotide (NADH) and a decrease in the expression of oxidative phosphorylation proteins, which shows that the spermatozoa from affected men had inefficient mitochondria and low redox capabilities.[30] To better understand the significance of these measures and assess how well they might predict the degree of hypoxia, more research is needed.

DEOXYRIBONUCLEIC ACID DAMAGE AND APOPTOSIS

Varicocele-induced OS may cause sperm pathology. Varicocelectomy improves spermatogenesis and DNA integrity as well as spontaneous and assisted reproductive technique (ART) pregnancy rates. A morphologically normal spermatozoon may also have inadequate chromatin compaction. The effect of sperm DNA damage on pregnancy, embryonic development, and offspring health is a cause for concern. Sperm DNA compaction/fragmentation can be additional diagnostic and prognostic markers for subfertile men with varicocele. Standardization and clinical implementation of sperm DNA fragmentation tests are recommended.[31,32]

Apoptosis, or programmed cell death, is involved in varicocele pathogenesis. Developing germ cells, testicular tissues, and ejaculated spermatozoa show higher apoptosis in men with varicocele. ROS, cadmium, and genetics can induce apoptosis. Cadmium is a metal ion that promotes apoptosis. Left varicocele patients with bilaterally elevated testicular cadmium levels had higher apoptosis, inverse association to postoperative semen parameter improvement. Spermatozoa apoptosis was higher in men with varicocele.

Colloidal microbeads coupled with annexin V can be used to select spermatozoa for intracytoplasmic sperm injection (ICSI). Neuronal apoptosis inhibitory protein (NAIP) and survivin prevent apoptosis. In rats with varicocele, these proteins were drastically reduced, along with spermatogenesis. Polydeoxyribonucleotide (PDRN) administration before varicocele production in rats blocked these effects. PDRN may increase spermatogenesis following experimental varicocele.[33]

TABLE 1: Grading of varicocele.

Grade	*Description*
Grade 1	Palpable during Valsalva maneuver and in standing position
Grade 2	Palpable without performing Valsalva maneuver and in standing position
Grade 3	Visible through the scrotal skin and palpable in standing position

CLINICAL GRADING

A clinical varicocele is one that is only palpable during the Valsalva maneuver; a grade 2 varicocele is easily palpable with or without Valsalva but is not visible, and a large varicocele that is easily palpable and detected by visual inspection of the scrotum is classified as grade 3. Clinical varicoceles are detected and graded based on physical examination. **Table 1** describes the different grading of varicocele based on the criteria described by Dubin and Amelar.[34]

MANAGEMENT

Evaluation

Varicoceles are mainly diagnosed on clinical examination. Various imaging modalities are available to improve detection rates and provide further anatomic detail of varicoceles. However, the benefit of obtaining imaging studies in a subset of varicoceles that are only found on imaging and not appreciated on physical examination has been debated. The current guidelines from the American Urological Association/American Society for Reproductive Medicine (AUA/ASRM) recommend against the use of routine imaging studies for the detection and screening of subclinical varicocele.[35]

Ultrasonography

Ultrasonography is the primary imaging modality for diagnosing varicocele. The characteristic appearance of a varicocele is described as "multiple, anechoic, serpiginous, tubular structures" near the superior and lateral aspects of the testis.[36] Numerous classification systems have been described for grading of varicoceles based on ultrasound and Doppler findings. The most widely accepted systems are the Sarteschi and Chiou classifications mentioned in **Tables 2 and 3**, respectively.

Another classification used in ultrasound is the Chiou et al. scoring system **(Table 3)**.[38]

Computed Tomography

Computed tomography (CT) has gained popularity since its introduction in the 1970s and has become a mainstay in the evaluation of abdominal pathology. Small vessels, including the gonadal veins, are better evaluated by using submillimeter thickness slice and multiplanar image reconstruction.[39]

TABLE 2: Sarteschi classification for color Doppler ultrasound diagnosis of varicocele.[37]

Grade	*Description*
1	Venous reflux at the emergence of the scrotal vein only during the Valsalva maneuver; hypertrophy of the venous wall without stasis
2	Supratesticular reflux only during the Valsalva maneuver; venous stasis without varicosities
3	Peritesticular reflux during the Valsalva maneuver; overt varicocele with early stage varices of the cremasteric vein
4	Spontaneous basal reflux that increases during the Valsalva maneuver, possible testicular hypotrophy, overt varicocele, varicosities in the pampiniform plexus
5	Spontaneous basal reflux that does not increase during the Valsalva maneuver, testicular hypotrophy, overt varicocele, varicosities in the pampiniform

TABLE 3: Chiou et al. scoring system for color Doppler ultrasound diagnosis of varicocele.

	Score
Maximum vein diameter (mm)	
<2.5	0
2.5–2.9	1
3.0–3.9	2
≥4.0	3
Plexus/sum of diameter of veins	
No plexus identified	0
Plexus (+) with sum diameter <3 mm	1
Plexus (+) with sum diameter 3–5.9 mm	2
Plexus (+) with sum diameter ≥6 mm	3
Change of flow velocity on Valsalva maneuver	
<2 cm/s or duration <1 s	0
2–4.9	1
5–9.9	2
≥10	3
Total score	0–9

Note: Total score of >4 is defined as varicocele.

However, the increased radiation exposure and ease of availability of ultrasound have reduced the desirability of this investigation. The role of CT in the evaluation of varicoceles has mainly been limited to investigating retroperitoneal pathology. CT is the study of choice when a retroperitoneal abnormality is suspected. Causes of varicocele formation that could be identified on CT imaging include renal tumors, retroperitoneal tumors causing compression, vena caval thrombi, and retroaortic renal veins.[40-43]

Magnetic Resonance Imaging

Early changes within the tissue parenchyma can be detected early by using diffusion-weighted imaging (DWI).[44] The

effects of varicocele on fertility can be potentially quantified by using magnetic resonance imaging (MRI). Çekiç et al. showed that decreased apparent diffusion coefficient (ADC) values calculated from DWI in patients with varicoceles correlated with semen parameters.[45]

Venography

Percutaneous venography has now become obsolete and diagnostic modality of historical significance and research interest. In today's practice, venography is a useful adjunct to guide intraoperative decision-making. It has also been described for the planning of definitive treatment in cases where varicoceles recur.[46]

Thermography and Scintigraphy

Thermography evolved as a screening tool to identify areas of hyperthermia for subclinical varicocele. It measures the temperature and surface of scrotal skin and utilizes a film with heat-sensitive liquid crystals. The World Health Organization (WHO) Task Force on Diagnosis and Treatment of Infertility compared contact thermography with ultrasound to the gold standard of retrograde venography. In this multicenter series, ultrasound combined with contact thermography had the highest diagnostic accuracy with a 1% false-negative result and 44% false-positive results.[47]

Scintigraphy has now been rendered to be largely of historical and research interest due to the time required and impracticality compared to other modalities. The patient's red blood cells (RBCs) are labeled by intravenous administration of pyrophosphate 20 mCi prior to administration of ^{99m}Tc pertechnetate. The patient is then examined standing with the penis strapped in the midline to the abdomen. The scrotum is located in the lower third of the area of interest, while a gamma camera evaluates the accumulation of radioactive tracer-labeled RBCs.[48]

Varicocele Repair

Varicocele repair has been shown to improve both semen parameters and testosterone production in hypogonadal males with subfertility.[49,50] Varicocele repair in azoospermic and oligozoospermic patients improves pregnancy rates and live birth rates following the use of ART, even if azoospermia or oligozoospermia persists **(Table 4)**.[21]

Open Varicocele Repair

Open macroscopic, varicocele repair was the standard of care till the 1970s when microsurgery took over.[51] The traditional inguinal open varicocele repair (Ivanissevich technique) is done by making a skin crease incision in the inguinal region above and lateral to the ipsilateral pubic tubercle and extending laterally. External oblique aponeurosis is sharply incised along the length of the fibers to open the inguinal ring and expose the spermatic cord. External spermatic fascia is then incised to access the vascular structures within. Venous structures, including the internal spermatic vein, cremasteric veins, external spermatic veins, gubernacular veins, and periarterial veins, are identified and ligated.[52] Varicocele is also performed using the Palomo technique through either open or laparoscopic approach. The open retroperitoneal approach or open Palomo technique was first described by Palomo in 1949.[53] In Palomo's initial series, a 4 cm incision was made

TABLE 4: Comparison between different techniques of varicocele repair.

Procedure	*Advantages*	*Disadvantages*	*Recurrence*	*Complications*
Embolization	Minimal pain	Difficult canalization of the right spermatic vein	3.2–19.3%	• Extravasation NR • Thrombophlebitis NR
Laparoscopic	Simplified vascular anatomy, short operating time, can address bilateral varices simultaneously	• Difficulty visualizing lymphatics • Artery usually not spared	4.3%	Hydrocele 2.8–20%
Microscopic subinguinal	Adequate anatomic visualization, possibly less pain	Complex vascular anatomy	1.05%	Hydrocele 0–0.4%
Microscopic inguinal	Simplified vascular anatomy, adequate visualization	Pain at incision site	2.1%	Hydrocele 0.7%
Loupe-assisted high ligation	Simplified vascular anatomy	Incisional pain, poor visualization of structures	14.9%	Hydrocele 8.2–13%

(NR: not reported)

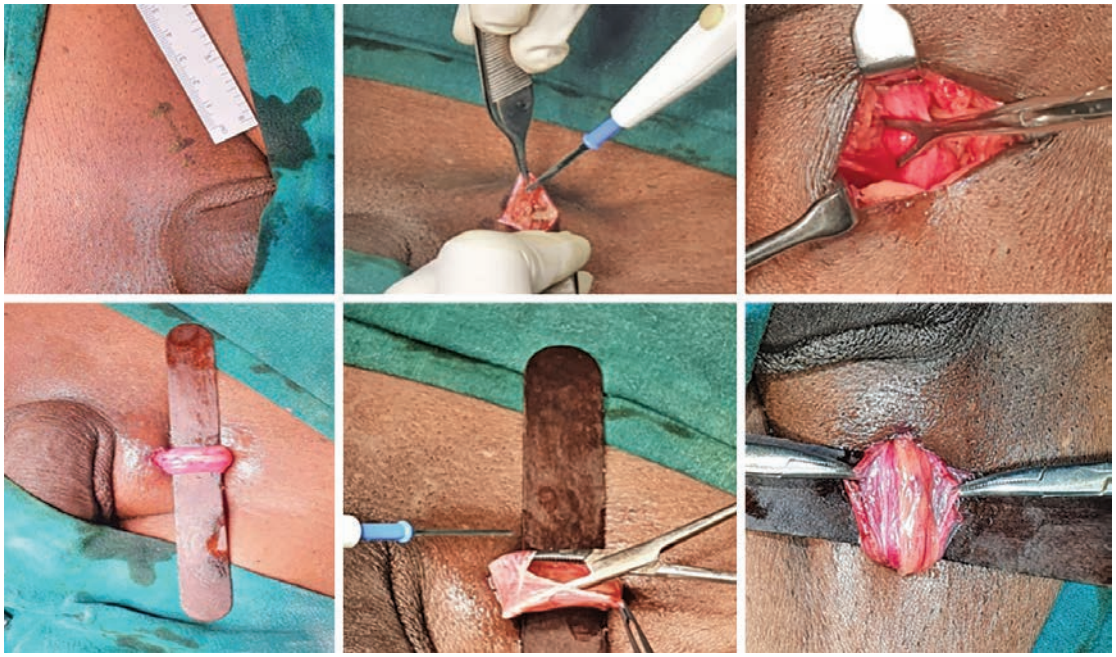

Fig. 1: Subinguinal microscopic varicocelectomy.

3 cm above the internal inguinal ring, and the large spermatic veins and testicular artery were ligated together at this location. Currently, an open Palomo technique uses Gibson incision and ligates the internal spermatic vein between the anterior superior iliac spine and renal vein.

Laparoscopic Varicocele Repair

Palomo technique can be performed laparoscopically and is the preferred technique in adolescent patients. Three transperitoneal ports are placed with a camera port at the umbilicus, one working port at midline between umbilicus and pubic symphysis and a third port lateral to ipsilateral inferior epigastric vessels. The peritoneum is opened 3 cm proximal to the deep inguinal ring. Spermatic vessels are dissected from surrounding tissues. Veins are then ligated with clips and divided. The testicular artery may or may not be spared.[54]

Microscopic Varicocele Repair

Microscopic varicocele repair is currently considered as the gold standard for varicocele repair.[55] It can be done by inguinal and subinguinal approaches. The subinguinal approach provides the highest success with least complications. For the subinguinal approach, a 2 cm incision is made along Langer lines located above the superficial inguinal ring. The incision is then deepened to open the wound in layers. Blunt dissection is carried out till spermatic cord identification. The cord is then delivered atraumatically using a Babcock clamp. The cord is placed over a 1″ Penrose drain or a sterile scale to provide for stability and to allow for the use of countertraction for dissection. Under the magnification of an operating microscope, the external spermatic fascia is split, and the vascular structures within the cord are accessed. Once the vas deferens is identified, it is isolated. Veins are identified and ligated with sutures (usually 4-0 silk) or dissected using a bipolar cautery. Micro-Doppler is used for the effective identification of testicular artery and avoidance of inadvertent arterial injury. After all veins have been ligated, the cord can be repositioned back. The external spermatic fascia may or may not be closed. Care should be taken to preserve at least two to three lymphatic vessels to prevent hydrocele formation. Finally, the incision is closed in layers using absorbable sutures **(Fig. 1)**.

Embolotherapy

The main indications for interventional treatment are pain, infertility, and recurrence after surgical ligation. This recurrence is usually attributed to collateral circulation that was missed during surgery.[56]

The most frequently used agents for embolization are sodium tetradecyl sulfate (STS), endovascular coils, vascular plugs, glue, and absolute ethanol. Complications to varicocele embolization include groin pain, hematoma formation, contrast agent reactions, fever, nausea, and thrombophlebitis. The risk of hydrocele formation is said to be the least in this technique.[57]

CONCLUSION

- Varicocele is one of the important causes of male infertility
- Prompt diagnosis and correction of the condition leads to improved fertility results.
- Microscopic varicocelectomy is the gold standard in varicocele repair.

KEY POINTS

- Varicocele
- Male infertility
- Microscopic varicocelectomy.

CHAPTER 31

Spinal Cord Injuries and Male Infertility

Yalavarthi Pavan Ganesh, Tarun Dilip Javali, Mahendra V Javali

INTRODUCTION

Spinal cord injury (SCI) is a devastating neurological condition.[1] SCI is one of the most disabling events that involves the central nervous system. It causes temporary or permanent loss of muscle function, sensation, or autonomic function in the parts of the body served by the spinal cord below the level of the injury. SCI affects every aspect of the life of an injured person ranging from their normal day-to-day activities to their reproductive health including fertility. It is more commonly seen in young men.[1,2] The role of SCI in affecting female fertility is limited as compared to male infertility. In women, the challenges are usually restricted to self-care during pregnancy, labor, delivery, and for activities of daily functioning. Infertility following SCI in men occurs due to a combination of erectile dysfunction (ED), ejaculatory dysfunction, and semen abnormalities.[1,3] The treatment of ED in SCI can be done through similar therapies as used in the general population. Treatments that are effective in non-SCI male factor infertility are effective for management in couples with SCI male factor infertility. But the major difference in symptoms between SCI-related male factor infertility and non-SCI-related male factor infertility is higher occurrence of atypical profile of the semen and anejaculation in men with SCI. The role of health professionals is of paramount importance in identifying people with SCI-related male factor infertility and educating them and their family about the problem, ways to approach them, and types of support available for them to have children. A lot of advances have been made over the years in the field of medical sciences with regard to SCI-related infertility. This chapter will provide an overview of SCI-related male factor infertility and its management.

SPINAL CORD INJURY

Definition

The term "Spinal Cord Injury" can be defined as any damage to the spinal cord that results from trauma or due to a disease or due to degenerative conditions or disorders like cancer. Around 90% of the cases of SCI occur due to trauma.[2,3]

Epidemiology

Majority of SCIs occur in young men, who are at the peak of their reproductive health.[1] According to the reports of World Health Organization (WHO), globally around 2,50,000–5,00,000 people suffer from SCI.[2] The annual incidence of SCI is estimated globally to be around 40–80 cases per million population, according to WHO. There were 0.93 million new cases of SCI with 95% confidence interval (CI) of 0.78–1.16 million in 2016. The prevalence was 27.04 million with 95% CI of 24.98–30.15 million. SCI was responsible for 9.5 million years lost due to disability in 2016.[3] There are no reliable countrywide estimates of SCI in India **(Fig. 1)**.

Majority of them occur due to causes that are preventable such as road traffic crashes, violence, or falls. Falls and road injuries were the leading causes of new cases of SCI and traumatic brain injury (TBI) in most regions.[3]

Males are more commonly affected than females in the ratio of 1:1 to 8:1. Males are four times more likely to sustain an SCI in comparison with females.[4] SCI subjects are likely to die, two to five times more prematurely, on comparing them to those without SCI. The survival rates in subjects with SCI are low in countries belonging to low- and middle-income groups. SCI is associated with substantial individual and

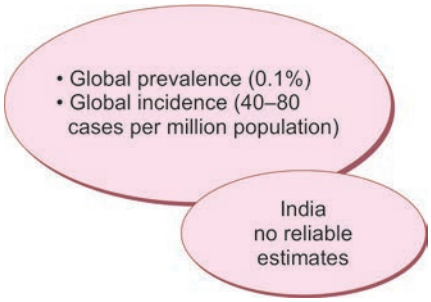

Fig. 1: Estimates of global prevalence and incidence of spinal cord injury (SCI) in relation with India.

societal costs, besides lower rates of school enrolment and economic participation. Approximately 78% of new cases of SCI occur in men in the United States of America.[5] According to SCI data in United States, the average age at injury has increased in the recent decades from 29 (1970s) to 43 years.[5]

A report of the WHO shows that 15% of the world's population is affected by disability, 0.1% by SCI.[6] The incidence of SCI varies substantially between countries. Only a very few countries have a countrywide SCI registry system. The incidence estimates are often extrapolated from data available from a region. Also, there is no central worldwide registry. Population-based surveys are also rare for estimating the SCI in the general population. It was reported in 2012 that nearly 20,000 cases of SCI are added every year in India and there are 1.5 million people with SCI in India.[7] There is a lack of population-based studies in India. Epidemiological data are available only from various hospital-based studies.[8-10]

Spinal cord injury can be primary, secondary, or immune response SCI. Primary injury is due to input from primary mechanical forces while secondary injury is due to a series of biological phenomena that occurs following the primary injury. The neuroinflammation can be beneficial or detrimental following an SCI.

Etiology

Based on etiology, SCI can be classified as:

- Traumatic SCI
- Nontraumatic SCI.

Majority (90%) of SCI occurs due to trauma.[2,3] The most common global causes for traumatic SCI are road traffic accidents followed by falls and violence.[11] Traumatic causes of SCI include:

- Falls from height
- Road traffic accidents
- Sports-related accidents
- Violence
- Other causes of injury.

Nontraumatic causes include diseases or degenerative conditions or disorder such as cancer. The etiology of nontraumatic SCI includes:

- Vertebral spondylosis
- Compression due to tumors
- Vascular ischemia
- Injuries due to congenital disease.

Nontraumatic SCI is commonly seen in older age groups on comparison with the predominance of traumatic SCI in younger age groups. With increase in lifespan in the recent decades, incidence of nontraumatic SCI can increase and can overtake that of traumatic SCI.[12] In nontraumatic SCI, the etiology varies according to the region like infectious diseases such as human immunodeficiency virus (HIV) and nutritional disorders.[13,14]

Clinical Presentation

A typical presentation of SCI includes a young male, with a history of trauma. Symptoms of SCI may range from partial or total loss of sensation to loss of movements of arms, legs, and the body. Bowel and bladder control, breathing, heart rate, and blood pressure are affected in most severe SCIs. The symptoms depend on the location of injury on the spinal cord and severity of injury. They may include:

- Partial or complete loss of sensory function and/or motor function
- Inability to move arms, legs, and/or body
- Loss of control of bladder and bowel
- Unnatural positioning of neck
- Chronic pain
- Unconsciousness
- Signs of sock.

Spinal cord injury can affect almost every aspect of the reproductive system in males like ED, sexual dysfunction, poor spermatogenesis, and ejaculation problems.[15,16] Complete loss of sensory function or motor function bilaterally below a certain level indicates a complete SCI.[17] Respiratory function may be impaired due to loss of central ventilatory drive, loss of ventilatory muscle function, chest wall injury, lung injury like hemothorax and pneumothorax. Vital capacity is severely affected in high lesions at C1 to C2 while respiratory dysfunction is minimal for injuries at T11.[18] In case of a complete injury above T11, the ability to achieve psychogenic erection is lost. Sacral nerve root injuries impact the reflex or tactile erections.[19] In SCIs of T11 to L2, the ability to achieve erection by one or both pathways is variable[20] **(Fig. 2)**.

Natural Progression

Spinal cord injury is a devastating condition that can lead to death. In SCI due to traumatic injuries, the course is more or less well defined, depending on the level of injury.[21] Depending on the severity of the lesion and level of the lesion, death can occur within a few days to months. Pneumonia can occur in lesions of the high cervical cord due to respiratory function impairment. Lack of therapeutic measures can lead to death in the long run. Depending on the lesion level, pressure sores, urinary tract infections can also occur. With establishment of dedicated rehabilitative therapies, the life expectancy and the quality of life have increased in SCI. The disease course now mainly depends on the functional recovery.[22]

The life expectancy in subjects with SCI has increased over the last few decades but it still remains lower in comparison with age-matched able-bodied individuals.

The American Spinal Injury Association Impairment Scale (AIS) standardizes a careful, detailed documentation of the injury.[23] It has tremendous prognostic value as it guides further assessment radiographically and management.

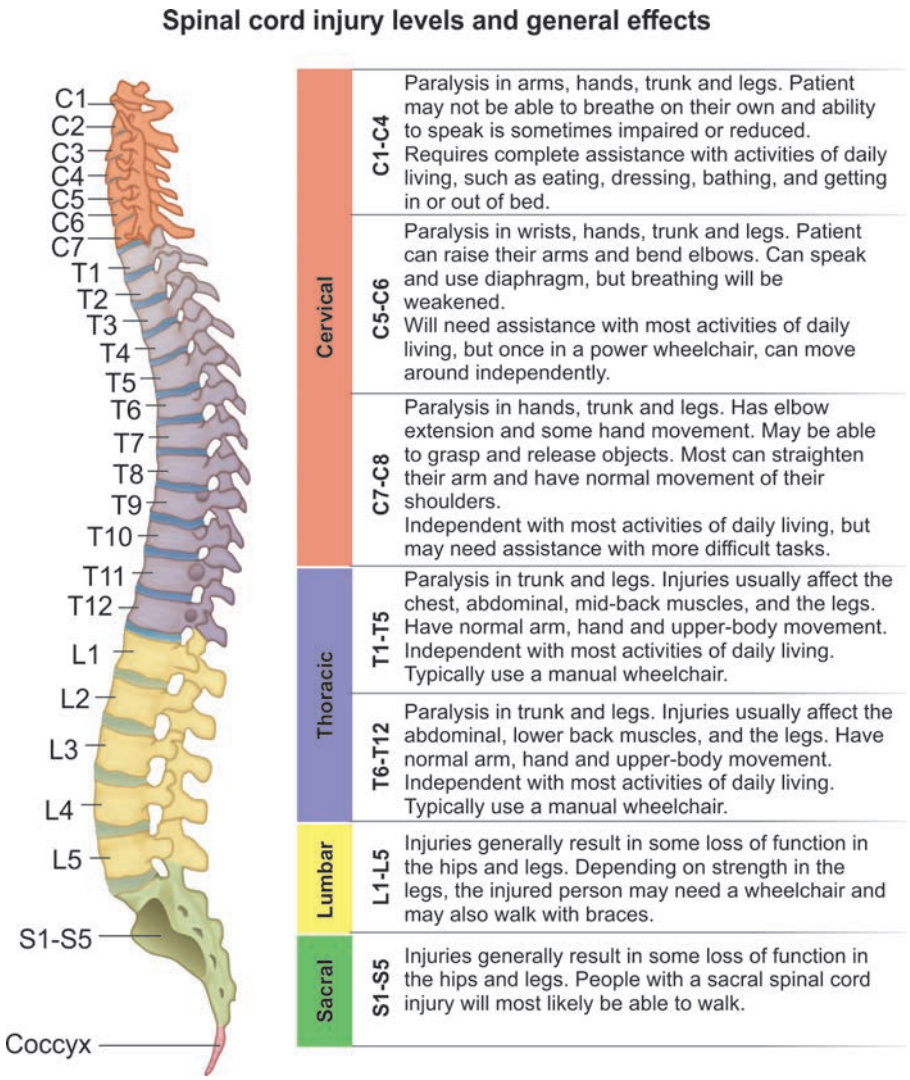

Fig. 2: Levels of spinal cord injury and corresponding clinical presentation.
Source: BY MATT LALANDE in Spinal Cord Injuries on May 01, 2021, (https://injured.ca/what-is-a-cervical-spinal-cord-injury/)

It determines the injury as complete or incomplete. AIS also allows for better counseling of the patient regarding expectation of recovery.[23]

MALE INFERTILITY DUE TO SPINAL CORD INJURIES

The natural fertility rate in men after a complete SCI lesion is estimated to be around 5–10%.[24,25] They may be unable to achieve either erection or ejaculation or both.

Male infertility is the condition where in the female partner has reduced the chances of getting pregnant in spite of being normal.

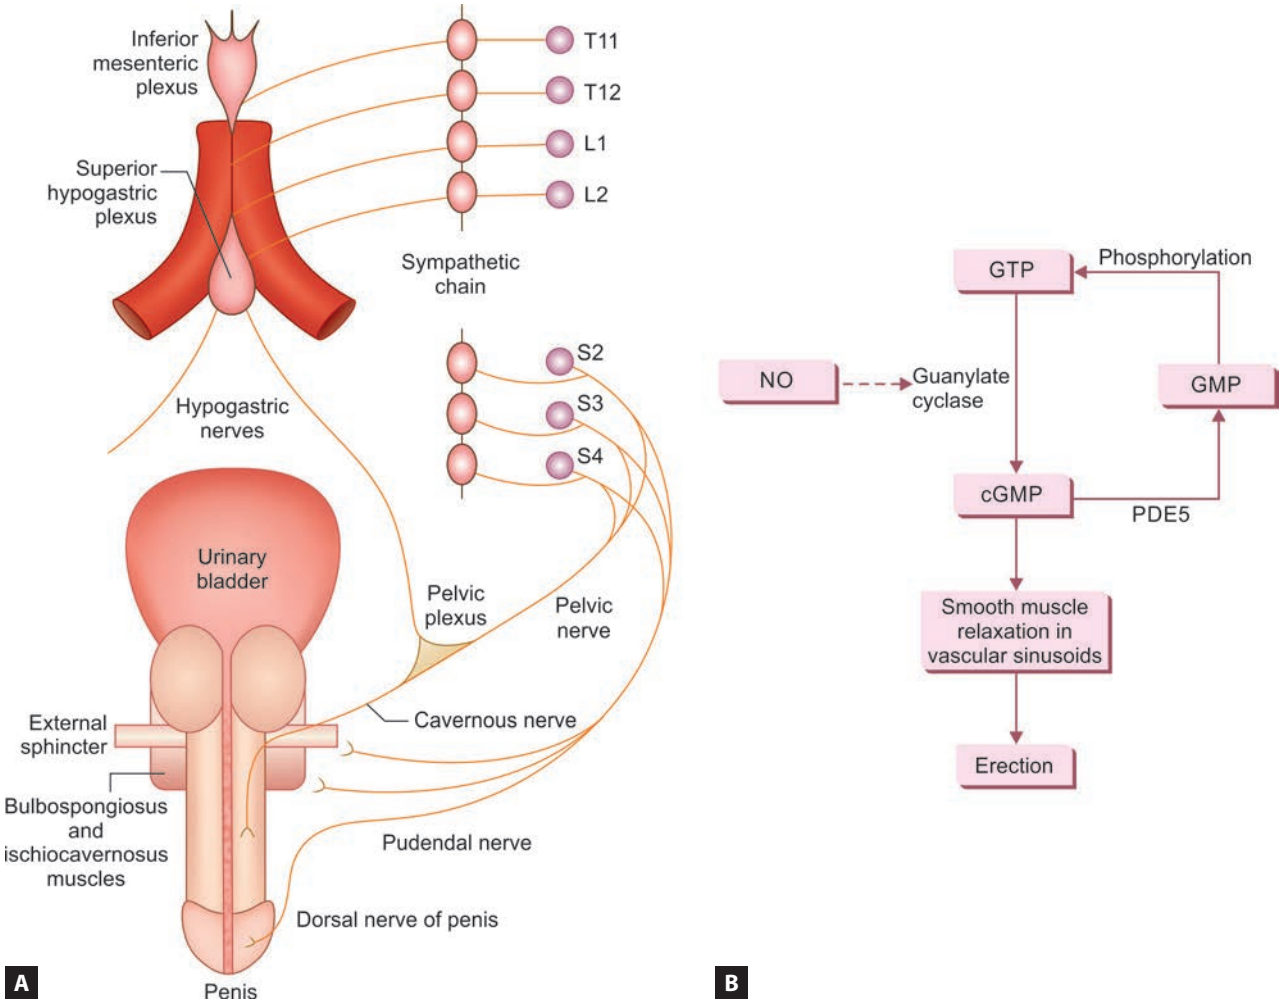
Spinal cord injury occurs commonly in young men, who are most probably at the peak of their reproductive health. It leads to infertility in them. Three major complications that are responsible for infertility in men with SCI are:[16]

- ED
- Ejaculatory dysfunction
- Abnormal quality of the semen.

Sexuality and Fertility in Men with SCI

In males, SCI can affect almost every aspect of the reproductive system. ED, sexual dysfunction, endocrine dysfunction, poor spermatogenesis, and problems in ejaculation and semen emission may occur.[15,16] After SCI, majority of the men may experience severely impaired fertility. The sexual dysfunction arising in neurological disorders has several causes. A model proposed for multiple sclerosis consisting of primary, secondary, and tertiary sexual dysfunction is considered valid for all neurological problems causing sexual dysfunction **(Figs. 3A and B and 4A to D)**.[26-28]

Primary sexual dysfunction is due to neurological lesions that affect the pathways responsible for sexual function. Lesions affecting the nervous system from the cerebrum to the peripheral nerves including the autonomic nervous system (ANS) can cause sexual dysfunction. It may manifest in the form of decreased libido or loss in libido, altered orgasmic response, and painful genital sensation like burning. There is also difficulty in erection, its maintenance, and ejaculation.



Figs. 3A and B: Neurophysiology of normal penile erection. (A) Sympathetic and parasympathetic penile innervation, pudendal nerve innervation. (B) Cyclic guanosine monophosphate (cGMP) pathway responsible for ejection. (GTP: guanosine triphosphate; NO: nitric oxide; PDE5: phosphodiesterase-5)
Source: Brackett NL et al. (2010b) 24 and Ibrahim E et al. (2016).[29]

Secondary sexual dysfunction can be due to fatigue, weakness of muscles, cognitive impairment, poor bladder control, and medications. It can also arise due to non-neurological comorbidities, such as depression, hypertension, diabetes mellitus, and obesity.

Tertiary sexual dysfunction is associated with psychological, psychosocial, and cultural issues affecting sexual response.

Loss of muscle movement, loss of touch sensation, and loss of sexual reflexes can occur commonly after SCI. The effect on one's sexuality such as arousal, orgasm, and their fertility is dependent on the level of injury and the type of injury as complete or incomplete injury.

Erection, Emission, and Ejaculation in SCI

The process of erection can be classically divided into:

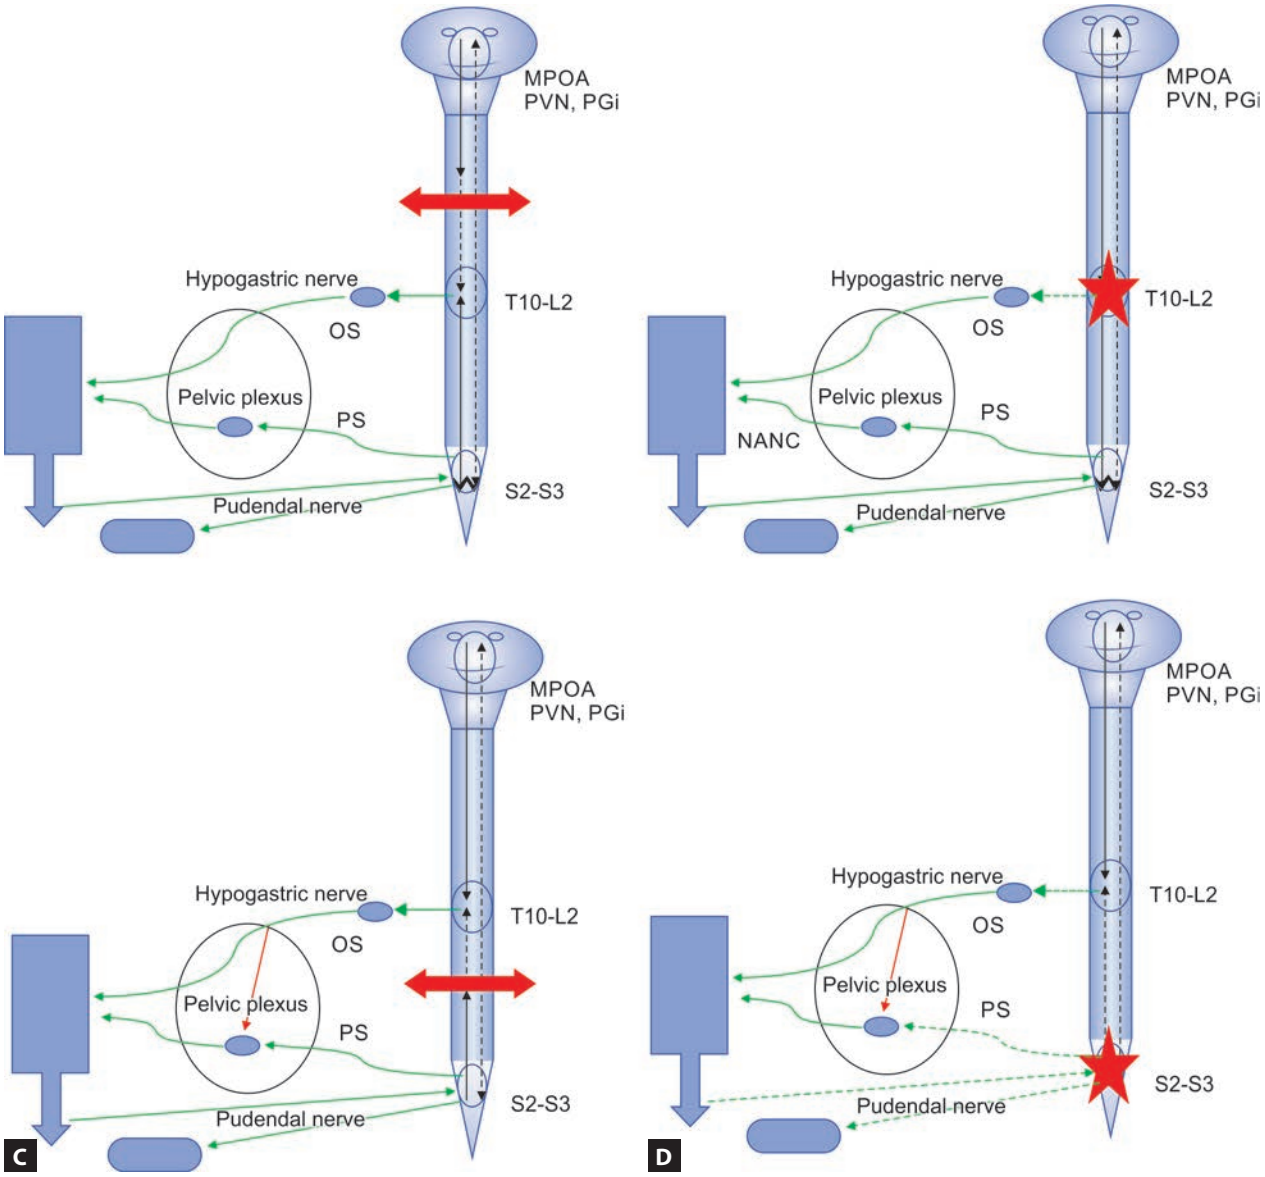
- Reflex
- Tactile or psychogenic.

They are dependent on intact lower motor sacral nerves and spinal cord, respectively.[30] A complete injury above T11 may lead to loss of psychogenic erection. Injuries at the level of sacral nerve root impact the reflex or tactile erections.[19] In SCIs of T11 to L2, the ability to achieve erection by one or both pathways is variable.[20]

Emission involves the process by which semen is deposited in the urethra. It involves afferent signals from penile nerves and sympathetic input from T11 to L2 sympathetic nerve roots. It induces rhythmic contraction of vas deferens, seminal vesicles, and ejaculatory ducts.[20]

Ejaculation involves adequate deposit of semen in an antegrade fashion. It needs a closed bladder neck besides the somatically controlled rhythmic contraction of bulbocavernosus and ischiocavernosus muscles with concomitant relaxation of the external sphincter.[31]

The process of erection, emission, and ejaculation is a highly coordinated one. In a male with SCI, this process can break down and can result in infertility without medication or assisted reproductive technology. The completeness and level of injury determine the ability to ejaculate naturally in an antegrade fashion.



Figs. 4A to D: Neuroanatomy and neurophysiology related to sexual dysfunction due to lesions of spinal cord.
(OS: orthosympathetic, PS: parasympathetic, PGi: nucleus paragigantocellularis)
Source: Everaert K, de Waard W, Van Hoof, T. et al. Neuroanatomy and neurophysiology related to sexual dysfunction in male neurogenic patients with lesions to the spinal cord or peripheral nerves. Spinal Cord. 2010;48:182-191. https://doi.org/10.1038/sc.2009.172

It has also been reported that only 18% retain the ability to ejaculate after lower motor neuron injury. In case of complete upper motor neuron injury, only around 11% can ejaculate.[32,33]

Erectile Dysfunction, Neurophysiology and Evaluation of Erectile Dysfunction in SCI Patients

Neurogenic ED encompasses the disorders, which impair erections because of neurologic compromise or dysfunction. The disorders can be central, peripheral, or both. Neurogenic ED accounts for about 10–19% of all ED causes.[28,34] Several components of the normal pathway can be affected in SCI, leading to ED. Much emphasis has been placed on penile smooth muscle function and cavernosal hemodynamics with regards to penile erection. Although the neuroanatomy and neurophysiology of erection has been extensively characterized, there is still some poor understanding of the full extent of the process.[28]

The penile innervation is derived from both:

- ANS (sympathetic and parasympathetic) and
- Somatic innervation supplying sensory and motor inputs **(Fig. 5)**.[30,31]

The sympathetic preganglionic neurons rise from T11 to L2 while parasympathetic preganglionic neurons come from S2 to S4. Somatic innervation comes from the Onuf's nucleus in the lumbosacral region.

Reflexogenic erection needs intact S2 to S4 nerve roots. It happens by direct stimulation of genital region by involving

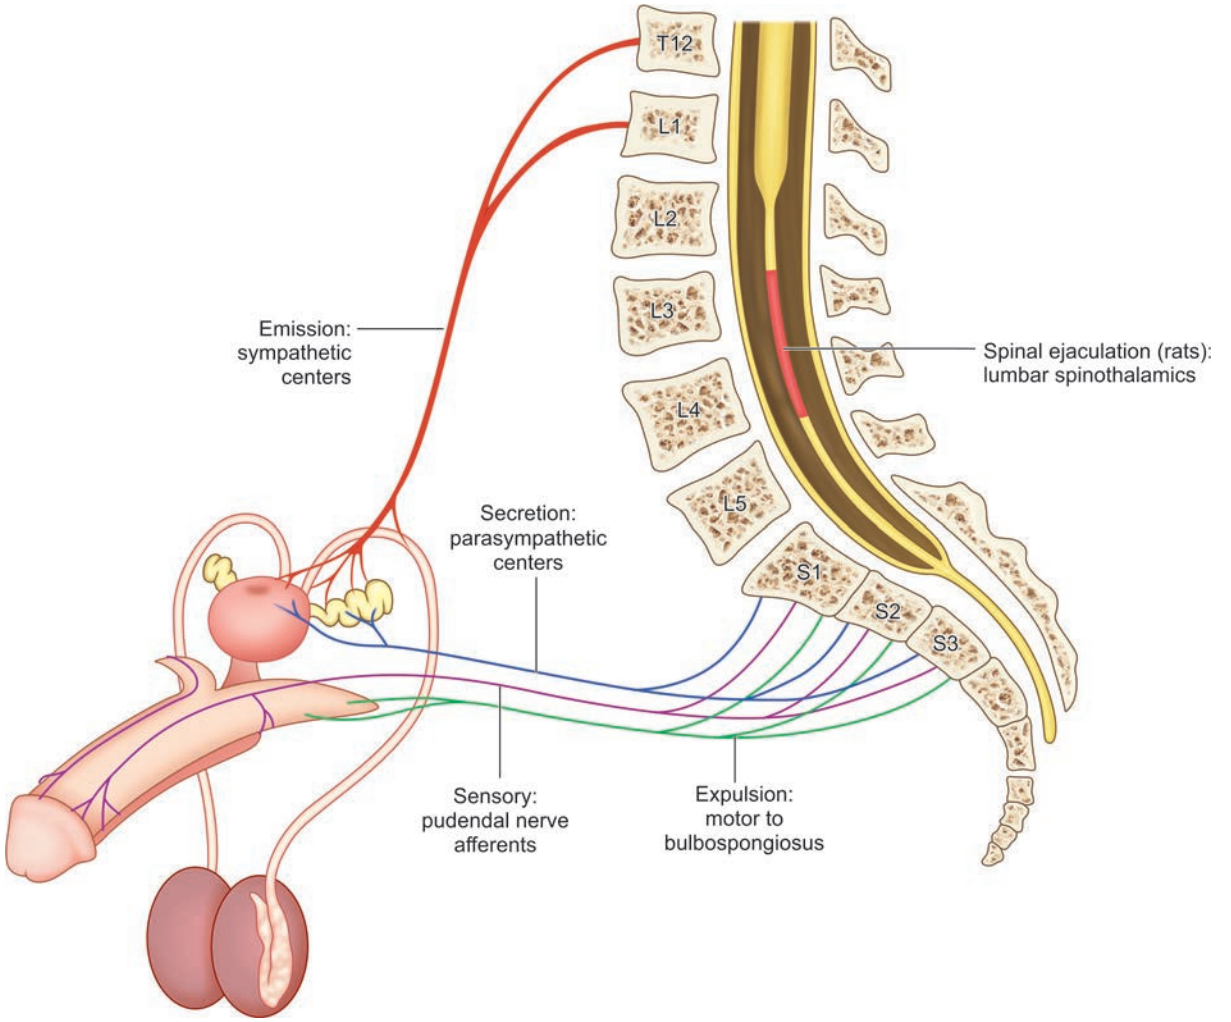


Fig. 5: Neuroanatomy and neurophysiology of erection, emission, and ejaculation.

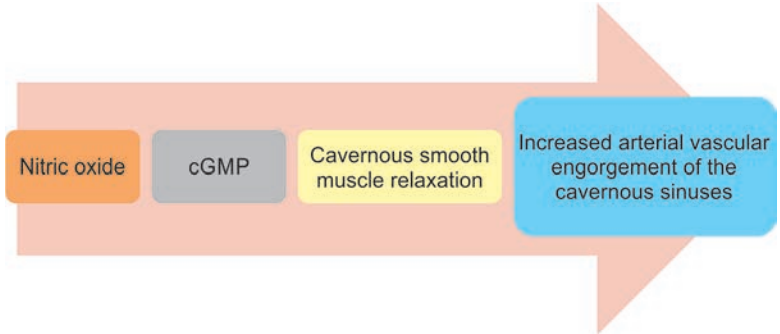

Fig. 6: Vascular process for erection.
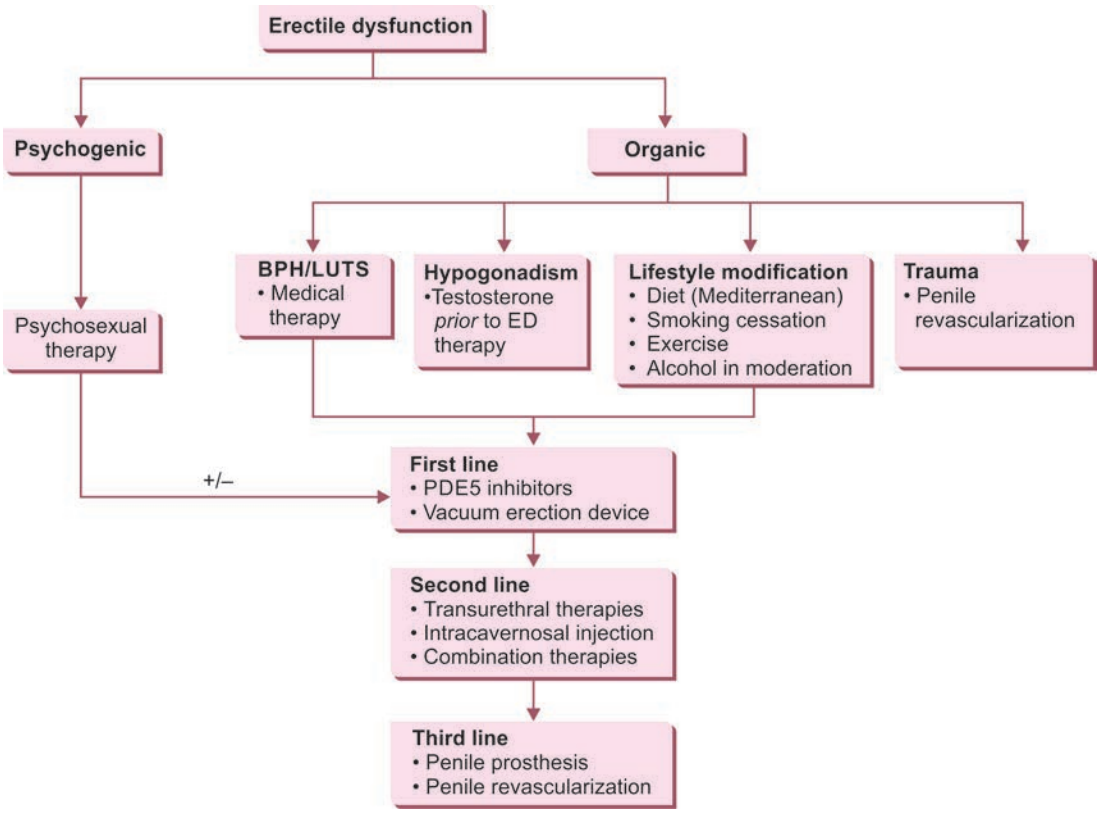
(cGMP: cyclic guanosine monophosphate)

the dorsal nerve of the penis, which is a sensory branch of the pudendal nerve.

Independent of this direct genital stimulation, psychotic stimulation can happen with erotic stimuli and thoughts. It needs an intact thoracolumbar nerve root. In injuries of the thoracic and cervical spinal cord, it is often lost. The maintenance of erection during sexual intercourse is mainly due to psychogenic erection. Balance between the relaxing and contracting factors controlling corpora cavernosa is essential for initiating and maintaining penile erection. The NO (nitric oxide)-guanylate cyclase-cGMP (cyclic guanosine monophosphate) pathway is the relaxing factor which allows for rapid engorgement of venous sinuses of corpus cavernosum **(Fig. 6)**. Inhibition of erection is due

Flowchart 1: Management of erectile dysfunction (ED).



(BPH: benign prostatic hyperplasia; LUTS: lower urinary tract symptoms; PDE5: phosphodiesterase-5)

to phosphodiesterase-5 (PDE5) activity. PDE5 inhibits the engorgement of the cavernosal sinuses by causing persistent cyclic nucleotide signaling, resulting in penile detumescence.

Erectile dysfunction in SCI is mainly neurogenic **(Flowchart 1)**. But other causes of ED should also be evaluated such as psychogenic, penile factors, organic, vasculogenic, medical disorders, endocrine disorders, urological disorders, and drug-induced and iatrogenic factors.[35]

The evaluation of the men with ED comprises:

- Clinical history and physical examination including psychosocial assessment
- Laboratory testing including hypothalamic pituitary gonadal axis and metabolic conditions
- Imaging and other adjunct modalities.

Sequelae of SCI that Affect Male Fertility

The integrity of both the sympathetic and parasympathetic branches of the ANS is responsible for the complex process of erection through ejaculation. The control of ANS is most often affected in SCI, leading to unmodulated reflexes **(Box 1)**.

The vascular process seems to be intact in SCI in absence of any other injuries/comorbidities.

In SCI, spermatogenesis seems to be little affected as seen by the normal numbers in several ejaculates. But the motility and viability of the sperm in most of the men are abnormally low.[36-38]

BOX 1: Sympathetic and parasympathetic outflow necessary for erection, emission, and ejaculation.[27]

Sympathetic outflow from T11 to L2	• Psychogenic erections • Seminal emission • Closure of the bladder neck during ejaculation
Parasympathetic outflow from S2 to S4	• Initiation of reflexogenic erections • Pulsatile expulsion of the semen during ejaculation • Integrity of the pudendal nerve and the dorsal nerve of the penis

Ejaculatory Dysfunction

Majority of the men cannot ejaculate after SCI, without medical assistance. It is dependent on spinal cord coordination and supraspinal input from the brain. Supraspinal stimulation with erotic thoughts can cause ejaculation without any peripheral stimulation, and also the vice versa. Anejaculation after SCI is the absence of seminal emission in the posterior urethra. It mainly results from neuromuscular dysfunction and involvement of ANS. Ejaculation is often possible in SCI, which are incomplete with techniques such as masturbation and/or non-vibrostimulatory methods **(Table 1)**.

TABLE 1: Level of injury in SCI and chances of ejaculation.

Damage to T12 to L2 region[39]	*Testicular atrophy, poor ability to ejaculate*
Complete upper motor neuron lesions above T11[40]	5–10% chances of ejaculation during sex or masturbation
Complete lower motor neuron lesions below L2[40]	18% chance of emission
If upper limit of spinal cord injury (SCI) is below T12	Psychogenic emission with motile spermatozoa can occur

In SCI patients, those with a level of injury which is at or rostral to T10 have increased chances of response to penile vibratory stimulation (PVS) in comparison with level of injury at T11 or caudal. This is because of the integrity of sympathetic and parasympathetic components of the ejaculatory reflex, and the dorsal nerve of the penis in lesions, that are at T10 or rostral to it. In many of the SCI cases, S2–S4 segments are intact, allowing the reflex action to occur. In 95% of males with upper motor neuron lesions, reflex action is preserved. Similarly in 25% of those with lower motor neuron lesions, reflex action is preserved.[41] These reflex erections are often inconvenient and do not last long.

Semen Abnormalities in Men with SCI

In men with SCI, sperm production is usually normal. But there could be deterioration of sperm quality leading to infertility.[1,16,42] Although they may not be able to achieve erection or ejaculation, semen could be collected from them using medical methods. After SCI, there is sufficient evidence to suggest the disturbance of sperm production, the maturation of the sperm, storage and transport because of the altered neuroendocrine milieu.[42]

The quality of semen in men with SCI is poor. The changes in the quality of semen are seen as early as 2 weeks after the time of injury.

- Abnormal sperm motility and
- Viability.

These are the distinguishing characteristics of poor quality of semen seen in men with SCI. The sperm count is not abnormal in the majority of the subjects with SCI. The total sperm count was commonly reported to be high (>100 million/mL) in men with SCI, but the motility of the sperm was poor (asthenozoospermia, that is usually <10%) with poor viability.[38,43,44] Although, it was previously thought there could be progressive decline in the spermatozoa number over the years, the spermatozoa number appears to be normal in spinal cord injured patients with regular urological follow up. Brackett et al. reported that there was no difference in the motility, total number, and concentration of spermatozoa in the ejaculate on consideration with time lapsed from the injury.[44] There was no relationship between decline in semen parameters and time post injury.[44] Momen et al. in their study reported that in SCI men, the seminogram is characterized by normal volume (2.3 ± 1.9 mL), normal sperm count ($85 \times 10^6 \pm 83.8 \times 10^6$/mL), decreased motility (11.6% ± 0.1%), decreased vitality (18.5% ± 5.2%), and normal forms (17.5% ± 3.4%) besides increased number of pus cells ($6 \times 10^6 \pm 8.2 \times 10^6$/mL).[38] They also observed that total motility and progressive motility were higher significantly in subjects having lower scrotal temperatures.[38]

Utida et al. observed that sperm motility is abnormal in SCI patients despite the normal spermatozoa number.[45] They reported that these changes are not related to changes in thermal regulation of scrotum, ejaculation frequency, or duration of spinal cord damage but are due to the factors related to seminal plasma. In spite of poor seminal quality, using techniques from simple homologous insemination to sophisticated assisted reproduction techniques, many SCI men have become fathers.[45] Kathiresan et al. observed that motility of the sperm was comparatively higher in men with SCI, who could ejaculate by masturbation compared to those who could not ejaculate by masturbation. This difference could be attributed to the level of completeness of injury.[43] In a follow-up study, it was observed that there was a decline in semen quality starting 16 days after SCI and it was also recommended to store semen within the first 2 weeks after injury for future use.[46]

Semen Quality and Factors Contributing to Poor Semen Quality in SCI

The quality of semen is reported to be normal for 6–10 days after injury. But after a period of 2 weeks from injury, it is reduced to levels as commonly seen in those chronic SCI, typically with reduced viability and abnormal sperm motility.[38,43,44] It was reported that men with SCI capable of ejaculation by masturbation had significantly higher sperm motility on comparison to those with SCI not capable of ejaculation by masturbation.[43] It was also reported that quality of semen collected by masturbation in SCI subjects had significantly lower sperm motility on comparison with normal control subjects without SCI.

The difference in the degrees of dysinnervation to seminal vesicles and prostate glands can result in abnormal constituents to the seminal plasma that are toxic to sperm.[43] The motility of the sperm tends to be higher in cases of incomplete SCI and lesions that are situated above the spinal ejaculation centers.[43]

Poor semen quality in men with SCI seems to be primarily due to post-spermatogenic causes, such as ANS dysfunction, impaired ejaculatory function, abnormal constituents of seminal plasma, dysfunction of the sperm, and type of bladder management.[42]

It has also been reported that around 51% of men with SCI have at least one hormonal abnormality and also

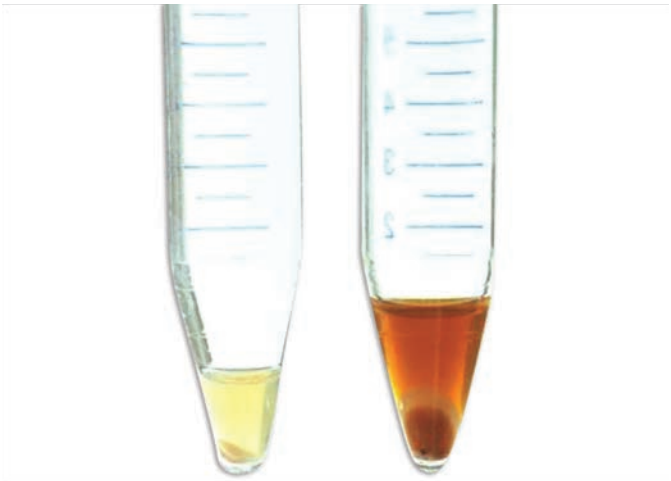


Fig. 7: Semen in spinal cord injury. Left tube shows prostatic fluid, right tube shows brown-colored semen.
Source: Image adapted from Wieder et al. (1999).[47]

that 86% of men with SCI have some abnormality of the hypothalamic-pituitary-testicular axis.[48]

There are multiple theories for the abnormal semen motility in subjects with SCI such as increased scrotal temperature, antisperm antibodies, leukospermia, and seminal plasma proteins and cytokines. The color of the ejaculate also appears to be brown or dark after SCI **(Fig. 7)**.[47] Many factors affecting the quality of semen in SCI are interconnected.

Seminal plasma was observed to be affecting the motility in SCI.[49] Seminal plasma in SCI men is characterized by high number of leukocytes, especially activated T-cells. They can secrete cytotoxic substances and cytokines. It has been reported that spermatogenesis may improve after an initial period of impairment.[50] The evidence is inconsistent regarding short- and long-term hormonal changes seen following SCI in men, which could affect the semen quality.[16] SCI affects multiple organs including testis. Testicular hypofunction and prostate gland dysfunction may also play a role.[51] SCI is a highly inflammatory process. The semen of SCI men was reported to have elevated cytokines and caspases. The factors affecting the semen quality are shown in **Figure 8**.

MANAGEMENT OF COUPLES WITH SCI-RELATED MALE FACTOR INFERTILITY

Most men with SCI are infertile. ED, ejaculatory dysfunction, and semen abnormalities contribute to the problem. Treatments for ED include PDE5 inhibitors, intracavernous injections of alprostadil, intraurethral injections, penile prosthesis, and vacuum constriction devices besides psychosocial counseling.[1] In anejaculatory patients who wish to father children, semen retrieval is necessary. PVS is recommended as the first line of treatment. Patients who fail PVS can be referred for electroejaculation (EEJ). If this

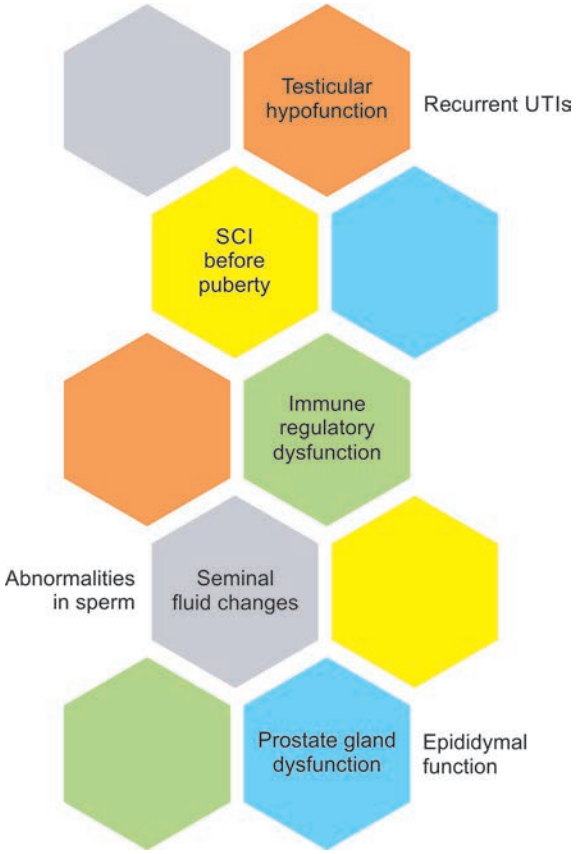

Fig. 8: Factors affecting semen quality in spinal cord injury (SCI). (UTIs: urinary tract infections)

approach is not possible, prostate massage is an alternative. Surgical sperm retrieval should be considered as a last resort when other methods fail. Despite abnormalities, sperm from men with SCI can successfully induce pregnancy. In selected couples, the simple method of intravaginal insemination is a viable option. Another option is intrauterine insemination (IUI). The efficacy of IUI increases as the total motile sperm count inseminated increases. In vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) are options in cases of extremely low total motile sperm count. Reproductive outcomes for SCI male factor infertility are similar to outcomes for general male factor infertility.

Administration of the PDE-5 inhibitors can be used for treating ED, as the vascular mechanism is intact and they help in maintaining erection during sexual activity. In case of inability to obtain a reflexogenic erection or failure of PDE-5 inhibitors to induce sustained erection, more invasive methods may be needed like intracavernous injection of prostaglandins. A combination of prostaglandins, phentolamine, and papaverine can also be tried on them.[52,53] The counseling of patients is essential with regard to side effects. There has been varied patient satisfaction rates and success rates in methods such as intraurethral application of alprostadil and vacuum constriction devices.[54,55] Penile prosthesis can also be surgically implanted as a last resort. Inflatable devices are usually preferred in men with SCI.[56]

Management of Anejaculation in Men with Spinal Cord Injury

Anejaculation occurs due to interference in the afferent or efferent innervation of the seminal vesicles, bladder neck, posterior urethra, or vas deferens after SCI. Treatment to improve dysfunction in the general population can be used to improve ejaculatory dysfunction in men with SCI. There can be disruption of the nerve pathways in SCI for ejaculation. Hence, medical assistance is required to procure sperm for insemination like:

- PVS
- EEJ
- Prostate massage
- Sperm retrieval surgically.

Although SCI patients with injury level above T9 experience frequently some degree of erectile impairment, the most important barrier to fertility in these subjects is complete absence of ejaculatory reflex.[57]

Penile vibratory stimulation is recommended as the first line of treatment for anejaculation in men with SCI.[58] PVS involves placing a vibrator on the dorsum or frenulum of the glans penis.[59] Ejaculation is induced by the ejaculatory reflex and hence it is more effective in men with intact ejaculatory reflex, that is, men with a level of injury T10 or higher. An intact dorsal penile nerve, which terminates in sacral spinal cord segments between S2 and S4, is required for a successful ejaculatory reflex.[60] On comparison with other methods, PVS is safe, cost-effective, and reliable method.[61] The success rate was reported to be 86% in subjects with neurological injury level at T10 or rostral. But one dangerous problem in PVS is the potential for occurrence of autonomic dysreflexia.

Patients who fail this therapy should be referred for EEJ.[24,32] It has a high success rate of 95%. In this procedure, ejaculation is induced by placing the patient in lateral decubitus position, inserting the probe with electrodes into rectum with electrodes facing prostate gland and seminal vesicles.[62,63] Then, electric current is delivered in a pattern of 5 seconds of stimulation followed by rest periods of approximately 20 seconds, during which ejaculation can occur. By this procedure, ejaculation occurs in a dribbling, nonprojectile manner. To retrieve as much semen as possible, the urethra should be milked. The delivery of current is increased in 2-volt increments if there is no ejaculation.[64] Majority of SCI men can undergo EEJ without anesthesia. But it can cause significant discomfort in men with preserved sensation, for whom sedation or general anesthesia may be required. Similar to PVS, it can also cause autonomic dysreflexia.

In *prostate massage*, the seminal vesicles and also the prostate are emptied by a physician by pressing on these structures using a finger inserted into the patient's rectum. It is based on the concept that sperm are stored in the ampulla of the vas deferens and in SCI, they are sequestered also in the seminal vesicles.[65] Hence, it is mechanically pushed out through the ejaculatory ductal system. The yield of sperm is low in prostate massage in comparison with EEJ or PVS. Hence, it is used in countries without access to EEJ, after PVS fails.[66]

Surgical semen retrieval (SSR): This involves retrieval of sperm from reproductive tissue, by aspiration or through surgical exploration. It is done through a variety of techniques such as testicular sperm aspiration, testicular sperm extraction, microepididymal sperm aspiration, percutaneous epididymal sperm aspiration, and aspiration of sperm from the vas deferens.[1,67,68] SSR was developed as a technique for retrieval of sperm from azoospermic men without SCI. But PVS and EEJ were developed to manage and treat anejaculation. SSR should be performed only when PVS or EEJ fail or are not feasible. Because they are less invasive and expensive in comparison with SSR. Also, there is a need for more expensive assisted reproductive techniques such as ICSI, with the use of SSR, as the yield often has low motile sperm count. Use of SSR as the first line of treatment for anejaculation in men with SCI is controversial, when other methods are available. The complications include hematoma, pain, and other risks associated with ICSI through IVF.

Reproductive Options and Outcomes

The options for fertility in male SCI-related infertility include:

- Intravaginal insemination
- IUI
- IVF (in vitro fertilization) or ICSI (intra cytoplasmic sperm injection).

"*In-home insemination*" is the least invasive and least expensive of the assisted reproductive options. It is also called *intravaginal insemination*. The couples should be evaluated at a clinic for determining the optimal method for ejaculation at home, which is effective and safe. The optimal method will be evaluated, and guidelines will be set regarding the number of intravaginal insemination cycles for choosing more advanced methods of assisted conception. Any tubal or uterine pathology should be evaluated for the female partner. She is counseled about timing of insemination and methods to detect ovulation. If semen cannot be ejaculated during intercourse, PVS can be used to collect it and can be deposited into the vagina with the help of a syringe. The success rate has been good at 43% pregnancy rate from a multicentric study.[69]

"*Intrauterine insemination*" involves collecting semen from male partner affected with SCI usually by PVS or EEJ. It is processed to separate sperm from the semen and for isolating motile from the nonmotile sperm. The processed sperm is then placed inside the uterus of the woman. In a study on 121 consecutive couples including 87 couples with SCI male partners, a pregnancy rate of 8.6% per cycle and 32.2% per couple was reported. EEJ was done in combination with assisted reproductive technology (gamete intrafallopian transfer or IVF) in these couples for treatment of anejaculatory

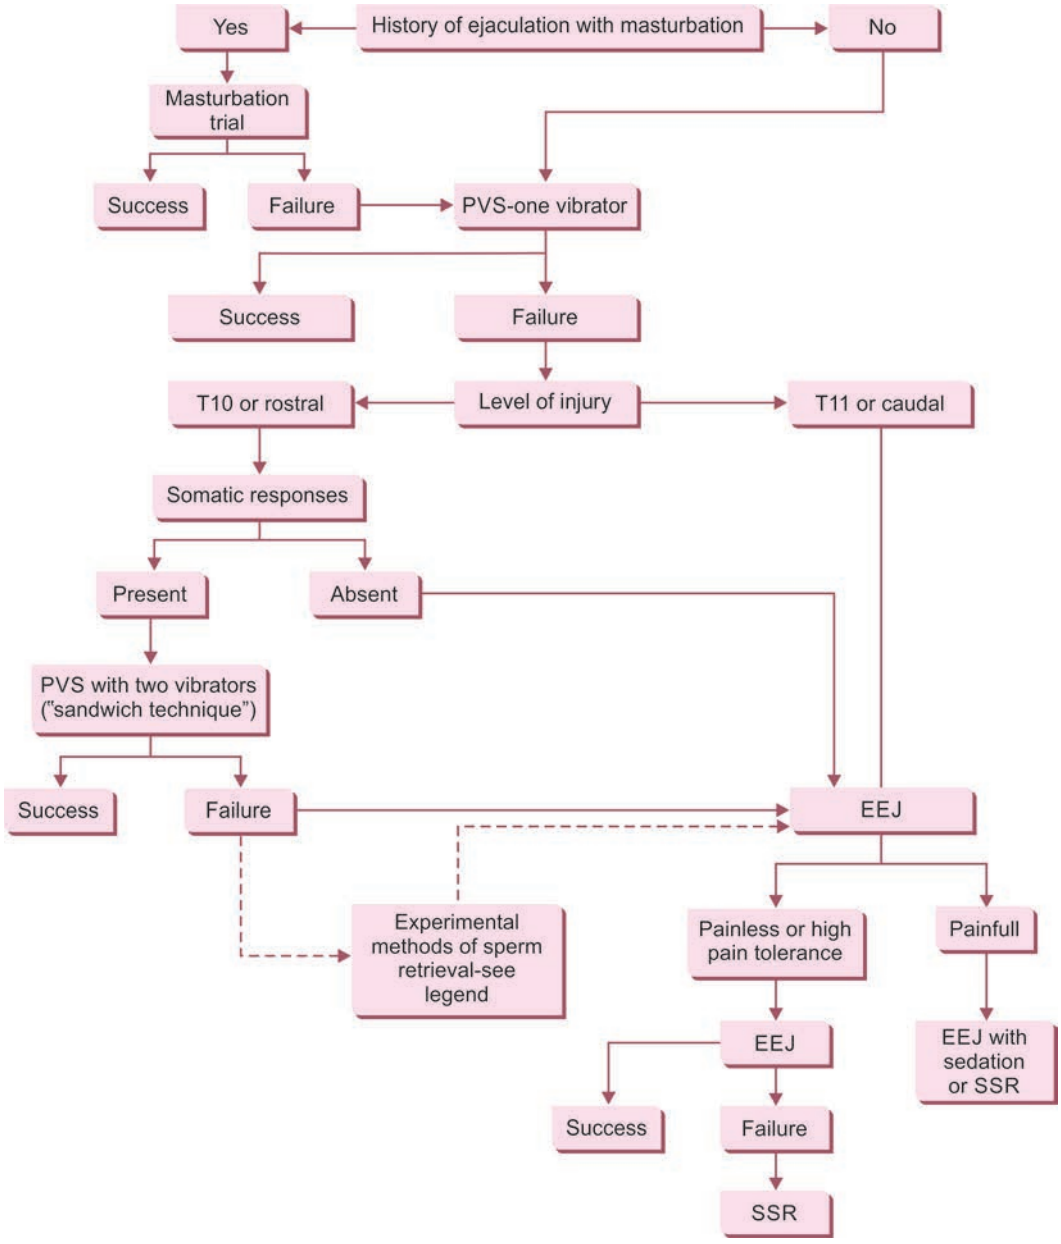
infertility.[66] They also suggested that in couples with total motile sperm count of <4 million, high-level assisted reproductive technologies should be done directly as the pregnancy rates to 1.1% per cycle. They also suggested that around 3–6 cycles of IUI should be attempted before proceeding to IVF. It was also reported that with inseminated total motile sperm counts of >40 million, the pregnancy rate was 17.6% per cycle. IUI warrants consideration before taking up IVF.

Advanced assisted reproductive technology techniques like in vitro fertilization or ICSI are indicated in case of fertilization not being possible or not indicated by IUI. IVF involves placing the sperm retrieved from a man in a laboratory dish with ova retrieved from the woman. This mixture is then incubated for up to 5 days to allow for fertilization of ova. Then high quality embryos reaching blastocyst stage are placed into the uterine cavity.[70] When the number of motile sperm is too low for conventional IVF, the method of ICSI is often used to achieve fertilization. ICSI is a procedure in which a single sperm is injected directly into the egg. IVF and ICSI have been used to achieve pregnancy in couples with male partners with SCI.[71,72]

Semen Retrieval Methods

In men failing pharmacological conversion or who are contradicted to pharmacological conversion, assisted ejaculation may be used to harvest sperm. For men with SCI, who do not respond to medical management of

Flowchart 2: Semen retrieval methods.



(EEJ: electroejaculation; PVS: penile vibratory stimulation; SSR: surgical semen retrieval)

anejaculation, sperm retrieval can be attempted using either PVS or EEJ. If no viable sperm can be retrieved with these methods, surgical sperm retrieval may be performed using microsurgical epididymal sperm aspiration, percutaneous epididymal sperm aspiration, testicular sperm aspiration, or testicular sperm extraction. Postejaculatory harvesting of sperm in the bladder can be done. Urinary sperm retrieval is achieved by alkalinization of urine using oral sodium bicarbonate. It is then catheterized to obtain a postejaculatory urine specimen and then centrifuged. The urine specimen is then resuspended in medium before using it for vaginal or IUI **(Flowchart 2)**.

The effects of sperm freezing were similar in both healthy patients and those with SCT. After thawing the decrease in motility was around 60–80%. Because of inferior seminal quality in SCI patients, there is no clear advantage with routine seminal cryopreservation. But it can be indicated in conditions such as personal wish of the patient, difficulty in transportation of ejaculate, or time constraints for transportation.[73]

Current Issues in Managing Couples with SCI-related Infertility in Men

Assisted conception is possible in couples with SCI in men, whose semen quality is impaired. The infertility treatment methods that are used for the general population can be used on them. But instead, these couples are preempted to surgical sperm retrieval and IVF/ICSI. Main problems faced by the couples are cost and lack of accessible procedures and equipment. In methods like PVS or EEJ, the main obstacles were a lack of equipment and lack of training.[63] IVF/ICSI is more invasive and expensive. In contrast, the ejaculate of men with SCI often has a sufficient number of motile sperm for considering IUI or intravaginal insemination.[63]

CONCLUSION

The majority of individuals with SCI are young men. ED, ejaculatory dysfunction, and semen abnormalities are the major obstacles for fertility in SCI. The treatment of these conditions and assisted reproductive techniques have the same use in SCI-related male infertility in comparison to those men who have infertility without SCI. Atypical semen profile and anejaculation are the main culprits in SCI for infertility. It is typically characterized by normal sperm concentration with low sperm motility and viability besides other factors affecting semen quality like altered seminal plasma. There is not much of a difference in pregnancy outcomes with sperm from SCI men in comparison with non-SCI men.

Penile vibratory stimulation is a safe, cost-effective, and reliable method and should be the first line of treatment for men with SCI. SSR should be performed only when PVS or EEJ fail or are not feasible because they are less invasive and expensive in comparison with SSR. Future research should focus on improving the semen quality in men with SCI and promoting natural ejaculation.

KEY POINTS

- Infertility following SCI in men occurs due to a combination of erectile dysfunction, ejaculatory dysfunction, and semen abnormalities.
- A lot of advances have been made over the years in the field of medical sciences with regard to SCI-related infertility.
- Treatments that are effective in non-SCI male factor infertility are effective for management in couples with SCI male factor infertility.
- Atypical semen profile and anejaculation are the main culprits in SCI for infertility.
- Penile vibratory stimulation is a safe, cost-effective, and reliable method and should be the first line of treatment for men with SCI.
- SSR should be performed only when PVS or EEJ fail or are not feasible.

CHAPTER 32

Algorithms for Genetic Evaluation of Infertile Males

Stacy Colaco, Deepak Modi

INTRODUCTION

Male infertility is most commonly caused by problems in the ejection of semen, absence of sperm or low sperm count, or abnormal shape (morphology) and movement (motility) of the sperm. The causes of male infertility include endocrine defects leading to hypogonadism, primary testicular defects, and post-testicular defects such as the absence of vas deferens. Genetic defects are reported in all forms of male fertility, and more than 200 genetic conditions are associated with male infertility. The genetic defects seen in infertile males are karyotype abnormalities, Y chromosome microdeletions, gene copy number variations, gene duplications, mutations, and polymorphisms. These genetic defects interfere with the development of the male gonads and the urogenital tract, cause degeneration of the germ cells, lead to arrest in spermatogenesis due to faulty meiosis or lead to the production of nonfunctional spermatozoa including defects in the flagella.

Irrespective of their clinical history, infertile men need to undergo genetic testing. Men with nonobstructive azoospermia (NOA) or oligozoospermia will require to undergo karyotyping and Y chromosome microdeletion testing, while for those with obstructive azoospermia cystic fibrosis transmembrane conductance regulator (*CFTR*) gene testing is recommended. Beyond abnormal sperm count, motility, and sperm head morphology defects, a condition termed multiple morphological abnormalities of the sperm flagella (MMAF) has been characterized. Men with MMAF have morphological abnormalities of the flagellum such as coiled, bent, irregular, short, or/and absent flagella. In MMAF, mutations in a set of autosomal genes are reported. Along with mutations in several autosomal genes, gene copy numbers, variations, deletions, and mutations in different autosomal genes and mitochondrial deoxyribonucleic acid (mtDNA) are reported in men with an abnormal seminogram.[1] However, most of these tests are in the research phase, and their applications in a clinical setup are restricted. **Table 1** provides the genetic tests to be offered to infertile males based on semen parameters.

TABLE 1: Genetic tests to be offered to infertile males.

Diagnosis	*Genetic testing to be done*
Nonobstructive azoospermia	Karyotyping and Y chromosome microdeletions
Obstructive azoospermia	CFTR gene mutation
Oligozoospermia	Karyotyping and Y chromosome microdeletions
Azoospermia and oligozoospermia with normal karyotype and no Y chromosome microdeletions	Exome analysis
Multiple morphological abnormalities of the sperm flagella (MMAF)	Panel for DNAH1, CFAP43, CFAP44, and CFAP69 genes or exome analysis
Asthenozoospermia	Exome analysis

(CFTR: cystic fibrosis transmembrane conductance regulator)

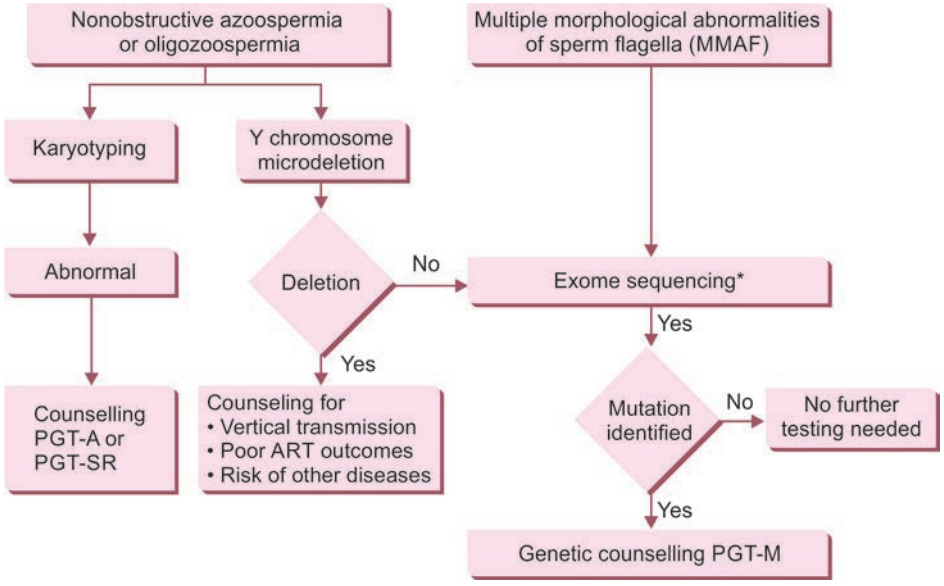
PRACTICAL APPROACH FOR GENETIC TESTING FOR INFERTILE MALES AND ITS APPLICATIONS IN CLINICAL PRACTICE

As per the clinical history and semen parameters, appropriate tests should be offered to infertile men **(Table 1)**. Clinical decisions can be made based on the results of these tests and as per the algorithms described below.

Nonobstructive Azoospermia and Oligozoospermia

Patients with azoospermia (absent or very few sperm in semen) must be thoroughly examined to be classified as obstructive or nonobstructive type. A differential diagnosis of these two conditions requires a thorough clinical examination of the presence or absence of vas deferens (see below). Along with clinical examination, serum follicle-stimulating hormone (FSH) is elevated in a subset of men with

Flowchart 1: Algorithm for genetic testing in men with nonobstructive azoospermia, oligozoopsermia, multiple morphological abnormalities of sperm flagella (MMAF).



Mutations, *Still in research phase

(PGT-M: preimplantation genetic testing for mutations; PGT-A: preimplantation genetic testing for aneuploidies; PGT-SR: preimplantation genetic testing for structural rearrangements; ART: assisted reproductive technologies)

NOA and can be used as a guiding tool. However, not all men with NOA will have elevated FSH, and clinical examination is the only reliable method of diagnosis. Once the diagnosis of NOA or oligozoospermia is established, karyotyping and Y chromosome microdeletion testing are recommended. The algorithm for the same is given in **Flowchart 1**.

About 10–15% of men with NOA or oligozoospermia will have karyotype abnormalities. These will include mosaic or nonmosaic 47,XXY karyotype (Klinefelter syndrome), 45,X/46,XY mosaic, and 46,XX syndrome (de la Chapelle syndrome). Structural abnormalities include Robertsonian translocations, inversions, ring Y, truncated Y, or isodicentric Y. It must be remembered that polymorphic variants of certain chromosomes (commonly chromosomes 1, 9, 16, or Y) are often reported in karyotyping; these should be considered as normal variations and should not be considered as a genetic cause. A geneticist must be consulted to understand the prognosis and decide the course of action. Except in the case of 46,XX phenotypic males, there is a good possibility of obtaining sperm after testicular sperm aspiration (TESA). These sperm can be used in intracytoplasmic sperm injection (ICSI); however, the success rates of ICSI are quite low. TESA need not be performed in XX males as there is no chance of even focal spermatogenesis due to the absence of any of the genes required for spermatogenesis.

In couples where karyotype abnormalities are detected, a proportion of embryos are aneuploid and will result in implantation failure or miscarriage. In such couples, preimplantation genetic testing (PGT) for aneuploidy (PGT-A) or PGT for structural rearrangements (PGT-SR) is recommended to identify euploid embryos **(Flowchart 1)**. This should increase the chance of a successful pregnancy.

The European Academy of Andrology (EAA), American Society for Reproductive Medicine (ASRM), and Indian Council of Medical Research (ICMR) recommend testing for the Y chromosome microdeletions in all men with NOA and oligozoospermia. The Y chromosome microdeletions cannot be identified by standard karyotyping methods and need polymerase chain reaction (PCR) techniques. These microdeletions cause the removal of one or more azoospermia factor (AZF) loci on the long arm of the Y chromosome. There are three AZF loci on the Y chromosome, namely AZFa, AZFb, and AZFc. These loci are rich in genes required for spermatogenesis, and deletions in these regions cause azoospermia or oligozoospermia.[2] Another type of microdeletion called the AZFc sub-deletions, i.e., gr/gr, b1/b3, and b2/b3, are also associated with infertility. In the Indian population, the gr/gr deletions are found at a higher frequency in infertile males,[2,3] and hence, testing for gr/gr deletion as a part of Y chromosome microdeletions testing is imperative.

Y chromosome microdeletion testing is done by PCR and it requires a panel of sequence-tagged site (STS) markers to be used for accurate diagnosis. However, different laboratories use different numbers and types of STS markers. It must be borne in mind that the STS markers recommended by the EAA are not sufficient in all populations and there are reports of misdiagnosis.[4] Hence, clinicians must insist on Y chromosome microdeletion testing using the appropriate markers for their population.

The results of the Y chromosome microdeletion testing should aid clinicians in deciding management modalities, deciding to offer assisted reproduction, appropriate counseling, and predicting future risks of other diseases.[2,5]

Deciding Management Modalities

Various treatment modalities such as hormonal therapies and/or antioxidant supplementation, lifestyle changes, or surgery to treat varicocele are offered to men with low sperm count and motility in order to improve the seminogram. Although some men (mainly with oligozoospermia) show a marked improvement in semen quality, men with Y chromosome microdeletions will not respond to such treatment. Therefore, men with Y chromosome microdeletions should not be subjected to medical treatments to improve sperm count and motility.

Decision to Offer Assisted Reproduction

In general, men with AZFa and AZFb deletions will rarely have sperm in their testis, while AZFc-deleted men would have hypospermatogenesis.[4] Thus, TESA may be avoided in men with AZFa or AZFb microdeletions. In men with AZFc deletions, there is a good chance of focal spermatogenesis, and hence TESA can be considered for biological parenthood.

However, irrespective of the type of microdeletions, the embryos derived from sperm of men with Y chromosome microdeletions are poor in quality and have impaired blastocyst rate and result in lower overall success of assisted reproductive technology (ART).[2,3] Thus, patients with Y chromosome microdeletions must be appropriately counseled about the low success rates.

Counseling for Vertical Transmission of the Genetic Defects in the Family and Perpetuating Infertility

While men with Y chromosome microdeletions (especially AZFc deletion) can father a child via ICSI, all male offspring will inherit the paternal deletion and, in turn, will also be infertile. Thus, in men with Y chromosome microdeletion, the couple and the clinician must make an informed choice of having biological parenthood at the risk of perpetuating infertility in the family.

Risk of Other Diseases

With increased biomedical research, the role of the Y chromosome beyond the regulation of fertility is emerging. Studies show that the presence of Y chromosome microdeletions predisposes men to the development of testicular germ cell tumors.[2] Other studies have described instances where men with Y chromosome microdeletions have mild to severe neuropsychiatric disorders with increasing age.[5] The loss of the Y chromosome is associated with a spectrum of disorders such as the increased risk of heart failure, age-related macular degeneration,[6] and colorectal/prostate cancer.[6-8] Although these reports are preliminary, genetic counseling may be offered and regular checkups can be recommended for timely diagnosis of these life-threatening conditions.

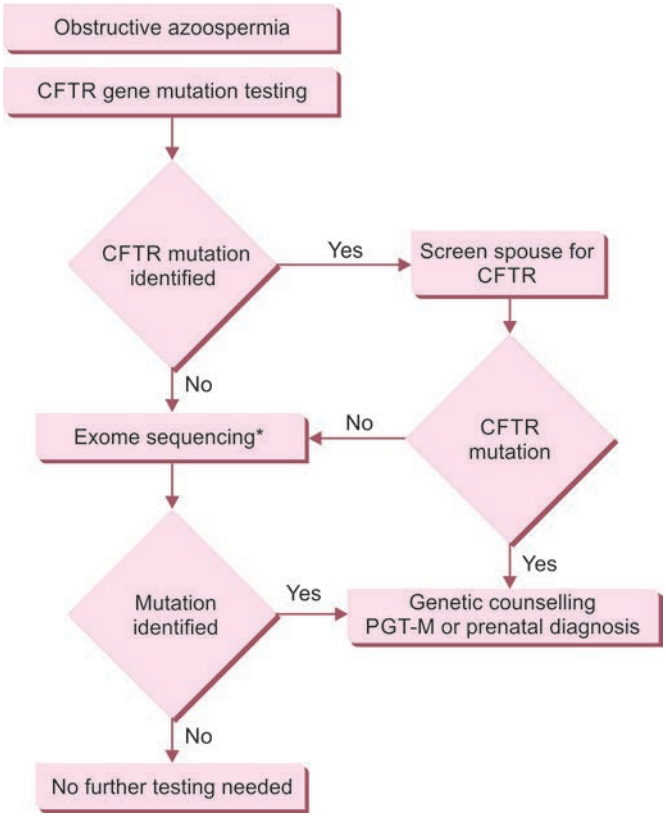
Beyond karyotype and Y chromosome microdeletions, men with azoospermia and oligozoospermia have mutations in other autosomal genes, X chromosome genes, and in the mitochondrial genome.[1,9] Testing for these requires specific technologies such as exome sequencing or mtDNA sequencing to identify defects. While data from studies exploring these conditions look promising, the involvement is at best associative and the cause–effect relation is yet not conclusively established in most cases. Hence, these tests are not recommended to be offered routinely in a clinical setup but may be considered in research/academic applications.

Obstructive Azoospermia

Men with obstructive azoospermia have blocked flow in the male ductal system due to absence of vas deferens but have normal spermatogenesis. There are five phenotypes associated with obstructive azoospermia. These include (1) congenital bilateral absence of the vas deferens (CBAVD) with normal kidneys, (2) CBAVD with unilateral renal anomalies (CBAVD-URA), (3) congenital unilateral absence of the vas deferens (CUAVD), (4) CUAVD-URA, and (5) CBAVD/CUAVD with ejaculatory duct obstruction.[1] For differential diagnosis of obstructive and NOA, the presence of the vas deferens and the characteristics of the epididymis should always be determined. Patients with NOA typically have palpable vasa deferentia and flat and firm epididymis, whereas in obstructive azoospermia, the vasa is non-palpable and the epididymis is soft. As CBAVD may occur concurrent to unilateral renal agenesis, these men should undergo an ultrasound scan to uncover this potentially health-threatening condition. In contrast, most patients (~60%) with CUAVD are nonazoospermic. The algorithm to be followed for men with obstructive azoospermia is shown in **Flowchart 2**.

CFTR gene mutations are observed in 60–70% of men with CBAVD.[10] These are also detected in patients with cystic fibrosis; however, 30–40% of cases may have a genetic etiology other than *CFTR*. Two types of *CFTR* mutations are reported in men with CBAVD: the severe mutations that result in absence/inadequate amount or poorly functional *CFTR* protein and the mild mutations where a CFTR protein with sufficient residual *CFTR* activity is produced. If a patient has two severe mutations, he will have cystic fibrosis. Almost 90% of men with CBAVD have one mild and one severe *CFTR* mutation, while two mild *CFTR* mutations are reported in 10% of cases with CBAVD. F508del *CFTR* gene mutation is the most commonly reported defect in Caucasian men with CBAVD, while IVS-9 c.1210-12 is a commonly reported

Flowchart 2: Algorithm for genetic testing in men with obstructive azoospermia.



*Still in research phase
(PGT-M: preimplantation genetic testing for mutations; CFTR: cystic fibrosis transmembrane conductance regulator)

CFTR variant in non-Caucasian men with CBAVD.[10] Several other mutations are also observed in the *CFTR* gene, and there is a need for sequencing the entire gene and not just screening for the frequently reported mutations. In CBAVD men without *CFTR* gene mutations, pathogenic variants in the *ADGRG2*, *PANK2*, *SCNN1B*, and *CA12* genes are reported.[11] The functional significance of these mutations or how these genes cause CBAVD is yet not understood, and hence testing for these mutations is not applied in routine clinical use.

In men with *CFTR* gene mutation, there is active spermatogenesis and good-quality sperm can be retrieved. Thus, TESA–ICSI can be offered for biological parenthood in men with CBAVD. While having the mutation in the male partner alone will have no consequence, if the female partner is also a carrier for *CFTR* gene mutations (females are usually phenotypically silent), there is a high-risk cystic fibrosis in the offspring. Thus, it is mandatory that testing for the *CFTR* gene be performed on the female partner as well in such couples. If the female partner is a carrier for *CFTR* gene mutation, the couple should be counseled for the possible occurrence of CBAVD and cystic fibrosis in the offspring.

In the event of both partners having *CFTR* gene mutations, prenatal diagnosis or preimplantation genetic testing for monogenic disease (PGT-M) should be offered to prevent the birth of a child with cystic fibrosis. However, if the female partner has a normal *CFTR* gene, embryonic/prenatal testing is not mandatory. In the event of *CFTR* gene mutations not being identified, the couple may be tested via exome sequencing to identify rare mutations and appropriate genetic counseling followed by PGT-M may be offered in such cases **(Flowchart 2)**. Exome analysis in men with obstructive azoospermia is still in the research phase and must be applied with caution.

MULTIPLE MORPHOLOGICAL ABNORMALITIES OF THE SPERM FLAGELLA

Multiple morphological abnormalities of the sperm flagella are diagnosed in a semen sample as total asthenozoospermia with different sperm flagellar anomalies. These anomalies may be absent, short, irregular shaped, and/or angulated flagella. The current World Health Organization manual does not provide any classification for MMAF based on semen analyses, and hence MMAF will not be obtained in a diagnostic report. However, such patients are very likely to have genetic defects. The algorithm to be followed in men with MMAF is shown in **Flowchart 1**.

With the advent of the whole exome and genome analysis, mutations in many genes associated with flagella development or functions have been identified. In men with MMAF, mutations in the *DNAH1*, *CFAP43*, *CFAP44*, and *CFAP69* genes have been reported.[12] Presently, the detection of these mutations requires whole-exome sequencing and this is not feasible in a clinical laboratory. A network of molecular genetic laboratories and counselors will be required to offer genetic screening for MMAF in infertile males. However, it must be remembered that these genes account for only 30% of patients with MMAF and the cause in others is still unknown.

As men with MMAF have impaired sperm motility, medicinal therapies will not improve semen parameters making ICSI the only treatment option. There are limited reports on ICSI outcomes of men with MMAF. In general, in men with MMAF, rather than using immotile ejaculated sperm, testicular sperm is recommended for ICSI. The outcomes of ICSI suggest that the fertilization rates are relatively low (40–75%) and clinical pregnancy rates are almost 50%.[13] Thus, males with MMAF resulting from genetic defects are likely to experience disappointing outcomes in assisted reproduction.

In men with MMAF, mutations occur in the autosomal genes that are also functional in other tissues where ciliary/flagellar activity is required (like lungs and brain); there is a risk of the development of other defects apart from the sperm morphological defects. To date, there is no information on the health outcomes of offspring of men with MMAF due to genetic defects. Therefore, genetic counseling

and PGT-M are a must for MMAF patients when ICSI is utilized **(Flowchart 1)**. However, the utility of gene mutation testing in MMAF is in its infancy, and extensive research in different populations is required to decide on its routine clinical use.

CONCLUSION

With a clear-cut cause–effect relationship between impaired spermatogenesis and abnormal karyotype or Y chromosome microdeletions, their testing is mandatory in clinical practice. The detection of *CFTR* mutations is recommended in men with obstructive azoospermia. These tests will not only allow the determination of the exact cause of male infertility but also aid in predicting the success rates of ART and offering PGT. Further, the infertile couples need to be aware that they will transmit their genetic defect to their future generations and may additionally also perpetuate other diseases along with infertility. With the proper implementation of androgenetic, the clinician and the patients will be able to decide on the appropriate and timely management of infertility.

Female Factor Infertility

CHAPTER 33

Uterine Factors in Infertility

Mala Arora, Mahesh Koregol, Soumya Mahesh Koregol, Navya N

INTRODUCTION

Around 1 in 500 reproductive age women is affected by uterine factor infertility (UFI).[1,2] Success in assisted reproductive techniques (ART) cycle involves transferring a good quality embryo atraumatically at the right time into a receptive endometrium for implantation. A healthy uterus is crucial in allowing a woman to achieve pregnancy and carry it to term successfully. Any structural and functional abnormalities of the uterus will affect success rates of both spontaneous and ART conception. When a patient first presents for evaluation of infertility, the uterine factors have to be assessed. Uterine factors encountered can be congenital or acquired. In this chapter we shall elaborate on the following conditions of the uterus:

- Congenital uterine anomalies (CUAs)/Müllerian anomalies
- Myomas
- Adenomyosis
- Intrauterine adhesions or polyps or foreign bodies
- Chronic endometritis (CE).

CONGENITAL UTERINE ANOMALIES

Congenital anomalies of the female reproductive tract may involve uterus, cervix, fallopian tubes, or vagina.[3] Cruveilhier and von Rokitansky first described uterine anomalies in the 1800s.[4] The prevalence of CUAs in general population is around 4.3–6.7% while the prevalence in the infertile population is around 3–13%. In patients with recurrent miscarriages, the CUAs are as high as 12.6–18.2%.[5] As reproductive medicine specialists, we are more likely to encounter not only infertile population but also those with recurrent first and second trimester losses. Therefore, we should have a high suspicion when assessing our cohort of patients right from the initial evaluation. It is prudent to make an accurate diagnosis as each anomaly has differing reproductive outcomes and treatment approaches.[5] Karyotypes are normal (46XX) in majority (92%) of women with Müllerian anomalies and abnormal in 7.7% of these women.[6,7]

Embryology of the Female Reproductive Tract and Etiology of Müllerian Anomalies

The development of the female gonads and the Müllerian system are separate processes. Women with Müllerian developmental anomalies will often have normal functioning ovaries and female hormones. The uterus and the fallopian tubes are developmentally derived from the paramesonephric (Müllerian) ducts, which arise lateral to the mesonephric (Wolffian) ducts from the coelomic epithelium of the urogenital ridge **(Fig. 1)**. This begins at around seventh week of intrauterine development. The paramesonephric ducts grow downward across the mesonephric duct to fuse in the midline to form the uterovaginal canal. The lower end of the uterovaginal canal connects with the urogenital sinus. Finally, the fused Müllerian ducts are canalized internally forming two channels separated by a septum. This septum is resorbed around 20 weeks in a caudal toward the cephalad direction. The uterus and the upper vagina are derived from the caudal portion of the Müllerian ducts. The upper portion becomes the fallopian tubes. The lower vagina is derived from the urogenital sinus and the sinovaginal bulb.[3]

Normal development of the Müllerian ducts depends on the completion of three phases:

- Organogenesis
- Fusion
- Septal resorption

Organogenesis leads to the formation of both Müllerian ducts. Failure of this results in uterine agenesis or hypoplasia

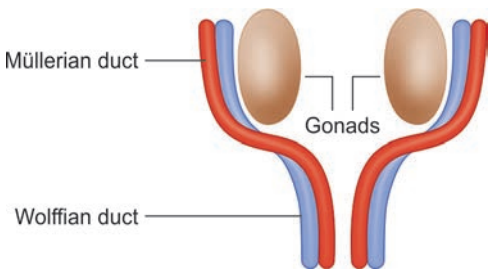

Fig. 1: Embryology of the female reproductive duct.

or a unicornuate uterus. Fusion of the ducts leads to formation of the normal uterus. Failure of this results in a bicornuate or didelphic uterus. Septal resorption defects result in a septate or arcuate uterus.[8] The etiology behind this failure is unknown and there have been no genetic linkages identified.[9]

Classification of Congenital Uterine Anomalies

Classification plays an important role in communicating diagnoses between clinicians (gynecologists, radiologists, etc.) and their patients. The very recent American Society of Reproductive Medicine (ASRM) 2021 and the European Society of Human Reproduction and Endocrinology/ European Society of Gynecological Endoscopy (ESHRE/ ESGE) consensus[9] (CONUTA—CONgenital UTerine Anomalies) classification 2013 (reaffirmed in 2016) are the two most important classifications currently.

American Society of Reproductive Medicine Müllerian Anomalies Classification 2021 (also referred to as MAC 2021)—What is New in This Classification?[10]

The old American Fertility Society (AFS) classification was only for the uterine anomalies, but this new one added the cervical and vaginal anomalies. The old AFS classification was no definite criteria whereas this new one has added clear measurements for each subtype type. The old one is not suitable for complex anomalies but the new one is suitable. Unlike the AFS classification, anomaly categories are no longer numbered but instead are identified by descriptive terminology **(Box 1 and Fig. 2)**.

ESHRE/ESGE Classification System (2013, 2016)

European Society of Human Reproduction and Endocrinology/ European Society of Gynecological Endoscopy classifies female genital tract anomalies into the main classification for the uterine body (U) and supplemental classification for the cervix (C) and vagina (V).

The schematic and the diagrammatic representations of the classifications have been discussed in **Figures 3 to 5**.

So there are several thoughts from the various international societies regarding the classification of Müllerian anomalies. However, which of these methods is better is a moot point. Ludwin et al.[11] were of the opinion that application of the CONUTA classification leads to unnecessary overdiagnosis of septate uterus which will be elaborated later in the chapter.

BOX 1: American Society of Reproductive Medicine (ASRM) classification of mullerian anomalies 2021.

- Müllerian agenesis
- Cervical agenesis
- Unicornuate uterus
- Uterus didelphys
- Bicornuate uterus
- Septate uterus
- Longitudinal vaginal septum
- Transverse vaginal septum
- Complex anomalies

Clinical Presentation and Diagnostic Modalities

Most women are asymptomatic. Women may present with cyclic or noncyclic pelvic pain and dysmenorrhea suggestive of an obstructive anomaly, retrograde menstruation, and endometriosis.[9] Patients may present with primary amenorrhea as in the case of Müllerian agenesis or Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome which involves congenital absence of the uterus and vagina (ASRM-Müllerian agenesis, CONUTA-U5b). Patients with septate uterus and uterus didelphys may present with abnormal uterine bleeding (AUB) because of the increased surface area of the endometrium and also in a longitudinal vaginal septum when only one tampon is used while two are required because of the two separate tracks. Endometriosis are more common in patients with congenital anomalies probably due to obstruction and retrograde menstruation which may also lead to infertility.[12]

Hysterosalpingography (HSG) helps in the assessment of uterine cavities and tubes, but it is limited by the nonvisualization of the external contour of the uterus.[13] The gold standard diagnostic modality for CUA is magnetic resonance imaging (MRI). 3D ultrasonography (USG), being noninvasive and better than 2D USG, has the potential to surpass MRI.[14,15]

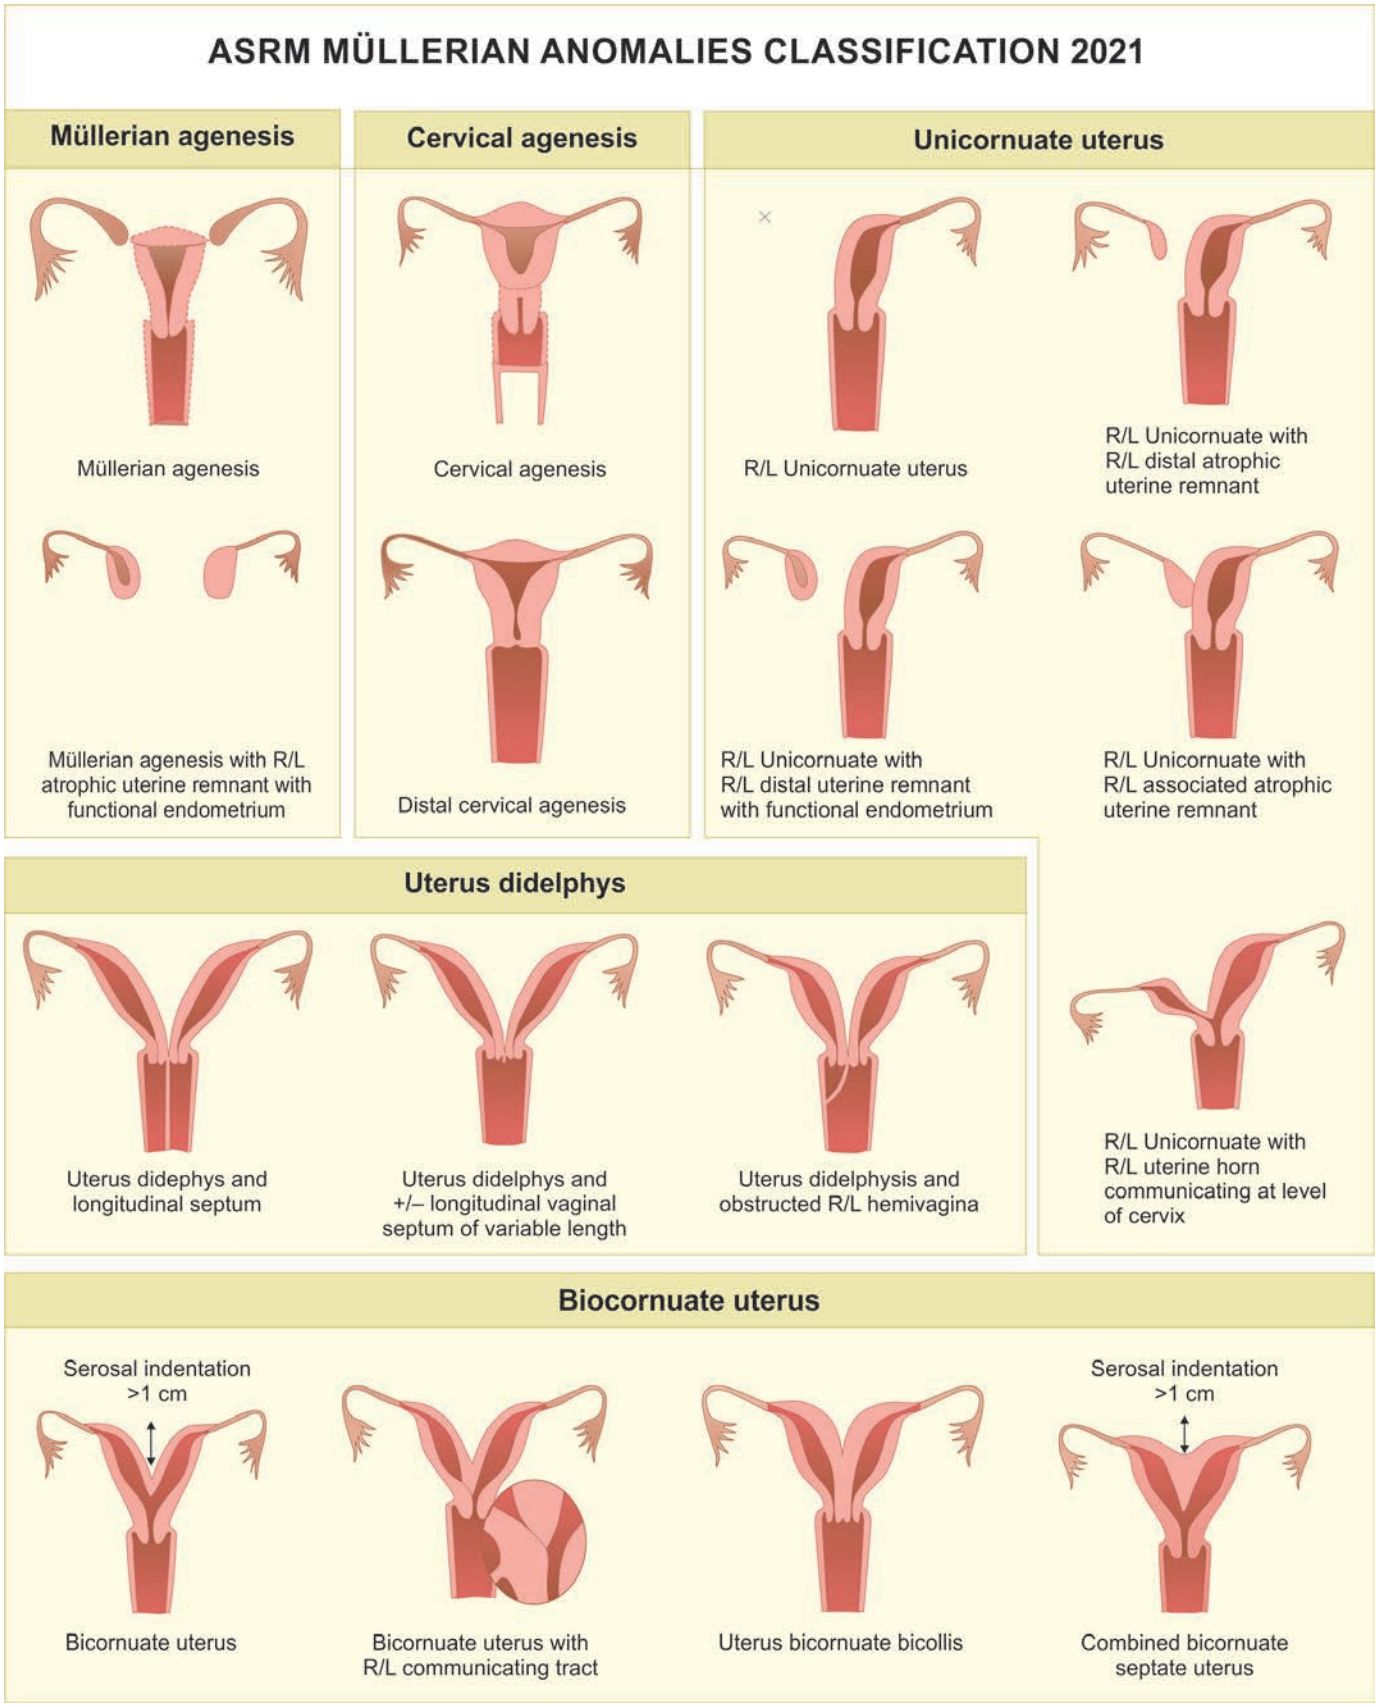
Reproductive Outcomes

In an elaborate systematic review and meta-analysis, Venetis et al.[6] concluded that the presence of CUA is associated with a decreased, albeit not significantly so, probability of pregnancy achievement both in natural and ART cycles.

Women with a septated or bicornuate uterus had a higher probability of spontaneous miscarriage even in the first trimester, whereas in women with arcuate, didelphys, and unicornuate uterus the effect on reproduction is small and not statistically significant. Women with CUA are at increased risk of preterm birth and second trimester losses, which are the hallmark of all types of CUA. The implantation failure, spontaneous abortion, and impaired obstetrical outcome could be due to impaired vascularization of the endometrium, abnormal uterine contractility, and decreased uterine volume.[6]

Management

Management of the CUA depends on the type of the abnormality present and the obstetric goals of a patient. **Table 1** summarizes the treatment approach.[5]



ASRM MÜLLERIAN ANOMALIES CLASSIFICATION 2021
Müllerian agenesis
Müllerian agenesis
Müllerian agenesis with R/L atrophic uterine remnant with functional endometrium
Cervical agenesis
Cervical agenesis
Distal cervical agenesis
Unicornuate uterus
R/L Unicornuate uterus
R/L Unicornuate with R/L distal atrophic uterine remnant
R/L Unicornuate with R/L distal uterine remnant with functional endometrium
R/L Unicornuate with R/L associated atrophic uterine remnant
Uterus didelphys
Uterus didephys and longitudinal septum
Uterus didelphys and +/– longitudinal vaginal septum of variable length
Uterus didelphysis and obstructed R/L hemivagina
R/L Unicornuate with R/L uterine horn communicating at level of cervix
Biocornuate uterus
Serosal indentation >1 cm
Bicornuate uterus
Bicornuate uterus with R/L communicating tract
Uterus bicornuate bicollis
Serosal indentation >1 cm
Combined bicornuate septate uterus

ESHRE/ESGE classification
Female genital tract anomalies

Name Birth Date:

Diagnostic Method:

	Uterine anomaly		Cervical/vaginal anomaly
	Main class	*Sub-class*	*Co-existent class*
U0	Normal uterus		
U1	Dysmorphic uterus	a. T-shaped b. Infantilis c. Others	
U2	Septate uterus	a. Partial b. Complete	
U3	Bicorporeal uterus	a. Partial b. Complete c. Bicorporeal septate	
U4	Hemi-uterus	a. With rudimentary cavity (communicating or not horn) b. Without rudimentary cavity (horn without cavity/no horn)	
U5	Aplastic	a. With rudimentary cavity (bi- or unilateral horn) b. Without rudimentary cavity (bi- or unilateral uterine remnants/aplasia)	
U6	Unclassified malformations		
U			*C* *V*

C0	*Normal cervix*
C1	*Septate cervix*
C2	*Double 'normal' cervix*
C3	*Unilateral cervical aplasia*
C4	*Cervical aplasia*
V0	*Normal vagina*
V1	*Longitudinal non-obstructing vaginal septum*
V2	*Longitudinal obstructing vaginal septum*
V3	*Transverse vaginal septum and/or imperforate hymen*
V4	*Vaginal aplasia*

Associated anomalies of non-Müllerian origin:

Fig. 3: Classification of female genital tract anomalies.

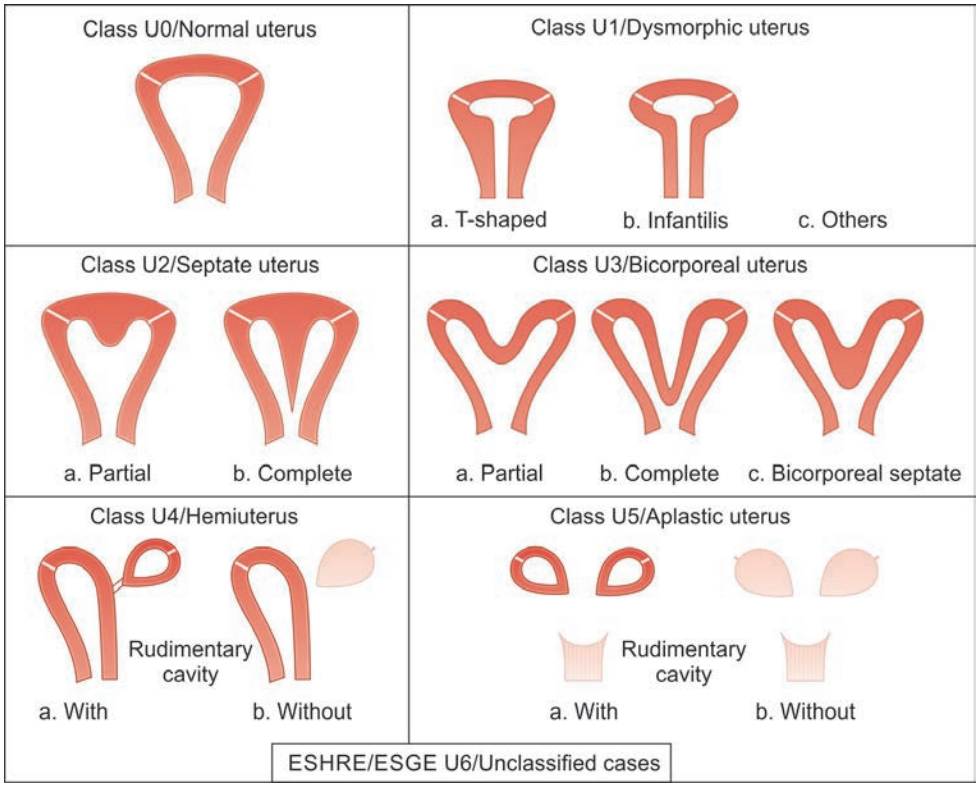

Fig. 4: European Society of Human Reproduction and Endocrinology/European Society of Gynecological Endoscopy (ESHRE/ESGE) classes of female genital tract anomalies.

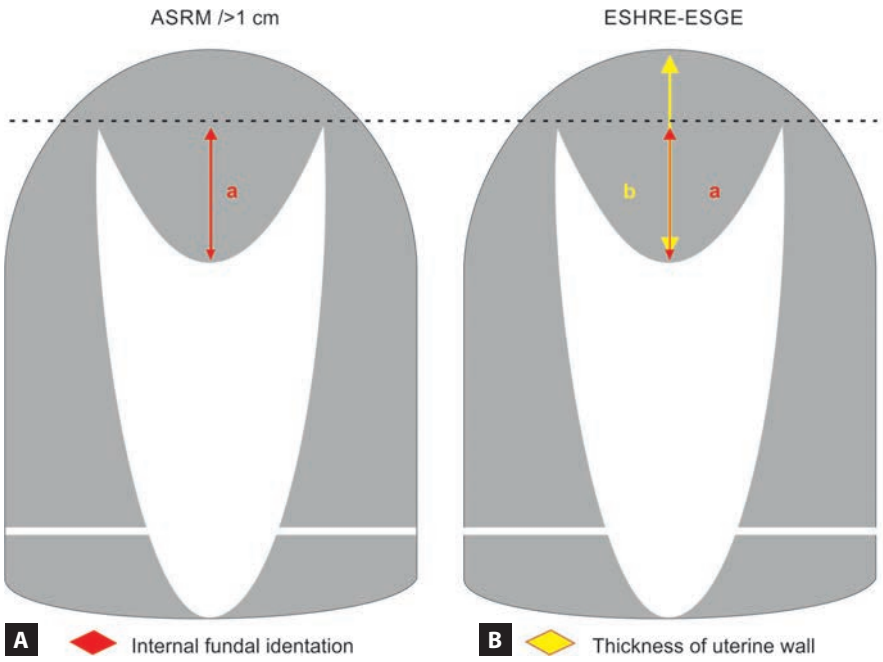


Figs. 5A and B: (A) American Society for Reproductive Medicine (ASRM) recommended considering a uterus as septate when there is both an indentation depth >10 mm and an indentation angle <90°, while a normal/arcuate uterus should have both an indentation depth <10 mm and an indentation angle >90°, and a uterus that does not fit these criteria would be left in an unclassifiable 'gray-zone'; (B) European Society for Gynecological Endoscopy (ESGE) recommended using an indentation-to-wall-thickness (I:WT) ratio >50% to diagnose septate uterus. Over diagnosis of uterine septum (50% of the septum is 4–5 mm if the myometrial wall thickness for example is 8 mm so if you measure the internal fundal indentaion more than 4 mm it will be considered as septum by the ESHRE/ESGE classfication.
(ASRM: American Society of Reproductive Medicine; ESHRE-ESGE: European Society of Human Reproduction and Endocrinology-European Society of Gynecological Endoscopy)

TABLE 1: Management of congenital uterine anomalies.

	Management
Müllerian agenesis	In vitro fertilization (IVF) of harvested ova and surrogacy
Unicornuate uterus: • Noncommunicating, cavitary horn • Noncommunicating, noncavitary horn • Communicating, cavitary horn • No horn	1. Always surgically resected, as it is associated with dysmenorrhea, hematometra, endometriosis, and ectopic pregnancy. 2. Surgery not currently recommended. No complications of endometriosis, etc., as there is no endometrium. 3. Also, surgically removed because pregnancy that implants in the rudimentary horn rarely is viable. 4. No treatment. Reproductive potential is possible.
Uterus didelphys	May consider metroplasty; however not usually advised, full term pregnancies have occurred
Bicornuate	Surgical intervention rarely needed; may consider metroplasty

In case of MRKH syndrome, apart from the fertility management, one has to consider the restoration of the vaginal anatomy and sexual function on priority. Emphasis should be placed here about the need for psycho-socio-sexual counseling, especially in cases of complete Müllerian agenesis.[16]

Mayer–Rokitansky–Küster–Hauser Syndrome

Serial Frank's dilators can be used for the creation of the neovagina without any surgery. The self-dilation to create a neovagina involves patients manually placing successive dilators on the vaginal dimple for 30 minutes to 2 hours per day. Alternatively, a bicycle seat stool can provide perineal pressure while allowing the patient to participate in other activities. A number of surgical techniques can be used to create a neovagina. The modified Abbè–McIndoe operation is the most common surgical procedure used to create a neovagina. This procedure involves the dissection of a space between the rectum and bladder, placement of a mold covered with a split-thickness skin graft into the space, and the diligent use of vaginal dilation postoperatively.[16] The laparoscopic Vecchietti procedure is a modification of the open technique where a neovagina is created using continuous dilation with an external traction device that is temporarily affixed to the abdominal wall.[17,18]

Use of a syringe mold with a split skin graft over the mold ensures patency of the passage.[18] Laparoscopic creation of a neovagina using an ileal loop has the advantage of providing adequate lubrication which is absent with the skin graft.[19]

Around 75–90% cases of a *bicornuate uterus* with rudimentary horn are noncommunicating. Literature suggests the need to remove the rudimentary horn through a laparoscopic approach.[20,21]

Bicornuate Uterus

When both the horns are equal in size and well developed, no further treatment is required. Most often one horn may be rudimentary and underdeveloped and the other of normal size. In such a scenario, conception is encouraged in the larger horn both at the time of ovarian stimulation and intrauterine insemination as well as embryo transfers. Another option is to place an intrauterine contraceptive device (IUCD) in the rudimentary horn to discourage implantation and subsequent pregnancy loss.[22]

In the event of a noncommunicating horn presenting as hematometra or pregnancy, evacuation of the horn should be followed by unification procedure or excision of that horn, whichever is feasible. Laparoscopic metroplasty is performed for recurrent poor reproductive outcomes.[23]

Septate Uterus

Diagnosis: The diagnosis depends on visualization of the external and internal contour of the uterus. The best diagnostic tool should be noninvasive, accurate, and inexpensive, and can evaluate the external and internal contour at the same time. HSG and hysteroscopy for example can evaluate the internal contour only. Laparoscopy can evaluate the external contour only. Combined laparoscopy and hysteroscopy can evaluate the external and internal contour but it is invasive and expensive.

Evaluation by 2D transvaginal ultrasound specially in the transverse plane with movement up and down from the fundus to the cervix can be used as a screening tool but not a diagnostic tool. Both MRI and 3DUS are adequate modalities for diagnosing women with Müllerian duct anomalies (MDAs) in trained hands. However, 3DUS is more sensitive and specific than MRI in categorizing some specific types of MDAs. The high sensitivity, specificity, and convenience of 3DUS makes it an ideal tool for identifying women with uterine anomalies. Hence, three-dimensional sonography has become the gold standard tool for the diagnosis of CUAs.

Uterine Septum

The ASRM 2021 criteria for diagnosis of the septum:[10] This new classification has changed the criteria for diagnosis of uterine septum from 1.5 cm in the ASRM guideline 2016 into more than 1 cm in the new 2021 classification **(Figs. 5A and B)**. ESGE recommended using an indentation-to-wall-thickness (I:WT) ratio >50% to diagnose septate uterus.[11] This may result in over diagnosis of uterine septum (50% of the septum is 4–5 mm if the myometrial wall thickness for example is 8 mm). So if you measure the internal fundal indentation >4 mm it will be considered as septum by the ESHRE/ESGE classification **(Figs. 5A and B)**. This is considered a limitation of the ESHRE/ESGE classification of uterine septum.[24]

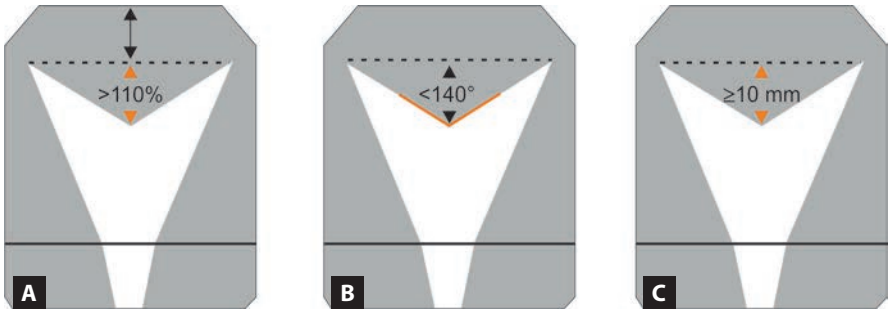
Congenital Uterine Malformation by Experts (CUME) **(Figs. 6A to C)**: For compiling a better criterion for distinguishing between normal/arcuate and septate uterus the following has been proposed:

- Indentation depth ≥10 mm
- Indentation angle <140°
- I:WT ratio >110%

They suggest using internal indentation depth ≥10 mm to distinguish between a normal/arcuate and a septate uterus, because it is the simplest and most reliable measurement of these three.[24]

Management: Incidentally diagnosed: treatment for incidentally diagnosed septum in infertile women is debatable and unproven [Royal College of Obstetricians and Gynaecologists (RCOG) Scientific Impact Paper November, 2019].

Uterine septum and miscarriage: This is what is mentioned in the ASRM 2016, ESHRE 2017, and RCOG 2019.



Figs. 6A to C: Congenital Uterine Malformation by Experts (CUME): Better criteria for distinguishing between normal/arcuateand septate uterus? The criteria are: (A) I:WT ratio >110%; (B) indentation angle <140°; (C) indentation depth ≥10 mm.
They suggest using internal indentation depth ≥10 mm to distinguish between a normal/arcuate and a septate uterus, because it is the simplest and most reliable measurement of these three.

A meta-analysis evaluated the effect of CUAs on reproductive outcomes and found that septate uterus was noted to have a higher rate of first-trimester miscarriage when compared with controls [relative risk (RR): 2.65, 95% confidence interval (CI): 1.39–5.06]. ASRM guideline 2016 stated that there is fair evidence that a uterine septum contributes to miscarriage and preterm birth. Some limited studies indicate that hysteroscopic septum incision is associated with a reduction in subsequent miscarriage rates and improvement in live birth rates in patients with a history of recurrent pregnancy loss (RPL).[25]

A Cochrane review septate uterus could have no randomized controlled trials (RCTs) evaluating hysteroscopic metroplasty with expectant management in women with RPL.[26] Another meta-analysis which was not specific for RPL reported a significantly decreased risk of pregnancy loss in women who underwent hysteroscopic septotomy as compared to women who differed undergoing treatment (RR: 0.37; 95% CI: 0.25–0.55; $I^2 = 0\%$; five studies).[26]

European Society of Human Reproduction and Endocrinology guideline 2017 recommended that whether hysteroscopic septum resection has beneficial effects in improving live birth rates, and decreasing miscarriage rates, without doing harm needs further evaluation in the context of surgical trials in women with RPL and septate uterus.[27]

Royal College of Obstetricians and Gynaecologists Scientific Impact Paper 2019 has mentioned that high-quality evidence on the efficacy and safety of surgical treatment to improve reproductive in septate uterus outcomes is lacking. However, controlled studies have indicated that hysteroscopic septal division reduces miscarriage rates, resulting in improved live birth rates.[28] On this basis hysteroscopic resection of a uterine septum can be offered on an individualized basis for women with recurrent miscarriage by specialists after appropriate counseling.

Historically T-shaped uterus was secondary to diethylstilbestrol (DES) exposure in utero. This is managed by hysteroscopic metroplasty, which involves incision on lateral uterine walls to expand the uterine cavity.[29] It is important to diagnose a T-shaped uterus because many studies were recently published about the reproductive outcome of T-shaped uterus and its relation to RPL, infertility, and in vitro fertilization (IVF) failure and also many studies were published about the lateral metroplasty as a treatment of T-shaped uterus. The main limitation of these studies is the absence of clear criteria to diagnose T-shaped uterus. The ESHRE/ESGE classification mentioned dysmorphic uterus (T-shaped) with narrow cavity and thick lateral wall but there is no measurement for diagnosis. The ASRM 2021 classification did not mention the criteria for diagnosis of T-shaped uterus. The CUME has tried to solve this problem.[30] The diagnosis of T-shaped uterus is not simple and the agreement among top experts is only moderate. A single expert judgment is commonly insufficient for accurate diagnosis. The group of experts described,[30] what they considered reliable and accurate, a measurable criteria for the classification of T-shaped uterus.

1. Lateral indentation depth ≥7 mm
2. Lateral indentation angle ≤130°
3. T-angle ≤40°

If the three criteria are present, the case is T-shaped uterus. If two criteria are met, the case is borderline T-shaped uterus. In case one or no criteria is met, then it is a normal uterus. This classification should be applied only when there is no internal fundal indentation ≥10 mm (according to CUME). It is also mentioned that the clinical relevance of the non-DES-related T-shaped uterus is unknown. Moreover, the results may help in understanding and validating the quality of evidence on T-shaped uterus, and may help to improve the quality of studies and our understanding of this morphology. It may well be that non-DES-related T-shaped uterus is not a congenital anomaly and need not be treated as such. Further efforts should be aimed at determining whether a T-shaped uterus is a true uterine anomaly with clinical consequences.[30]

MYOMAS

Leiomyomas that distort the uterine cavity (submucosal or intramural with an intracavitary component) cause difficulty in conception and an increased risk of miscarriage.[31,32] Myomectomy is the preferred treatment modality for symptomatic women who desire future fertility in comparison to uterine artery embolization (UAE), high-intensity focused ultrasound (HIFU), and magnetic resonance-guided HIFU (MRgHIFU).

Impact of uterine myomas on fertility:

- Greater distance for sperm travel
- Encroachment on tubal ostium
- Distortion of uterine cavity
- Vascular changes
- Interfere normal rhythmic uterine contractions
- Impaired implantation
- Abnormal endometrial maturation
- Alteration on oxytocinase activity.

Mechanism of Impaired Fertility in Case of Intramural-submucosal Myoma

- The number of caveolae in host myometrium and fibromyomata is conceivably decreased compared to normal myometrium.
- This specific structural abnormality may affect calcium metabolism by causing a decrease in defect in calcium extrusion and thus raising the intracellular calcium.
- Increased intracellular calcium produces myometrial irritability and hyperactivity.

- Resulting in disruption of the rhythmical contraction process of the junctional zone (JZ).

Subendometrial tumors:

- Causing endometrial erosion with subsequent inflammation altering the nature of the intrauterine fluid, results in a hostile environment
- Disrupt the endometrial blood supply, affecting nidation and sustenance of early embryo.

Effect on fertility of noncavitary uterine myoma is still controversial. In patients with infertility or history of pregnancy loss, other causes should also be thoroughly looked at and involvement of uterine cavity is checked.[31] Buttram and Reiter reviewed 1,699 cases of myomectomy and determined that 27% of these women also had infertility.[33] When all other causes were ruled out, myomas were found to play a role in only 2.4% of the cases.[32] Hence, it was concluded that although myomas may be coincidentally present in 25% of the cases of infertility, myomectomy would directly benefit only 2.4% of these women, where all other infertility factors have been ruled out. The rest will conceive following treatment of an identifiable cause without resorting to myomectomy. The above concept is important to understand. Most gynecologists feel that operating on myomas would enhance fertility in all patients with myomas. On the contrary, myomectomy leads to peritubal adhesions and distortion of the tubo-ovarian relationship as well as the uterine cavity in a large number of patients that will actually reduce further fertility potential leaving IVF as the only treatment option post myomectomy.

Hence, the decision to perform myomectomy or not in an infertile patient with intramural myomas is a crucial one.[32] It must be taken only after all other identifiable factors have been treated, and pregnancy has not ensued. Indications are:

- Failure of three cycles of controlled ovarian stimulation and intrauterine insemination after optimizing all other factors
- Recurrent implantation failure (RIF)
- Intramural myoma >5 cm in size
- Intramural myomas with submucous extension.

Yet myomectomy will benefit some patients with infertility. A recent meta-analysis concluded that the presence of leiomyoma without cavity involvement reduces the success rate of ART cycles.[34,35]

Classification of Leiomyomas

The International Federation of Gynecology and Obstetrics (FIGO) proposed the leiomyoma classification system. It is based on the relationship between the leiomyoma and the endometrial and serosal surfaces of the uterus[36] **(Table 2)**.

TABLE 2: International Federation of Gynecology and Obstetrics classification of leiomyoma.

Submucous	0	Pedunculated intracavitary
	1	<50% intramural
	2	>50% intramural
Others	3	Contacts endometrium, 100% intramural
	4	Intramural
	5	Subserous ≥50% intramural
	6	Subserous <50% intramural
	7	Subserous pedunculated
	8	Others (specify, e.g., cervical and parasitic)

Submucous Myomas

For women desiring future fertility, or who are currently infertile, hysteroscopic myomectomy is required for all submucous myomas.

An abdominal approach to multiple submucous myomas should be considered in following situations:[37]

- Three or more submucous myomas
- When hysteroscopic myomectomy might be anticipated to damage a large portion of the endometrial surface
- When submucous myoma extends to the uterine serosa (e.g., type 2–5 or 2–6 lesions).

Concomitant laparoscopy or ultrasound in cases of hysteroscopic myomectomy of deep type 2 submucous myoma can be considered. Abdominal approach is also necessary to remove intramural (types 3 and 4) or large subserosal myomas (types 5, 6, or 7).

Among various techniques available for abdominal myomectomy in infertile women, preferably minimally invasive approaches like laparoscopic myomectomy should be selected. Robotic assisted laparoscopic myomectomy (RALM) is also an option but cost remains a limiting factor. Whichever approach is selected, surgeon should not only be skilled in proper enucleation of myoma but also in adequate suturing of the myoma bed in two layers with minimal possible blood loss.[32]

Preoperative Evaluation

Thorough medical history followed by abdominal pelvic examination is a must. On bimanual examination, the size, contour, and mobility of the uterus should be noted, along with any other pelvic pathology. Baseline complete blood count, blood grouping, and routine blood investigations are ordered. USG, saline infusion sonography, MRI, or hysteroscopy are important in evaluating an infertile female with submucous myoma. Abdominal and transvaginal USG is carried out for location, number, and size of myoma along with the measurement of the distance between endometrium and myoma or serosa and myoma, which should be

documented prior to surgery.[35,36] Though ultrasound is highly sensitive for preoperative mapping of myomas, due to limited tactile sensation in laparoscopic and robotic myomectomy, MRI is preferred in cases of difficult USG.[37,38]

Preoperative Preparation

Preoperative informed consent with proper explanation of the available alternatives to the procedure and potential complications of the procedure must be discussed and documented. In patients seeking pregnancy, need of cesarean delivery in future should be explained.[34] Other steps include:

- Correction of anemia with preoperative iron supplements.
- Gonadotropin-releasing hormone agonists (GnRH-a) should be considered in large myomas.
- Blood should be crossmatched, especially in cases where excessive blood loss is anticipated. In suitable cases, autologous blood transfusion may be arranged.
- Bowel preparation in case of myomectomy through abdominal route is mandatory.
- Cervical ripening with laminaria tents or misoprostol prior to hysteroscopic myomectomy prevents traumatic complications related to cervical dilatation.[32]

Preoperative and Intraoperative Measures to Achieve Hemostasis

Hemorrhage is probably the most frequent complication of myomectomy. Various surgeons all over the world have tried following interventions to reduce the bleeding during myomectomy.[39]

- Interventions on uterine arteries:
  - Laparoscopic uterine artery dissection and temporary clipping of the uterine artery
  - UAE
  - Pericervical mechanical tourniquet
  - Vasopressin injection around the myoma, or a vasoconstrictive solution of bupivacaine plus epinephrine.
- Uterotonics such as ergometrine, oxytocin, and misoprostol.
- Atraumatic myoma dissection techniques, these include:
  - Hydrodissection
  - Myoma enucleation by morcellation
  - Use of laser dissectors or, use of electrocautery or harmonics
  - Pharmacologic manipulation of the coagulation cascade with antifibrinolytic agents such as tranexamic acid and gelatin-thrombin hemostatic sealant.

Recently, a Cochrane review[39] was done to assess the effectiveness, safety, tolerability, and costs of these interventions to reduce blood loss during myomectomy. The review highlighted the paucity of randomized data on the use of such techniques.[40] It found significant reductions in blood loss with misoprostol mean difference (MD): –149.00 mL, 95% CI: –229.24 to –68.76), vasopressin (MD: –298.72 mL, 95% CI: –593.10 to –4.34), bupivacaine plus epinephrine (MD: –68.60 mL, 95% CI: –93.69 to –43.51), tranexamic acid (MD: –243 mL, 95% CI: –46.0 to –25.98), pericervical tourniquet (MD: –289.44, 95% CI: –406.55 to –172.32), and gelatin-thrombin matrix (MD: –545.00 mL, 95% CI: –593.26 to –496.74). There was no evidence of an effect on blood loss with oxytocin or morcellation. The best option appeared to be vasopressin injection **(Fig. 7)**. None of the interventions significantly increased myomectomy-related complications.

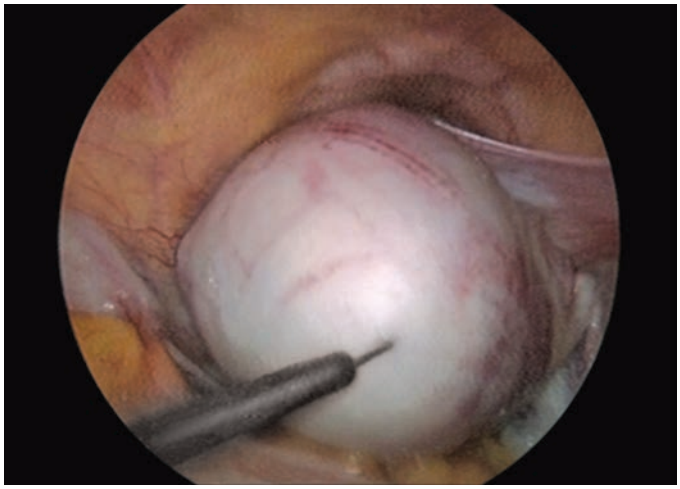


Fig. 7: Blanching of uterus due to vasopressin injection. *Courtesy:* Dr Kamini Rao Hospital.

Role of Pretreatment with GnRH Analogs

Pretreatment with GnRH analogs before myomectomy is controversial. GnRH-a cause myoma shrinkage by reducing the circulating estrogen levels.[41] Drawbacks of preoperative GnRH therapy are that it increases the difficulty in identifying and dissecting the cleavage plane during myoma enucleation[39] and also increases the chance of myoma recurrence, as small myomas may be totally missed. Additionally, GnRH therapy is expensive and commonly associated with menopause-like side effects.[41] The role for GnRH administered for the purpose of reducing operating time, the amount of systemic absorption of distension media, and the risk of incomplete resection of submucous myomas has not been established. It can be considered a useful tool to correct anemia prior to surgery[37] or to obtain the shrinkage with consequent optimal mobilization of a single and very large myoma.[42]

Various Surgical Techniques for Myomectomy

Open Myomectomy

Abdominal myomectomy is performed through a laparotomy by taking transverse incision (Pfannenstiel) or in very large myomas a vertical incision. Size, number,

location, and type of myoma are noted to accomplish the surgery. After taking measures to reduce blood loss, vertical, oblique or transverse uterine incision is taken, which is then extended down through myometrium and pseudocapsule to reach the myoma. Myoma is grasped by instruments such as tenaculum, allis, towel clip, or myoma screw and is further enucleated by blunt and sharp dissection.[43] In case of multiple myomas, removal of myoma by *tunneling* the same incision is preferred. Multiple incisions are taken when tunneling is not possible. Uterine defect is closed in a single or double layer with absorbable sutures. When the endometrial cavity is breached, it should be repaired with 5.0 Vicryl everting the endometrial edges toward the cavity. Inclusion of endometrial edges in the myometrium may cause foci of adenomyosis. Adequate tissue reapproximation and hemostasis is a must. The microsurgical principles inherent to all reproductive pelvic surgeries must be applied, namely atraumatic tissue handling, strict attention to hemostasis, continuous moistening of the pelvic tissues, and meticulous approximation of dissected tissue planes.[43-45]

Routine postoperative care includes monitoring of a patient's hemodynamic and fluid status, pain control, and reintroducing normal diet and activity. Early ambulation is preferred. Bleeding, fever, infection, visceral damage, ileus, bowel obstruction, pelvic abscess, and thromboembolism are reported as short-term complications of open myomectomy.[46] Long-term complications of abdominal myomectomy include pelvic adhesions, recurrent fibroids, and the risk of uterine rupture in subsequent pregnancies.[47,48]

Laparoscopic Myomectomy

The first laparoscopic myomectomy was performed by Dr Kurt Semm in 1979.[47] Laparoscopic myomectomy is an option in women with a uterus of less than 18 weeks' size, with ≤3 cm intramural or subserosal leiomyomas of ≤ 5 cm in diameter.[48] But with better instrumentation in laparoscopy and advanced surgical skills, laparoscopic myomectomy can be performed by experienced surgeons regardless of the size, number, or location of the myomas.[47]

The technique of laparoscopic myomectomy involves four steps:

- *Incision:* The incision on the uterus overlying the fibroid is created using a monopolar hook, monopolar needle electrode, harmonic scalpel, or sharp scissors. The direction of incision depends upon number, site and size of myoma, and surgeon preference. Horizontal incision minimizes blood loss as vessels run transversely along the uterine wall **(Fig. 8)**. Additionally, laparoscopic suturing is easier with horizontal and oblique incisions than with vertical incisions. Care must be taken to avoid extension and injury to fallopian tubes and ascending uterine vessels.[49]

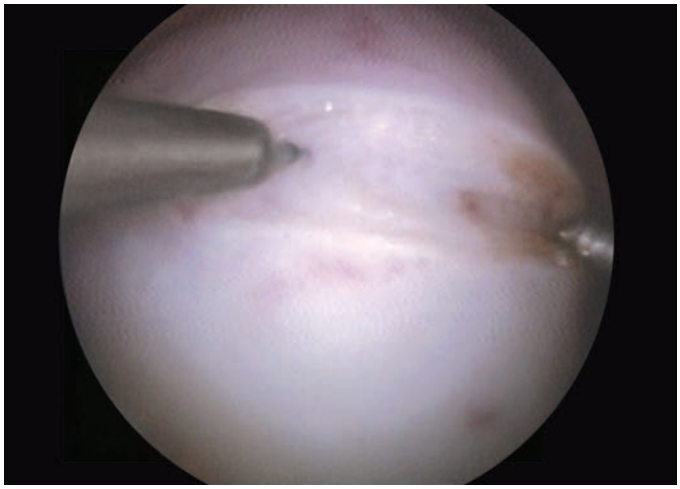

Fig. 8: Uterine incision by monopolar hook.
Courtesy: Dr Kamini Rao Hospital.

- *Enucleation:* Cleavage plane between myoma and pseudocapsule is created by blunt and sharp dissection. Traction is applied by myoma screw or tenaculum and myoma is then enucleated by gentle dissection and counter traction **(Fig. 9)**. Alternatively, hydrodissection with a suction irrigation cannula is convenient and atraumatic. Recognition of a proper cleavage plane between myoma and pseudocapsule is important to minimize bleeding and adequate enucleation. Bipolar coagulation of the vascular pedicle at the base of the myoma, prior to complete enucleation (after enucleation these vessels usually retract in the myometrium) will minimize blood loss.
- *Suturing:* Suturing is the key in laparoscopic myomectomy to avoid a number of complications ranging from postoperative bleeding to uterine rupture in subsequent pregnancy.[50] Depending upon the depth of defect, single or multilayer suturing is required **(Fig. 10)**. Delayed absorbable sutures such as polydioxanone, polyglactin, or a new kind of suture, bidirectional barbed thread is used. Barbed sutures consist of standard suture material with tiny barbs cut into the length of the filament facing in opposite directions from the midpoint with a needle on each end. It does not require knots, so decreases the mean suturing time and blood loss.[51,52] Excessive use of electrocautery during enucleation and for achieving hemostasis should be avoided as it causes necrosis of myometrium.
- *Myoma extraction*: Small myomas are removed by 10 mm primary port while large myoma requires electromechanical morcellation. Most surgeons perform morcellation after completion of myomectomy **(Fig. 11)**; however, morcellation of partially attached myoma can also be performed in case of large myoma. It should be performed with blade tips always under

direct vision to prevent injury to bowel and adjacent structures. Special care must be taken to remove all myoma fragments to avoid iatrogenic parasitic myomas as complications. In order to prevent inadvertent peritoneal dissemination of leiomyosarcoma during morcellation, the Food and Drug Administration (FDA) issued a directive to perform morcellation in a bag in order to minimize the spill of cellular debris all over the peritoneum.[53] This also ensures complete removal of fragments and minimizes the chances of injury to the surrounding bowel.

Figures 8 to 11 show various steps of laparoscopic myomectomy.

Prevention of Postoperative Adhesions

Adhesions are of concern whether the abdominal or laparoscopic route is used. Besides good hemostasis, the use of barrier methods has been shown to be of some use. Removal of more than five myomas leads to significantly lower pregnancy rates due to subsequent formation of adhesions. Tulandi[54] performed a second look laparoscopy after initial myomectomy and observed a greater degree of adhesion formation after posterior wall myomectomy (93.7%) than with anterior wall myomectomy (55.5%). These adhesions may be prevented by the use of *Interceed*[55] (Johnson and Johnson, New Brunswick, New Jersey, USA) or *Gore Tex* (WL Gore and Associates Inc., Flagstaff, AZ, USA).[56]

Hysteroscopic Management of Submucous Myomas

In women with intracavitary filling defects due to submucous myomas, causing AUB, infertility, or RPL, hysteroscopic resection is preferred. This results in less blood loss and postoperative pain, reduced hospitalization, and recovery time and lower risk of postoperative pelvic adhesions. The Wamsteker[57] classification system, used by the ESGE, is based upon the degree of myoma within the uterine cavity.

- Type 0, the submucosal fibroid is entirely within the endometrial cavity
- Type 1 represents myoma which is more than 50% in the cavity
- Type 2 represents myoma which is less than 50% in the endometrial cavity.

Lasmer[58] and colleagues introduced the STEP-W (size, topography, extension, penetration, wall) classification system for submucous myoma in 2005 **(Table 3)** and recently demonstrated significant improvement in its prognostic capabilities as compared to the ESGE classification system.[59]

Techniques for Hysteroscopic Management of Myoma

Traditional Monopolar Resectoscope Technique

Neuwirth and Amin[60] reported the first case of using the urologist resectoscope for the treatment of submucosal

TABLE 3: STEP-W (size, topography, extension, penetration, wall) classification system for submucous myoma.

	Size (cm)	*Topography*	*Extension of the base*	*Penetration*	*Lateral wall*	*Total*
0	>2–5	Low	≤1/3	0	+1	
1	>2–5	Middle	>1/3–>2/3	≤50%		
2	>2	Upper	>2/3	>50%		
Score	+	+	+	+	+	
Score	**Group**	**Complexity and therapeutic options**				
0–4	I	Low complexity hysteroscopic myomectomy				
5–6	II	High complexity hysteroscopic myomectomy; consider use of GnRH preoperatively; consider two step hysteroscopic myomectomy				
7–9	III	Consider alternatives to hysteroscopic techniques				

(GnRH: gonadotropin-releasing hormone)

myoma in 1976. Resection of myoma is performed using a telescope from 0° to 30° and standard resectoscope between 24F and 28F and loop electrode with monopolar current and hypotonic distension media (glycine or sorbitol-mannitol).[61]

After cervical dilatation, a resectoscope fitted with a cutting loop is introduced and myoma is systematically resected under direct vision using cutting current of 60–120 watts **(Fig. 12)**. During resection:

- Resectoscope loop alone is moved toward the surgeon using the spring mechanism of the loop alone (short chip technique) or
- Moving the entire resectoscope toward the surgeon (long chip technique).

Care should be taken to minimize endometrial and myometrial damage. Myoma chips are removed at the end of the procedure unless it is a big myoma or the view is obstructed. Facilitation of uterine contractions by deflation, bimanual massage, or use of prostaglandins has been advocated as this squeezes the myoma into the uterine cavity. Cavity is then inspected to ensure hemostasis and completion of the procedure.

Bipolar Resectoscopic Technique

This is a safer technique of myoma resection. It requires isotonic distension media like normal saline so the risk of electrolyte imbalance related to fluid overload is less.[62]

Use of Vaporizing Electrodes

Bulk electrosurgical vaporization is performed with a large surface area electrode activated with low-voltage current to vaporize relatively large volumes of tissue.[63] As the electrode is moved through the myoma, it completely vaporizes the tissue so that there is no vision obstruction by myoma pieces. The drawback is that there is no tissue available for histopathological examination (HPE).[64]

Hysteroscopic Morcellation of Myoma

In order to minimize the complications of fluid overload and electrosurgical injuries related to traditional monopolar resection of myoma, hysteroscopic morcellators are also used.[65] These morcellators have a hollow cylindrical blade with a side aperture that is used to morcellate the myoma sequentially. It has an integrated suction removal system to remove tissue fragments from the uterine cavity for histopathology. Simultaneous removal of tissue fragments from uterine cavity makes this procedure quick and reduces the risks of perforation by maintaining visibility.[66] Mechanical morcellators allow resection of type 0 and type 1 myomas using normal saline as distension media without the use of electric current.[67] This minimizes damage to the endometrium which may give us better implantation rates.

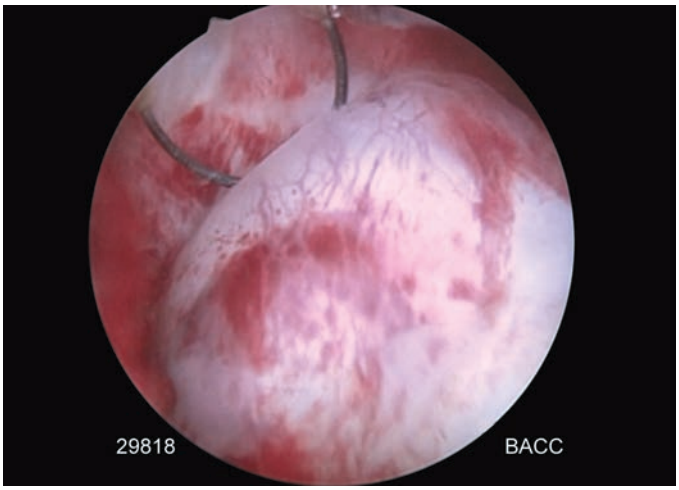

Fig. 12: Submucous myoma with loop electrode.

Complications Associated with Hysteroscopic Myomectomy

Following are the American Association of Gynecologic Laparoscopists (AAGL) recommendations to prevent complications:[37]

- Postoperative bleeding can be managed either with intracervical prostaglandin F2α (carboprost) or with tamponade by use of an inflated balloon catheter.
- Distension media complications can be minimized with strict monitoring of fluid deficit, preferably with weighted

monitoring systems and the adherence to institutionally predetermined fluid loss guidelines. The surgery should be abruptly terminated if the fluid deficit approaches 1,500 mL or the serum sodium level nears 125 mmol/L.

- *Thermal injury:* The risk of monopolar current diversion resulting in lower genital tract burns may be reduced by:
  - Maintaining contact of the external sheath with the cervix
  - Avoiding activation of the electrosurgical unit when the electrode is not in contact with tissue
  - Ensuring the sustained integrity of the electrode insulation
  - Minimizing the use of high-voltage ("coagulation") current when performing hysteroscopic submucous myomectomy.
- Post myomectomy intrauterine synechiae can be minimized if opposing tissue is not resected during a single surgery. These are more common after multiple submucous myomectomies. Moreover, when fertility is an issue, second-look hysteroscopy and appropriate adhesiolysis should be considered.[67,68]

Fertility Outcome after Hysteroscopic Myomectomy

Vercellini[68] in a study of 108 women that used the ESGE classification system reported 49%, 36%, and 33% fertility rates over a 3-year period in type 0, 1, and 2 myomas, respectively. Emanuel et al. reported 46% conception rate and 80.4% delivery rate after hysteroscopic resection of myoma.[69] In a systematic review of leiomyomas and fertility, Pritts et al. concluded that submucous myomas lower fertility rates and their removal enhances the rates of conception and live births.[70]

After hysteroscopic myomectomy, patients should wait for 2–3 months for endometrial healing prior to conception. As there are no reported cases of uterine rupture, patients may attempt vaginal delivery after hysteroscopic myomectomy.[71]

Vaginal myomectomy of intramural lower segment myomas is an alternative to laparoscopy or laparotomy. However, the chances of conversion are high as are the chances of pelvic infection. There are no good studies for comparative analysis.[72]

Cervical myomas account for about 5% of all myomas. They require excision if they restrict entry into the uterine cavity for ART procedures. Due to its close vicinity to bladder, rectum, ureter, and uterine vessels, the approach needs to be modified with relation to these surrounding vital structures. During laparoscopic myomectomy for cervical myoma, temporary blocking of uterine artery blood flow and the use of vasopressin are essential to decrease excessive bleeding.[73] Minimizing the risk of damage to surrounding organs by positioning the incision in the myometrium somewhat lateral to the uterine corpus and appropriate suturing to avoid leaving dead space are important. Hysteroscopic resection and vaginal myomectomy may be considered where appropriate. Embolization of the cervical branch of the uterine artery can be considered when removal is challenging.

Medical Management

Medical management with oral progesterone, progesterone intrauterine system (IUS), and oral contraceptive pills is seldom indicated in the infertile patient. However, in patients with multiple small myomas where surgery would be more traumatizing to the uterus, treatment with ulipristal acetate (UPA) may be indicated prior to ART cycles. UPA is a selective progesterone receptor modulator (SPRM) with antiproliferative effects on myoma cells.[74,75] UPA 5–10 mg daily helps in reducing myoma size and uterine volume; it also decreases pelvic pain and excessive bleeding, thereby normalizing anemia and restoring quality of life.[74-76] In women with large myomas, two courses of 3 months of UPA 5 mg daily can be given. Depending upon regression of myoma and restoration of uterine cavity, the patient may attempt a pregnancy after the second bleed following cessation of therapy.[77]

ADENOMYOSIS

Adenomyosis is a benign condition of the uterus, defined by the presence of endometrial glands and stroma within the myometrium.[78] Prevalence of adenomyosis is variable around 20% and increases with age reaching to about 32% in women aged 40–49 years.[78,79]

Adenomyosis may present with symptoms like:

- Infertility
- Dysmenorrhea
- Menorrhagia
- Pelvic pain

Variable symptomatology with difficult diagnosis of adenomyotic lesions at imaging makes this a challenging entity in gynecological practice.

Pathogenesis

A major pathogenetic mechanism suggests adenomyosis as a sex hormone-related disorder, in fact the most commonly used drugs are targeted or modulating estrogen/progesterone receptors (ER/PR). Studies have shown that polymorphisms in the ER-α gene are associated with a risk of adenomyosis.[80] Adenomyotic tissue is known to contain steroid receptors, apart from having increased activity of aromatase and sulfatase enzymes. These ER receptors under the influence of circulating and locally produced estrogens stimulate the growth of adenomyotic tissue.[81] Local hyperestrogenism is due to the action of aromatase

and sulfatase enzymes converting estrone-3-sulfate to estrone. This explains the increased levels of estradiol (E2) in menstrual blood, but not in peripheral blood of women with adenomyosis. The reduction of PR expression can be related to the development and progression of adenomyosis and may explain the mechanism of action of progestin agents on adenomyosis.[82]

Investigations

Transvaginal USG and MRI are reliable tools for a noninvasive diagnosis of adenomyosis.[83,84] MRI is more accurate as it helps to assess JZ thickening and extent of myometrial involvement. It will also differentiate adenomyosis from myoma and identify associated endometriotic lesions. HPE of biopsy or hysterectomy specimens provides the most definitive diagnosis.

Impact on In Vitro Fertilization

Women with adenomyosis are commonly known to suffer from infertility. These women encounter low success rates even while undergoing ART cycles. There is significant:

- Reduction in ovarian response to stimulation.
- Reduced implantation of good quality embryos.
- Low clinical pregnancy rates.
- Increased risk of early pregnancy loss.
- Lower live birth rates in women with adenomyosis undergoing IVF.[85-88]

Medical Management

The management of patients with adenomyosis is difficult and conservative treatment is required for those who require preservation of fertility and improvement of quality of life. The objective of medical treatment is pain reduction, control excessive bleeding in AUB, and restore fertility. The present medical treatments for adenomyosis follow the principles of the management of endometriosis, which are usually aimed at reducing the production of endogenous estrogen or inducing endometrial differentiation with progestins.[89]

Nonhormonal medications, such as procoagulating agents, iron supplementation and nonsteroidal anti-inflammatory drugs (NSAIDs), are also aimed at controlling symptoms of AUB and pain in adenomyosis. Hormonal medications commonly used in the treatment of adenomyosis is similar to those for endometriosis. These include GnRH-a, progestins [danazol, levonorgestrel-intrauterine device (IUD), dienogest], and combined oral contraceptives (COC).

Progestins

Progestins act via decidualization and subsequent atrophy of endometrial tissue apart from modulation of mitotic activity, local growth factors, and their receptor. There are other paracrine mechanisms and anti-inflammatory mechanisms as well.[90,91,92]

Norethindrone Acetate

The use of norethindrone acetate (NETA) in adenomyosis is associated with a marked degree of pain relief and symptomatic relief. The onset of action seems to be slow but with longer duration of use the efficacy improves.[93] The role of NETA in the management of adenomyosis has been well demonstrated in women presenting moderate or severe pelvic pain and bleeding. There is a significant improvement of both dysmenorrhea and bleeding after treatment (dose 5 mg/day).[94] The progestin treatment started at the beginning of the menstrual cycle, and was taken orally as a three-weeks-on and one-week-off regime. Since maximum response was obtained at 3 months, NETA may be considered an effective, well-tolerated and inexpensive medical treatment for adenomyosis, with fewer and milder side effects.[94] A drawback of NETA therapy is the reduction of libido in around one-fifth of women.

Danazol

The mechanism of action of danazol is complex. It acts by lowering the mid-cycle luteinizing hormone (LH) surge, and increasing serum-free testosterone levels. It also acts directly on adenomyotic tissue in vitro to inhibit DNA synthesis and induce apoptosis. Its use results in an androgenic and hypoestrogenic environment.[93] The use of danazol is associated with relieved pain and clinical improvement in 55–93% of adenomyosis patients treated for a duration of 6 months.[95] However, danazol is not suitable for prolonged use because of its adverse side effects. A low-dose of danazol (200 mg/day) is daily administered by vaginal route for 6 months in young women with adenomyosis. The severity of blood loss and uterine volume are significantly reduced.[96]

Levonorgestrel-releasing Intrauterine System

Several mechanisms may explain the role of the levonorgestrel-releasing intrauterine system (LNG-IUS) in the treatment of adenomyosis.[97] After insertion of the system there is a decidualization of the endometrium, followed by atrophic changes, which produces a marked reduction in menstrual blood loss. Direct action is thought to occur due to direct absorption into the myometrium and action on adenomyotic foci. Additionally, downregulation of ER, in both glandular and stromal endometrial layers, occurs shortly after placement of the device and persists for at least the first year of use. The LNG-IUS is highly efficient in decreasing AUB and uterine volume at 12 months and in resolving pain associated with adenomyosis (moderate or severe dysmenorrhea and dyspareunia).[98] The main side effects include irregular bleeding and amenorrhea during the first few months.

Dienogest

Dienogest has been reported to show high selectivity for binding to progesterone receptors[99,100] and has inhibitory effects on the secretion of cytokines in endometriotic stromal cells.[101] It also directly inhibits cellular proliferation and also induces apoptosis in adenomyotic stromal cells. In a pilot study, dienogest was effective in relieving the pain symptoms associated with adenomyosis and uterine fibroids. The regimen used was adenomyosis oral dienogest on days 2–5 of menstruation and followed up every 8 weeks after beginning treatment.[102]

GnRH Agonist

Gonadotropin-releasing hormone agonists act by binding to their receptors inducing a state of reversible iatrogenic menopause. With the fall in estrogen levels there is atrophy of the adenomyotic lesions, which in turn results in a reduction in the uterine size. There is a decrease in expression of aromatase cytochrome P450 in eutopic endometrium, mainly by promoting a hypoestrogenic state.[103] In assisted reproductive technologies, long agonist stimulation protocols along with pretreatment with GnRH-a for differed embryo transfer improve pregnancy rates.[95] The main adverse effect is due to the hypoestrogenic state. These include vasomotor syndrome, reduced bone mineral density, genital atrophy, and mood instability. When used with adequate precautions, add-back therapy with various kinds of hormone preparations has been successfully used to reduce the GnRH-a-included adverse effects which enables an indefinite extension of the treatment period.

Combined Oral Contraceptives

Mechanism of action: Combined oral contraceptives are useful in the management of adenomyosis-related pain and AUB. They decrease menstrual flow, cause decidualization and subsequent atrophy of the endometrium. Aromatase expression in the eutopic endometrium and adenomyotic foci is also suppressed by COCs.[104]

Future Medical Treatments

Several new drugs have been introduced in the treatment of adenomyosis. Selective estrogen receptor modulators (SERMs), SPRMs, and aromatase inhibitors (AIs) are the main drugs under investigation.

Aromatase Inhibitors

Mechanism of action: Aromatase cytochrome P450 (CYP19A1) is a key enzyme in the synthesis of estrogen from androgens. It is involved in the conversion of androstenedione and testosterone to estrone and E2, respectively.[105] CYP19A1 has been identified immunohistochemically in the cytoplasm of glandular cells of adenomyotic tissues and of eutopic endometrium from patients with this adenomyosis.[106] It is therefore an ideal target for inhibition of the E2 synthesis because it is the final step in steroid biosynthesis. Thereby no important downstream enzymes to be affected.[105] A single clinical trial employing AIs in the management of adenomyosis has been done.[107] In a prospective randomized controlled study which compared the efficacy of letrozole versus GnRH-a for 12 weeks in treating premenopausal women with uterine adenomyosis, there was no significant difference in total uterine size based on post-treatment uterine volumes in the two groups. AIs demonstrated the same efficacy as GnRH-a in reducing adenomyoma volume and improving symptoms.[107] The adverse effects most commonly associated with AI include headaches, hot flashes, mood changes, muscle aches, and breakthrough bleeding. E2 levels are significantly suppressed with this treatment, without the vasomotor symptoms and agonist flare-up effects of GnRH-a.[107] Their use would also be interesting in obese patients due to antiestrogenic action on both ovarian and adipose tissues. Hence, AIs appear to have a promising future for adenomyosis in cases of resistance to other treatments though additional studies are needed.

Selective Estrogen Receptor Modulators

Mechanism of action: The ideal SERM for management of adenomyosis needs to have an antagonistic activity in the endometrium (adenomyotic lesion) and agonistic activity for bone and lipids. Basic clinical studies indicate major roles for estrogen and progesterone in the pathology of adenomyosis. There is a need to conduct RCTs on the pharmacological treatment of adenomyosis with SERMs.[108,109]

Selective Progesterone Receptor Modulators

Selective progesterone receptor modulators are a new class of progesterone receptor ligands, which exhibit both progesterone agonist and antagonist activities in the endometrium. They reduce pain, bleeding, cell proliferation, and inhibit inflammation.[110] Thus they are beneficial in the treatment of myomas or endometriosis.[109,111] Mifepristone influences the caspase 3 expression in adenomyotic tissue. The role of SPRMs requires investigations and well-designed RCTs to assess their long-term action and their clinical use in patients with adenomyosis.[111-113]

Conclusions

The medical treatment of adenomyosis is an open field with a great possibility of new advancement. No double-blind placebo-controlled study was ever conducted on the management of adenomyosis and only observational studies are reported in literature.

Surgery can be beneficial for women who have experienced previous IVF failures. It also increases spontaneous pregnancy rates.

- If the adenomyosis is localized, laparoscopic excision is advisable as it may improve implantation rates as well as symptom control. Women less than 39 years of age were shown to have benefit with uterus sparing adenomyomectomy. Both robotic-assisted adenomyomectomy and laparoscopic adenomyomectomy (LAM) have better results when compared to GnRH-a therapy in symptom control.[114,115]
- If the lesions are mainly subendometriotic, i.e., <2.5 cm deep, they may be dealt with by hysteroscopic resection with a resectoscope and commencing estrogen replacement therapy postoperatively.[116]
- However in diffuse adenomyosis, prolonged pretreatment with GnRH-a has been tried prior to ART cycles. However, pregnancy rates remain low.
- Harvesting the oocytes and pooling them prior to prolonged suppression and performing frozen embryo transfer (FET) is currently the best option.
- Medical management with UPA for one or two courses, of 3 months each, has also been tried prior to ART cycles. However, no studies are available on pregnancy rates following such treatment.
- Use of HIFU[116,117] and HIFU MRg;[118] a clinical trial is currently recruiting patients to see the efficacy of this modality.[119]
- In multiple failed IVF cycles, surrogacy offers the best chances for the couple.

ENDOMETRIAL FACTORS

Implantation of the embryo in the endometrium is the bottleneck for the success of ART. Today most ART laboratories achieve a fertilization rate of over 80% but a clinical pregnancy rate of 30–35%. The gap is due to defects in the embryo-like aneuploidy or subtle defects in the endometrial environment that lead to failure of the embryo to implant in the uterus. The endometrium undergoes cyclical changes to accommodate a window of implantation (WOI) each month that is short-lived. It is characterized by formation of pinopodes and microvilli to allow embryo adhesion as well as secretion of Th2 cytokines in preference to Th1 cytokines. Embryo transfer should be done during this WOI which can be assessed by performing endometrial receptivity analysis (ERA) test done at a precise time, i.e., natural cycle—LH surge or human chorionic gonadotropin (hCG) + 7 days and in hormone replacement cycle—progesterone + 5 days. A displaced WOI is seen in 20% of patients with RIF.[120]

In order to understand the diverse causes of failed implantation, let us understand the process of implantation. This can be divided into following phases:

- *Apposition*
- *Adhesion* of the embryo to the endometrium
- *Burrowing* of the embryo into the endometrium
- Escaping *immune rejection*
- Establishing a *vascular connection* to derive nutrition.

Apposition

The timing and technique of embryo transfer is very important to allow for apposition of the embryo and endometrium.

Embryo transfer should involve:

- Ultrasound visualization of embryo placement
- Placement of embryos in mid cavity
- Minimal volume of media
- Minimal transit time between incubator and uterus of less than 1 minute to maintain embryo viability
- Gentle release of embryos
- Maintaining steady pressure on the plunger to prevent backflow
- No blood in the cavity that can alter the pH of the endometrial secretions[120]
- Abolishing uterine contractions by:
  - Not stimulating the cervix
  - Giving prostaglandin inhibitors like indomethacin
  - Giving oxytocin receptor blockers like atosiban during embryo transfer in patients with increased endometrial contractions visible on transvaginal scan (TVS).

The pattern of uterine contractions is different in fresh and FET thereby the difference in clinical outcome.[122]

Adhesion

It is believed that the sulfhydryl groups of the endometrium are chemotactic for the embryo. The embryo initially derives nutrition from the secretions of endometrial glands. Hence, it will implant on one of the glandular openings. Thin endometrium with poor secretory change will not support the nutrition of the implanting embryo. With this premise, estradiol valerate is used to cause glandular proliferation in the follicular phase and induce progesterone receptors, followed by the use of micronized progesterone in the luteal phase to enhance endometrial secretions.

Pinopod formation in the endometrium lasts for only 24 hours, and puts forth an increased surface area of the endometrium in the form of microvilli for the adhesion of the embryo. Missing the WOI may prevent adhesion of the embryo to the endometrium.

Adhesion can only occur if the embryo has successfully hatched out of the zona pellucida. In cases of zona hardening and improper hatching, the embryo will be unable to adhere to the endometrium. Hence, *assisted hatching* procedures are useful in a select group of patients that include:[119]

- Frozen thawed embryos as it hardens the zona
- Thickened zona pellucida of more than 15 microns
- Age more than 37 years
- Elevated basal follicle-stimulating hormone (FSH) level of more than 10
- Previous two cycles with failed implantation
- Embryos with increased fragmentation and delayed development

The use of hyaluronic acid (HA) as an adhesion molecule in the embryo transfer media has shown slightly improved implantation rates and also a higher incidence of multiple pregnancies.[123]

Blastocyst culture has taught us that the blastocyst is sticky and will readily adhere, a quality that makes it survive in the endometrium. However most aneuploid embryos will arrest at 4–16 cell stage and will not proceed to form a blastocyst. Hence, it is worthwhile replacing blastocysts in patients with implantation failures.

Blastocysts can now be screened for aneuploidy by performing *preimplantation genetic screening (PGS)* by complete genomic hybridization (CGH) or fluorescent in situ hybridization (FISH) on trophectoderm cells. Women with RIF will benefit from PGS and those with recurrent 100% aneuploid embryos will benefit with oocyte or embryo donation.

Blastocyst culture fluid can now be analyzed for specific *implantation marker proteins* secreted by the blastocyst. Those with positive secretion of these markers can be preferably transferred in patients with RIF.

Adhesion is a dynamic process which involves secretion of factors both by the embryo and endometrium. Hence the use of *embryo glue* to promote adhesion met with limited success.

A number of *adhesion molecules* have also been identified in the endometrium. These are:

- *Integrins* are maximally expressed in the endometrium during the implantation window. AlphaV beta 3 (αVβ3) integrin has been maximally studied as a potential marker for endometrial receptivity. It is secreted under the influence of progesterone. Low levels of this integrin were found in women with unexplained infertility[103,124]
- *Osteopontin* is a glycoprotein whose expression is increased in the endometrium during the implantation window, i.e., 7 days after the LH peak.[104,125]
- *Mucin 1 (MUC 1)* in the mouse model MUC 1 can prevent mouse embryo attachment to the polarized uterine endometrium. However in humans MUC 1 is maximally expressed during the implantation window. Expression of MUC 1 in the endometrium is regulated by estrogen and progesterone hormones, via the steroid receptors. It remains to be seen whether human MUC 1 is lost focally at the implantation site or undergoes a change in glycosylation to become an adhesive molecule.[126] Glandular MUC 1 levels were diminished in patients with recurrent miscarriages and implantation failures.

Burrowing

The burrowing of the embryo requires that the embryo should produce proteolytic enzymes like *matrix metalloproteinases* that will lyse the endometrium around it. This enzyme has to be produced in a controlled manner so that the path ahead is cleared without any buildup of free radicals, which means that its secretion needs to be regulated both spatially and quantitatively. Both over and under secretion of proteolytic enzymes will lead to failed implantation.

Failure to secrete these proteolytic enzymes will result in biochemical pregnancies without appearance of a gestational sac. On the other hand, buildup of free radicals in the endometrium will affect cell function and impair the secretion of growth-promoting cytokines. However, use of antioxidants and vitamin supplementation does not improve implantation rates in clinical studies.[127]

Chronic endometritis is identified in 15% of patients with infertility. It is generally asymptomatic and can be diagnosed on hysteroscopy and/or biopsy. The causative organisms are usually of low virulence, may be nonspecific but chlamydia and tuberculosis (TB) may also be responsible. A routine course of broad-spectrum antibiotics like doxycycline is often administered in the pre-IVF phase. CE will result in high levels of tumor necrosis factor alpha (TNF-α), free radicals or natural killer cells (NKC) that may hamper implantation. Hence, an endometrial biopsy is performed along with hysteroscopy to identify gross pathology in the endometrium like granulomas, leukocytic infiltration, or disordered proliferation. It is also postulated that hysteroscopy may help to remove bacterial biofilms and cure CE.[128]

In recent studies, *endometrial scratching* has shown to improve implantation rates by promoting secretion of growth factors and cytokines. However, it is still debatable whether maximum benefit comes from scratching the endometrium in the stimulated cycle or the cycle previous to ART.[129,130]

A multicenter randomized trial is recruiting patients for endometrial scratch in patients undergoing the first cycle of IVF.[131]

Immune Tolerance

The fetus is an allograft in the maternal body. Yet it is not rejected by the maternal immune system. The endometrium undergoes changes in its immune environment at the time of implantation so as to protect the developing embryo. The cytokine environment changes from a proinflammatory Th1 to an anti-inflammatory Th2 response.[132] There are reduced levels of proinflammatory cytokines like TNF-α. In cycles where there is an infective or autoimmune process activated in the endometrium the TNF-α levels are high that leads to implantation failure. In such cycles delaying embryo transfer

to a cycle where these levels are downregulated will help embryo implantation.

Uterine natural killer cells (uNKC) are large granular lymphocytes. Unlike peripheral NKC they lack cell differentiation (CD) 16 and CD3 antigens. These cells are increased in number during the midluteal phase of the cycle. Their population may be controlled by progesterone. They express families of receptors that are capable of recognizing specific antigens on the surface of extravillous trophoblast. Furthermore, the extravillous trophoblast does not express the classical MHC type 2 HLA antigens but expresses HLA G, so as to prevent recognition by the maternal immune cells. Besides, uNKC possesses less cytotoxic activity than peripheral NKC and their cytotoxic activity is downregulated in the peri-implantation period. Hence, the fetus does not face rejection by the uNKC. However subclinical infections of the endometrium with chlamydia, TB, or Gram-negative bacteria will upregulate the population of uNKC that may mediate rejection of the implanting embryo, resulting in failed implantation or recurrent miscarriage.[133] Hence, treatment of these infections is advisable prior to ART cycles.

Immunocytochemical studies enable us to do uNKC count in a biopsy taken during the luteal phase of the cycle. A count of more than 300 uNK cells/mm^2 was seen in patients with unexplained recurrent miscarriages when endometrial biopsy was performed in the luteal phase.[134]

The endometrium can also be tested for presence of anti-implantation proteins like apolipoprotein A1. This is present in high concentrations in the ectopic endometrial implants seen in endometriosis.[135]

Genomic study has compiled a human gene expression endometrial database (HGEx-ERdb). It was showed that 179 genes could be defined as receptivity associated genes (RAG) which may prove useful in identifying endometrial receptivity.[136]

Therapeutic Options

- Downregulation of the NK cells with immune modulation has been tried with variable results. Currently, it is advisable to correct hypovitaminosis D prior to ART cycles. Vitamin D is known to have immunomodulatory properties.[137]
- Use of progesterone as an immune modulator in the luteal phase is a routine in all ART cycles. However, its role in enhancing immune modulation and preventing RIF is debatable. The PROMISE trial was a double-blind randomized trial controlled on patients with recurrent miscarriages and showed no benefit of supplementing progesterone to prevent miscarriages.[138] However, systematic reviews done earlier show a lower miscarriage rate with progesterone supplementation.[139]
- Using paternal lymphocytes or third-party cells carries the risk of disease transmission and has no beneficial effect.[140]
- A short course of *steroids* during the peri-implantation phase has been used in patients with autoimmune diseases to downregulate the uNKC activity and to enhance implantation rates and reduce the chances of immune rejection. Although current evidence does not support the use of steroids for implantation,[141] a RCT is currently on, for its use in patients with high NK cell count, and the results are awaited.[132]
- The use of *intravenous immunoglobulin* (IVIg) prior to embryo transfer has also been tried.[133] It is indicated in a small subset of women with IgG subclass deficiency.[134] However, it is not beneficial in all cases of implantation failure.
- *Intralipids* have been used by some for immune modulation prior to embryo transfer and repeated every 3 weeks thereafter.[135]
- *Granulocyte colony-stimulating factor* was proposed by Scarpellini to improve implantation rates.[136] It was concluded in an RCT that it increased the rate of biochemical pregnancies by facilitating implantation but whether that translates to a higher clinical pregnancy rate is still uncertain.[137]
  - Intrauterine installation of 300 μg on day of hCG in women with thin endometrium and/or
  - Subcutaneous administration of 1 μg/kg (50–60 μg) two or three times a week for 4 weeks.
- *Human chorionic gonadotropin* is administered to trigger ovulation and improve pregnancy rates in women with oligomenorrhea. It has been shown that it enhances secretion of pro-implantation cytokines and growth factors during the periovulatory period.[138]

However, we need randomized trials to prove the efficacy of these empirical therapies.

Vascular Connection

The expression of vascular endothelial growth factor (VEGF) is increased in the endometrium during the postimplantation phase.[139] This allows the maternal spiral arterioles to establish a rich vascular network in the subendometrial layer, which can be studied by power Doppler studies of the endometrium in the mid cycle. Cycles with poor subendometrial flow may be associated with poor pregnancy rates.[140] The administration of *vasodilators* like sildenafil is used to improve pregnancy rates but there are no randomized studies supporting its use.[141]

However, *Doppler studies of the uterine artery* are helpful in women with RIF to identify cycles with improved uterine artery blood flow indices that will enhance implantation rates. Also, presence of power Doppler flow signals in the basal layer of the endometrium ensures better implantation rates.[141]

Use of *low-molecular-weight heparin* enhances uterine artery blood flow indices in a select group of patients. It has been suggested as a potential therapy in ART cycles for implantation failure. However RCTs on the subject are still lacking.[142]

Identification of implantation markers by *proteomic analysis* of culture medium has met with limited success. Presence of proteins like *glycodelin A* and *uteroglobin* in uterine secretions during midcycle has met with limited success. *Leukemia inhibitory factor (LIF)*, which was an implantation marker in the mouse model, has not been of value in human endometrium.

Growth factors secreted by platelet-rich plasma (PRP) injected into the uterine cavity under ultrasound guidance or in the endometrium under hysteroscopic guidance have shown to improve the quality of endometrium.[143] However, the procedure is new and we need to await results in terms of pregnancy rates.

Use of hematopoietic stem cells (SCs) or in conjunction with PRP helps in regenerating damaged endometrium but its effect on enhancing pregnancy rates are still awaited.[144] Severely damaged uterine cavity, not amenable to corrective measures, is an indication for surrogacy. Uterine transplant has also reported a successful pregnancy but is a cumbersome surgical procedure with risk of immunosuppression and rejection. Currently, it requires a hysterectomy post child birth.[145]

ASHERMAN'S SYNDROME

The Asherman's syndrome (AS) is characterized by the presence of intrauterine adhesions or adhesions in the endocervix with consequent risk of hypomenorrhea/amenorrhea, reduced fertility, pregnancy loss, and abnormal placentation. It can develop secondary to pregnancy-related curettage, infection or surgery related to the uterus, and TB. The pathophysiology involves trauma to the basal layer of endometrium.

Diagnosis

Intrauterine adhesions can be visualized by HSG, USG including contrast sonohysterography (SHG), 3D USG, hysteroscopy, and MRI. Hysteroscopy is the gold standard.

Treatment

The treatment of AS is indicated in women with infertility and those with painful hypo-/amenorrhea. This involves the division of adhesions under hysteroscopic guidance beginning in the central and safe part of the uterus and moving laterally and toward the fundus.[146] Overall restoration of normal menstrual cycle is observed in 75–100%.[147,148] The pregnancy rate ranges between 25% and 76%.[149] To prevent recurrent adhesions, IUCD, intrauterine application of hyaluronic gel, and estrogen therapy can be used. Regeneration of endometrium through SC treatment has been evaluated both in animal models.[150,151] Future randomized trials are needed to prove if SC treatment will have a clinical role in AS.

GENITOURINARY TUBERCULOSIS

Genitourinary TB is a common form of extrapulmonary TB (EPTB) worldwide (27%) with genital TB alone accounting for 9% of all EPTB cases.[152] TB infects the genital tract by four routes: hematogenous route, descending direct spread, lymphatic spread, and rarely as primary infection of the genitalia through sexual transmission.[153] The genital organs affected by *Mycobacterium tuberculosis* are as follows: fallopian tubes (95–100%), uterine endometrium (50–60%), ovaries (20–30%), cervix (5–15%), uterine myometrium (2.5%), and vagina/vulva (1%).[154]

Diagnosis

Hysterosalpingography: The uterine changes due to TB may be seen as specific features such as "collar-stud abscess," "T-shaped" uterus, and "pseudo unicornuate" uterus or nonspecific features such as synechiae formation, uterine contour distortion, and obliteration of the uterine cavity. Chronic infection may lead to extensive destruction of the endometrium and myometrium resulting in complete narrowing of the uterine cavity resulting in what is known as the Netter syndrome.[155]

Treatment

The WHO treatment guidelines for TB[156] recommend that patients newly diagnosed with TB should receive a regimen containing rifampicin (R) for 6 months: intensive phase with isoniazid (H), R, ethambutol (E), and pyrazinamide (Z) for a duration of 2 months followed by continuation phase with HR for 4 months.

KEY POINTS

- Around 1 in 500 reproductive age women are affected by UFI, which can be congenital or acquired.
- *Prevalence of CUAs:* General population 4.3–6.7%, infertile population 3–13%, and in patients with recurrent miscarriages 12.6–18.2%. Normal karyotype is found in 92% of women with Müllerian anomalies.
- Women with Müllerian developmental anomalies often will have normal functioning ovaries and female hormones and hence good reproductive potential.
- ASRM 2021 and ESHRE/ESGE consensus[9] (CONUTA) classification 2013 (reaffirmed in 2016) are the two most important classifications currently.
- Gold standard diagnostic modality for CUA is MRI. 3D USG has the potential to surpass MRI.
- Significant effect on reproduction seen in septate or bicornuate uterus, whereas the effect is statistically insignificant in women with arcuate, didelphys, and unicornuate uterus.
- Fertility management, restoration of the vaginal anatomy, and sexual function with emphasis on psycho-socio-sexual counseling are needed in CUA.

- Leiomyomas that distort the uterine cavity cause difficulty in conception and an increased risk of miscarriage.
- For myomectomy in infertile women, preferably minimally invasive approaches like laparoscopic myomectomy should be selected.
- Adenomyosis may present with infertility, dysmenorrhea, menorrhagia, or pelvic pain.
- TVS and MRI are reliable tools for noninvasive diagnosis of adenomyosis, MRI being more accurate. HPE of biopsy or hysterectomy specimens provides the most definitive diagnosis.
- Women with adenomyosis commonly suffer from infertility, success rate being low even with ART.
- Medical treatment of adenomyosis is an open field with a great possibility of new advancement. Medication or surgery as pretreatment for adenomyosis does not significantly increase the pregnancy rates in infertile women with adenomyosis. Surgery can be beneficial in previous IVF failures.
- Due to implantation failure, in spite of a fertilization rate of over 80%, clinical pregnancy rate is 30–35%.
- Use of hematopoietic SCs or in conjunction with PRP helps in regenerating damaged endometrium but its effect on enhancing pregnancy rates are still awaited.

CHAPTER 34

Tubal Factors in Infertility

Pratap Kumar, Aswathy Kumaran

INTRODUCTION

The fallopian tubes named after Gabriele Falloppio (also spelled Falloppia), a 16th-century physician and surgeon, are appendages of the uterus located on either side at the superior portion of the uterine cavity. They are 10 cm long muscular tubes originating at the uterine cornua and opening distally into the peritoneal cavity. Each tube is divisible into four parts and runs laterally within the mesosalpinx. The proximal narrowest segment comprises the interstitium (1.25 cm long, 1 mm wide) and the isthmus (2.5 cm long, 2.5 cm wide). The ampulla, the middle segment (5 cm long, 2.5–5 mm wide), gradually widens and merges with the distal segment, the broad funnel-like infundibulum (1.25 cm long, 6 mm wide) of the tubes that lies in close proximity to the ipsilateral ovary. Infundibulum has fimbriae that help in capturing the cumulus oophorus complex at ovulation.

The uterine tubes form a conducting channel for gametes and embryos. The tubes assist and modulate sperm transport and regulate oocyte transport; the ampulla promotes fertilization, nurtures gametes and embryos, and ensures the timely passage of the embryo to the uterus.[1] The patent healthy functional tubes are hence important for fertility.

Tubal disease contributes to 25–35% of female factor infertility and 11–30% of infertility in general depending on the population characteristics.[2,3] The main cause for tubal infertility is salpingitis which accounts for >50% of the cases as well as tubal surgery.[2] Published literature reveals that 20–30% of women regret that they have had a tubal ligation.[4-6] Therefore prevention, diagnosis, and management of tubal factor-dependent subfertility are important in reproductive medicine.

CAUSES FOR TUBAL SUBFERTILITY

Congenital

Developmental or inherent anomalies of the fallopian tubes are rare and most do not require treatment. Absence of one or both tubes is almost always associated with absence of the uterus as well as other anomalies.[7] Rudimentary oviducts, infantile ones, duplication of ostia, and accessory tubes are some other uncommon developmental anomalies.

Acquired

Pelvic inflammatory disease (PID) is the most frequent cause for tubal disease of which the single largest cause is *Chlamydia trachomatis* infection. Bulk of tubal disease is acquired and may be categorized into—proximal, mid, and distal tubal disease.

Proximal and Mid-tubal Disease

Pathology and blockage of proximal tube account for 10–25% of tubal disease.[3] Proximal block may be due to pseudo-obstruction or true anatomic blockage of the fallopian tubes **(Table 1)**.[8,9]

Salpingitis isthmica nodosa (SIN) is thought to arise from tubal inflammation of unspecified origin and affects the proximal tube prominently. Involvement of the distal tube and adhesions in pelvis and perihepatic areas, similar to PID, are also noted. Laparoscopy shows fibrosed tubal segments. Myosalpingeal hypertrophy encasing endosalpingeal diverticula is noted on histopathological examination.[8,9]

Pelvic inflammatory disease and endometriosis can cause anatomic tubal occlusion by direct involvement or secondary to adhesions.

TABLE 1: Causes of proximal tubal disease.

Pseudo-obstruction	*True anatomic blockage*
Plugs of mucus and amorphous debris	Salpingitis isthmica nodosa
Mucosal agglutination and viscous secretions	Pelvic inflammatory disease
Cornual spasm	Endometriosis
	Cornual polyps
	Intrauterine synechiae

TABLE 2: Causes of distal tubal disease.	
Pelvic inflammatory disease	85% sexually transmitted diseases • *Neisseria gonorrhoeae* • *Chlamydia trachomatis* • *Mycoplasma hominis* • 15% iatrogenic
Tuberculosis	
Peritonitis of any cause	
Tubal damage from previous surgery	
Endometriosis	

Mid-tubal disease is commonly caused by PID, endometriosis, or prior surgery-related inflammations and adhesions that cause steno-occlusions, bulbous termination, scarring, and fibrosis of tubes.

Distal Tubal Disease

Eighty-five percent of tubal infertility is due to distal tubal disease. Distal tubal disease includes hydrosalpinges and fimbrial phimosis. Hydrosalpinx is an end stage of distal tubal disease where the distal is completely occluded, whereas a stenosed fimbrial opening due to adhesions results in fimbrial phimosis.[8,9] Causes of distal tubal disease are enumerated in **Table 2.**

Iatrogenic

Tubal Sterilization

Tubal sterilization causes irreversible infertility unless tubal patency is restored. As many as 30% of women regret their decision for sterilization. Thus, tubal sterilization is an iatrogenic cause of tubal infertility that needs to be addressed.

Salpingectomy

Women who have had to have bilateral salpingectomy for ectopic gestations, tubal or tubo-ovarian pathology often needs assisted reproductive techniques (ARTs) to conceive.

EVALUATION FOR THE TUBAL FACTOR INFERTILITY—GUIDELINES AND RECOMMENDATIONS

When?

Evaluation of the fallopian tube function and patency is a component of the initial triad of diagnostic investigations for infertile couples and is the third in line after evaluation of semen and ovulation. Tests for tubal patency and function are recommended initially when the woman's history, examinations, and ultrasound evaluation are suggestive of a high risk for tubal disease. Tubal infertility should be suspected and ruled out in women with history of PID, endometriosis, prior pelvic surgery, or ectopic pregnancy. If she is considered unlikely to have tubal pathology, then evaluation of tubes is done only if she does not conceive for at least 3 months in spite of satisfactory ovulation and natural or artificial insemination around ovulation.[10] Invasive tubal patency testing should be offered depending on the treatment needs of the couple and is ideal in couples who need or opt for ovulation induction, natural conception, or intrauterine insemination (IUI).

Guidelines and Recommendations

Royal College of Obstetricians and Gynaecologists Guidelines for Investigation of Suspected Tubal and Uterine Abnormalities[11]

- Hysterosalpingography (HSG) should be offered to women with no suspicion of comorbidities (such as PID, previous ectopic pregnancy, or endometriosis) to screen for tubal occlusion.
- Where available, hysterosalpingo-contrast-ultrasonography (HyCoSy) screening for tubal patency should be considered because it is an effective alternative to HSG for women who are not known to have comorbidities.
- When comorbidities are suspected, laparoscopy and chromopertubation should be offered.
- Do not offer hysteroscopy as part of the initial investigation unless clinically indicated.

ESHRE Recommendations[12]

European Society of Human Reproduction and Embryology (ESHRE) Capri workshop in 2000 put forward three categories of tests that have established association with healthy pregnancy—semen analysis, tubal patency tests by HSG, or laparoscopy, and tests to detect ovulation.

The ESHRE 2008 guidelines recommend that semen analysis and ovulation assessment before a test of tubal patency is performed. Women suspected to have comorbidities should be offered laparoscopic assessment directly so that any treatable tubal or pelvic pathology can be evaluated and managed at the same time.

ASRM Recommendations[13]

American Society for Reproductive Medicine (ASRM) has suggested specific ruling out of tubal disease by tubal patency tests and chlamydia antibody testing.

Hysterosalpingography, saline infusion sonography (SIS), laparoscopy and chromotubation, and fluoroscopic or hysteroscopic selective tubal cannulation have all been put forward as complementary and not mutually exclusive methods for evaluating tubal patency.

More than one technique is often required for accurate diagnosis and effective treatment of tubal obstruction tests for tubal function.

ULTRASOUND EVALUATION OF FALLOPIAN TUBES

Transvaginal sonography (TVS) of the female pelvis provides valuable information with ease. In fertility evaluation, TVS is used universally almost like an extension to clinical examination. The clinical history and examination in conjunction with the TVS findings decide whether the patient has a high index of suspicion for tubal disease.

The healthy fallopian tubes are not seen on routine two-dimensional or three-dimensional (2D/3D) ultrasound imaging of the pelvis unless filled or surrounded by fluid.[14] The tubal wall is not sonologically discernible unless thickened or distended with fluid. The characteristic retort-shaped pseudoseptate appearance helps us diagnose hydrosalpinx.[15]

The diseased and distended fallopian tubes on the other hand can often be seen as adnexal masses.

The distended tubes on ultrasonography (USG) are:[15]

- Thin- or thick-walled (in chronic cases)
- Elongated or folded, tubular, and retort-shaped fluid distended structure
- Separate the uterus and ovary.

A "cogwheel" appearance from thickened longitudinal folds in a hydrosalpinx when imaged in cross section is pathognomonic of a hydrosalpinx. "Beads on a string" sign is noted when incomplete stations are present.[12]

Atypical hydrosalpinx appearance without any pseudo septation may lead it to be mistaken for an ovarian or paraovarian cyst. Densely adherent, thick, and multiloculated distended tubes may mimic a complex ovarian tumor.

TUBAL ASSESSMENT TESTS

Active pelvic infection is an absolute contraindication to performing tubal patency tests. Hence, the evaluation of fallopian tubes starts with ruling out of active pelvic infection. The testing may be performed after treatment and resolution of active pelvic infection. Thorough history taking and clinical examination play an invaluable role to assess whether a patient has a high index of suspicion for pelvic infection.

Evaluating for Pelvic Infections

Centers for Disease Control and Prevention Criteria to Diagnose and Manage PID

There is no single test or symptom that can diagnose salpingitis effectively. Even though laparoscopy was considered the gold standard to diagnose salpingitis, almost 20% of PID may show no evidence of salpingitis. The Centers for Disease Control and Prevention (CDC) criteria used to diagnose and manage PID is comprehensive and simple. PID may be treated following the parenteral or oral treatment regimens suggested by CDC as is described in the chapter on PID or may be managed in India following the syndromic management approach for sexually transmitted diseases (STDs).[16]

TABLE 3: Centers for Disease Control and Prevention (CDC) criteria to diagnose pelvic inflammatory disease (PID).

Minimum criteria	If one or more of following is present: • Cervical motion tenderness • Uterine tenderness • Adnexal tenderness
Additional criteria	• Oral temperature >101°F (>38.3°C) • Abnormal cervical discharge or cervical friability • Presence of lots of white blood cells on vaginal fluid microscopy • Elevated erythrocyte sedimentation rate • Elevated C-reactive protein • Laboratory confirmation of *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection
Most specific	• Endometrial biopsy showing endometritis • Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia) • Laparoscopic findings consistent with PID

We should also realize that about 15% of PIDs are iatrogenic with endometrial curettage, biopsy, or HSG. Intrauterine contraceptive device insertion being the main causative procedure. Hence, maintaining meticulous asepsis during the above procedures and avoiding unwarranted investigations will help decrease tubal infertility from iatrogenic PID **(Table 3)**.

Chlamydia Antibody Test[15,17]

Chlamydial infection is the most common infective cause of tubal disease. The detection of antibodies to *C. trachomatis* has been associated with tubal pathology. The meta-analysis by Broeze et al. (2011) evaluated the accuracy of different chlamydia antibody test (CAT) assays. They found that microimmunofluorescence (MIF) was significantly better than enzyme-linked immunosorbent assay (ELISA) or immunofluorescence (IF) assays.[15,17]

Chlamydia antibody test has sensitivity of only 40–50% and positive predictive value (PPV) of 60%, but high negative predictive value (NPV) of 80–90% for detection of distal tubal disease compared to laparoscopy.[15,18,19] ASRM suggests that the CAT has limited clinical utility. But in

women with low index of suspicion for tubal disease based on history and clinical examination, a negative CAT test reliably rules out the chance of tubal obstruction. The infection can be treated by treating the couple with a 14–21 day course of doxycycline.

Testing for Tuberculosis (in Endemic Countries)

Female genital tuberculosis (FGTB) is an undisputed cause for subfertility in countries like India where tuberculosis (TB) is endemic (incidence up to 16% in subfertile women).[20] It causes extensive tubal and endometrial damage. The fallopian tubes are involved in 90–100% cases. Ruling out of TB and curative treatment when diagnosed should be done prior to tube testing, and is ideal in women with hypomenorrhea, thin endometrium, or features of chronic PID. FGTB often coexists with other causes of PID like chlamydia and gonorrhea.

Female genital TB diagnosis is challenging as isolation of *Mycobacterium tuberculosis* by culture which is considered the requisite for diagnosis is often unreliable. A high index of clinical suspicion and multimodality testing is recommended. Genital TB may be diagnosed when one or two of the tests turn positive for TB. Premenstrual endometrial aspiration or biopsy and nucleic acid amplification (NAA) [TB polymerase chain reaction (PCR)] allow for rapid diagnosis and help to detect mycobacterial DNA in 80.9% of genital TB-suspected patients.[21] However, the PCR cannot differentiate between active and latent infection and may be unreliable in identifying the cases that actually require treatment. Hence, endometrial sampling and TB stain, BACTEC culture, histopathological examination for tubercles, and diagnostic laparoscopy are used in conjunction with TB PCR to diagnose genital TB. The new self-contained cassette-based analysis (GeneXpert) is faster than PCR and helps to identify rifampicin-resistant TB also.[21] TB when diagnosed has to be treated with appropriate antitubercular agents for 9 months.

Tubal Patency Tests

The various tests used to assess tubal patency and functional integrity are enumerated in **Figure 1** in the order of their coming into vogue. HSG/HyCoSy are the screening tests that are to be considered for tubal patency evaluation in women with no history/examination suggestive of tubal disease. In women with or without suspicion of comorbidities that can cause tubal disease and in women with inconclusive or positive screening on HSG/HyCoSy laparoscopy accompanied by hysteroscopy is to be offered as the gold standard for testing tubal integrity.

Laparoscopy and Chromopertubation

Laparoscopy is the gold standard for diagnosing tubal patency and inflammation. It is a minimally invasive procedure which allows visualization of the pelvic anatomy

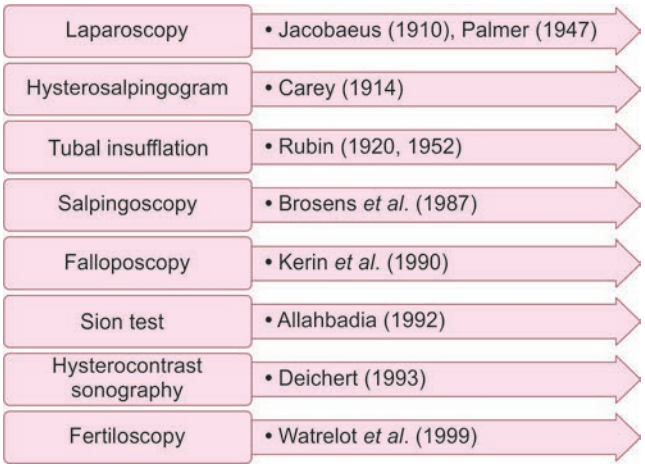

Fig. 1: Tests used to assess tubal patency and functional integrity.

and pathology, and spill of dye from the tube is seen. It allows diagnosis assessment and management of peritubal disease, adhesions, and endometriosis. Laparoscopy enables biopsy of suspicious lesions for further evaluation. Provided appropriate consent is taken, laparoscopy allows for surgical correction of pathology detected, where feasible.

Laparoscopy is a better predictor of fertility prognosis compared to other tubal tests like HSG and hence, the performances of other tests are compared to those of laparoscopy.[22] Although laparoscopy is considered the standard, it is not without error as around 3% of patients diagnosed with bilateral tubal block conceive spontaneously. Laparoscopy requires general anesthesia, creation of pneumoperitoneum as well as surgical skill and experience to perform. It is advocated in women suspected to have tubal infertility having comorbidities like PID, previous ectopic pregnancy, and endometriosis or history of appendicitis.

Laparoscopy has the distinct advantage that it can be complemented with hysteroscopy, falloposcopy, and salpingoscopy.

Falloposcopy introduced by Kerin is hysteroscopic proximal fallopian tube endoscopic examination using a flexible microendoscope (0.5 mm diameter, 1.73 mm length, 50× magnification), and guided catheterization.[23,24]

Salpingoscopy introduced by Brosens and Putemans (1987) is an endoscopic visualization of the distal tubal lumen via a laparoscopic approach. A 2.8-mm diameter telescope, within a 5 mm sheath that fits to the operating channel (5 cm longer than sheath), is used alongside a 10 mm operating laparoscope. A conical obturator helps the distal end of the sheath to enter the tubal ostium.

Laparoscopic Diagnosis and Grading of Salpingitis [25,26]

Laparoscopic diagnosis and grading of salpingitis are shown in **Table 4**.

TABLE 4: Jacobson and Weström laparoscopic criteria to diagnose and grade salpingitis.

Minimum visual criteria to diagnose salpingitis	• Pronounced tubal surface • Hyperemia • Tubal wall edema • Presence of exudates on tubes and from fimbriae when patent
Mild salpingitis	• Minimum visual criteria, mobile tubes • Patent ostia
Moderate salpingitis	• More evident inflammation, patchy fibrin deposits on tubes • Loose tubal and pelvic adhesions • Tubes not freely mobile
Severe salpingitis	• Intense congestion • Dense adhesions to pelvic structures • Pyosalpinx • Tubo-ovarian masses
Each adnexa should be graded separately	
The overall grade is that of the more severe pathology	

TABLE 5: Three hysterosalpingography (HSG)-based categories of tubal patency.[9]

Category 1 (normal)	***Category 2 (patent tube with tubal disease)***	***Category 3 (patent or blocked tubes, severe tubal disease)***
• Patency with free spill • Preserved distal tubal folds • Normal proximal, mid, distal tubal dimensions, and appearance • No fimbrial end clumping • No detected peritubal disease, normal tubal pressures with free flow • Lack of sharp pain on forceful flushing	• Patency with good spill • Almost fully preserved distal tubal folds, normal to slightly altered tubal dimensions • ±Fimbrial end clumping • ±Peritubal disease • Normal or elevated tubal pressures	• Patent/blocked tubes • Loss of distal tubal folds • Altered proximal, mid, distal tubal dimensions, and appearance with dilatation/narrowing/scarring/tubal rigidity • Fimbrial end dilatation/narrowing with clumping present peritubal disease may or may not be seen • Usually elevated tubal pressures but may be normal

Hysterosalpingography

Hysterosalpingography is an inexpensive and widely available screening test to rule out unilateral or bilateral tubal block and provides a permanent visual record of the uterus and tubes.

It involves instillation of approximately 10 mL water-soluble radiocontrast transcervically and serial X-ray imaging of the pelvis to visualize the uterine cavity, delineate the tubes, and to assess peritoneal spill. Cornual tubal spasm is the main reason for lower accuracy of this diagnostic imaging technique. Gentle handling and administration of an antispasmodic tablet or injection prior to the procedure tackles this problem effectively. PID and pregnancy are the two contraindications for performing HSG. Therefore, it is ideally performed in the late follicular phase (day 7–12) following a normal menstrual cycle. Performing the HSG with an oil-based radiopaque dye has been associated with increased live birth rates. In spite of this, water-based dye is preferred due to better image quality and safety.[27] Oil-based dyes may cause oil embolization or granulomas. The conventional HSG is safe as radiation exposure is only 0.4–5.5 mGy, much below the 100 mGy safety threshold for teratogenicity.

Hysterosalpingography has a low sensitivity of 53–65% and a high specificity of 83–87%, PPV of 38%, and NPV of 94%, i.e., HSG is a reliable indicator of tubal patency if bilateral spill is noted on evaluation.[13,28]

An abnormal HSG helps predict proximal tubal blockage and hydrosalpinges with moderate accuracy while it is very inaccurate in diagnosing or ruling out distal tubal obstruction and peritubal adhesions. Although an HSG might look normal, hydrosalpinges remain undiagnosed.[24]

Advanced HSG may be done with using fluoroscopic guidance, manipulation, tubal cannulation, and tubal pressure to yield more information and increase reliability of testing.[9] The information so gathered may be used to categorize tubal disease into three, based on which we can decide appropriate management.

- *Category 1:* Normal: Good chance for future fertility
  - Very low incidence of ectopic pregnancy
- *Category 2:* Patent tube with tubal disease:
  - 2a—mild tubal disease
  - 2b—moderate tubal disease
  - Moderate prognosis and outcome future fertility
  - Highest incidence of ectopic pregnancy
- *Category 3:* Patent or blocked tubes, severe tubal disease:
  - ART ideal
  - Very low incidence of ectopic pregnancy.

The HSG category allotment criteria are enumerated in **Table 5**.

Selective Salpingography and Tubal Catheterization/ Ultrasound or Hysteroscopy-guided Tubal Cannulation

Fluoroscopy-guided transcervical proximal tubal cannulation and selective salpingogram to identify and dislodge proximal tubal block were introduced by Corfmann and Taylor in 1966. Later, hysteroscopic and ultrasound-guided proximal tubal cannulation[29,30] became more commonly used modalities to identify and tackle proximal tubal obstruction due to spasm, plugs, and adhesions.

Sonohysterosalpingography

Sonohysterosalpingography is a test to determine tubal patency using transcervical fluid instillation, the filling and flow of which is monitored by transvaginal ultrasound monitoring. Although tubal patency can be observed by the appearance of fluid in the cul-de-sac with the saline infusion, the test does not differentiate between unilateral and bilateral patency.[13] The two common methods used are Sion's test or SIS and HyCoSy. Use of 3D ultrasound and color or power Doppler for sonographic visualization of insufflated tubes helps in identifying tubal and uterine pathology clearly.

The uterine cavity is insufflated slowly with about 300 mL plain saline (Sion's test), mixture of air and saline, or solution of galactose and 1% palmitic acid (Echovist, Levovist for HyCoSy), etc., after catheterizing the cervix with a narrow (no. 8 Foleys) catheter.

Where available, sonohysterosalpingography is a better alternative to HSG, as it has higher sensitivity and specificity of 76–96%, and 67–100%, respectively.[8,13]

Tubal Insufflation Test (Rubin's Test)

Rubin's insufflation test involves pushing air or carbon dioxide gas under pressure transcervically and noting whether it reaches the peritoneal cavity. Fall in pressure when the gas pressure rises above 120 mm Hg, hissing sound on auscultation at iliac fossa, and shoulder pain (due to gaseous irritation of diaphragm) were considered as signs of tubal patency. Tubal insufflation is now obsolete as patency testing is very subjective and unreliable and cannot identify the site or side of blockage.

Transvaginal Hydrolaparoscopy and Fertiloscopy

Transvaginal hydrolaparoscopy (THL) involves small diameter endoscopic visualization of the pelvis after instillation of 500 mL of a fluid medium through a needle inserted through posterior vaginal fornix. When hysteroscopy, falloposcopy, and distal tubal salpingoscopy are done along with THL, it is termed fertiloscopy.[31] Fertiloscopy provides a wealth of information, although consensus guidelines on how to interpret and put the findings into use has not yet been laid.

Fertiloscopy may be done in an outpatient procedure under local anesthesia. Minor adhesiolysis, endometriosis fulguration, etc. may be performed concurrently.[31]

The risk of bowel injury is much higher as compared to laparoscopy and THL is not useful in evaluating women with an obliterated pouch of Douglas.

Fertiloscopy findings are almost identical to laparoscopy findings and are reliable. The expensive instruments needed and lack of procedural experience may be the reason why THL is not commonly done.

The tubal assessment tests are summarized in **Table 6**.

MANAGEMENT OF TUBAL INFERTILITY

- Preventive approaches
- Identifying and treating pelvic infection/inflammation
- In established tubal disease, management depends on:
  - Site and extent of the tubal disease:
    - Unilateral or bilateral
    - Proximal or distal
    - Mild/moderate/severe tubal disease
  - Age of the patient
  - Duration of fertility
  - Ovarian reserve
  - Prior fertility
  - Presence of other infertility factors
  - Experience of the surgeon if tubal surgery is planned
  - Success rates of the in vitro fertilization (IVF) program or restorative surgery.

TABLE 6: Tubal assessment tests—summary.[8]

Test	*Sensitivity*	*Specificity*	*Limitations*	*Complications*
Laparoscopy—Gold standard	Unknown (no comparator)	Unknown	• Invasive • General anesthesia • Skill requirement expensive	Bowel/urological/vascular injury 0.13%
Hysterosalpingography	53–65%	83–87%	Failure to catheterize/cannulate, leak of dye around cervix, tubal spasm or debris causing false +ve report reporting errors	Anaphylaxis PID 3.1%—radiation exposure ~2 gray
HyCoSy	93.3%	89.7%		PID
SSTC	Unknown (lack of data)	Unknown	Unclear	Tubal perforation 2%
Fertiloscopy	86%	100%		Rectal injury 0.61%
Chlamydia antibody test	21–90%	29–100%		Unknown

(HyCoSY: hysterosalpingo contrast-ultrasonography; PID: pelvic inflammatory disease; SSTC: selective salpingography and tubal catheterization)

Prevention of Tubal Infertility

Prevention of tubal pathology from emerging is the best way to mitigate tubal causes of infertility.

Strategies include:

- General education and awareness to decrease the incidence of sexually transmitted infection (STI) and PID
- Proper precautions to reduce the incidence of iatrogenic PID/peritubal adhesions
- Early identification and treatment of STI and PID and treatment of the partners
- Identifying patients with unfavorable reproductive microbiome and optimizing their health to reduce the risk of infections.

Reproductive Tract Microbiome

Women undergoing IVF with tubal factor infertility (a pathology associated with infections) were found to be more likely to have a vaginal microbiota consistent with bacterial vaginosis (BV) by analysis of smears.[58] Studies have shown that presence of unfavorable non-lactobacillus dominant microbiomes are significantly more in infertile women.

Identification and Treatment of Sexually Transmitted Disease and Pelvic Inflammatory Disease

We should exert a high index of suspicion to diagnose and treat STI and PID in infertile couples as these are major culprits causing and worsening tubal infertility.

In Vitro Fertilization for Tubal Infertility

In vitro fertilization was originally developed to allow couples with untreatable tubal infertility to conceive and enjoy the joys of parenthood. Thus, IVF and embryo transfer (ET) remain ideal therapeutic options to achieve intrauterine pregnancy in women with absolute tubal infertility. Also, IVF is the treatment modality to be opted when there are other problems like male factor infertility, resistant anovulation, etc., contributing to infertility.

The ideal management of severe tubal disease, especially with hydrosalpinx and severe fimbrial phimosis is always IVF and ET after salpingectomy or occlusion of hydrosalpinges.[32]

However, IVF is an expensive treatment modality, and for some, unacceptable. IVF is also associated with complications like ovarian hyperstimulation syndrome (OHSS) and multiple pregnancies that cause significant morbidity and expenses. Women with mild or unilateral tubal disease may benefit from treatment approaches like IUI or tubal reconstructive surgery. Tuboplasty may be tried in women who cannot accept or afford IVF. The 2017 Cochrane review found that well-controlled randomized clinical trials (RCTs) or high-quality evidence comparing the post tuboplasty reproductive outcomes for diseased tubes with IVF are not available yet.[33]

Ovarian stimulation with IUI may be offered initially to patients with unilateral proximal tubal occlusion often obtaining satisfactory results. However in women with mid-distal or distal tubal occlusion on HSG, the IUI after ovarian stimulation is ineffective. They require laparoscopic evaluation and often IVF.[34]

On the other hand, tubal reanastomosis for infertility due to tubal sterilization offers a cumulative pregnancy rate that is comparable or even higher than IVF although the per cycle pregnancy rate is higher in IVF.[32] A cost-effectiveness analysis found that ongoing pregnancy rates were 75%, 66%, and 44% for maternal ages <35 years, 35–40 years, and >40 years in women undergoing tubal anastomosis while they were 46%, 35%, and 16% in women undergoing fresh IVF cycle for tubal infertility. They found that sterilization reversal was the most cost-effective approach for most women younger than 41 years, while IVF remained the best approach for women >41 years of age.[35]

Reconstructive Surgery for Tubal Infertility

Tubal surgery to overcome infertility is becoming an attractive option to many, as the benefits obtained from tubal surgery would potentially be sustained for many years and may allow conception through intercourse or IUI. However, tubal surgery requires specialized skill development.[33] Its efficacy has to be weighed against the cons of expenses, risk of tubal ectopic pregnancy (7–18%), reocclusion, and failure to conceive.[8]

Tubal restorative surgery is most effective in younger women with mild or moderate tubal disease. Integrity of the endosalpinx and mesosalpingeal thickening are the most important predictors of successful intrauterine conceptions following surgery. At least 50% of the endosalpinx should be healthy to ensure favorable outcomes. Tubal reconstructive surgeries include those for proximal tubal disease, distal tubal disease, and sterilization reversal **(Table 7)**.

Microsurgical Techniques[36]

Microsurgery was introduced into gynecology specifically to improve tubal reconstructive surgery outcomes. The microsurgical techniques should be applied universally for all tuboplasty irrespective of the approach (laparoscopy or laparotomy). The microsurgical principles include:

- Surgery under magnification—using a binocular microscope (20×) and/or loupe magnifier (6×)
- Gentle handling of tissues
- Use of lightweight microsurgical instruments (13–15 mm length)
- Use of fine sutures (7-0 to 10-0)
- Use of fine tapered needles (135° curvature, 50–150 μm diameter)

TABLE 7: Surgical management for hydrosalpinges.[32]

Method	*Advantages*	*Disadvantages*
Salpingectomy (laparoscopic)	• Total removal of chronically inflamed tissue • No further risk of abscess formation or torsion • Increased the accessibility of the ovary for oocyte pick up	• Invasive procedure, difficult if tube buried in adhesions • Interstitial/cornual pregnancy and rupture may rarely occur • May hamper with ovarian vascularity and function
		All chances of spontaneous conception lost
Tubal occlusion: • Electrocautery • Clips • Hysteroscopic-Essure microinsert	• Less invasive • Easier than salpingectomy when dense adhesions are present	Risk of abscess formation or torsion
Aspiration (Transvaginal/laparoscopic)	• Less invasive, easy • Tube retained	• May flare up infection • Recurrence of hydrosalpinx
Salpingostomy	Less invasive, easy	• Recurrence of hydrosalpinx • Increased risk of tubal ectopic pregnancy

- Meticulous hemostasis with electrocautery devices having microelectrodes, fingertip controls, and lowest current setting
- Copious irrigation
- Sharp precise dissection by an experienced surgeon who is ideally seated on the opposite site to the tube being operated on.

As laparoscopic visualization offers a significantly magnified view, the microsurgical approaches are applied more easily.

Surgery for Proximal Tubal Disease

Proximal tubal cannulation: Hysteroscopic proximal tubal cannulation or fluoroscopic selective salpingography and proximal tubal catheterization are effective modes to assess and treat proximal tubal obstruction due to tubal debris, sludge, and intraluminal adhesions. Proximal tubal cannulation may be done under sonological guidance too.[30] Ideally, proximal tubal cannulation is done after confirming that the distal tube is normal using prior laparoscopic evaluation. Gentle pressure and flushing by the cannula inserted through the cornual tubal ostia is enough to overcome mechanical obstruction of the proximal tube.[3,10] Tubal perforation may occur in 3–11% cases but does not cause any clinical consequences. Tubal cannulation relieves obstruction in approximately 85% and around half the patients conceive.[3,10] The meta-analysis by Holden et al. found that although fluoroscopic and hysteroscopic tubal canalization achieved similar patency rates, ongoing pregnancy rates were more following hysteroscopic tubal cannulation.

Tubal resection and reanastomosis: Proximal tube disease like SIN causes extensive intraluminal and mesenchymal damage of the proximal tube. IVF and ET are the best treatment options. Where IVF is not acceptable or possible, diseased proximal tubal resection and reanastomosis of tubes is the best option as it is associated with higher pregnancy rates compared to expectant management or proximal tubal cannulation.[37]

Surgery for Distal Tubal Disease

Surgical reconstruction for damaged distal tubes may be offered in mild to moderate disease where at least 50% of the endosalpinx and tubal wall is healthy.

Extent of tubal mucosal damage and increase in wall thickness are the most important determinants and are inversely related to successful tubal restorative surgery outcomes.[38]

The best prognosis is seen in patients with mildly dilated tubes (<3 cm) having thin and pliable walls, undamaged endosalpinx with intact mucosa, and only filmy adnexal adhesions.

Neosalpingostomy (opening up of a blocked distal tube) and *fimbrioplasty* (widening of stenosed distal tubal ostia) are commonly done to restore the fallopian tube patency. *Salpingo-ovariolysis* that involves the release of adhesions binding the tubes and ovaries restoring the normal tubo-ovarian relation is done alongside the above two options.[12,39]

American Society for Reproductive Medicine recommends that the reconstructive surgeries be done laparoscopically as they are less risky, less invasive, and associated with the same treatment outcomes as in laparotomy.[37]

Laparoscopic opening of mild or even moderately diseased tubes offers a satisfactory pregnancy outcome in comparison with IVF.[38]

Intrauterine and ectopic pregnancy rates after neosalpingostomy for mild hydrosalpinges range from 58% to 77% and from 2% to 8%, respectively. For severe disease, these values were 0–22% and 0–17%, respectively.[13,38,40]

Sterilization Reversal

Tubal sterilization reversal may be accomplished by opening the occluded ends of the proximal and distal segments and anastomosing them with fine nonreactive sutures using non-microsurgical or magnification and microsurgical techniques.[13] Microsurgical techniques require training and experience so that the gynecologist can operate using binocular or loupe magnification allowing precise placement of fine sutures (7-0 to 10-0) as well as undistorted and tension-free approximation of tissue edges. Tubal reanastomosis success depends on multiple factors including the woman's age, ovarian reserve, the sterilization procedure she underwent as well as the endoluminal and surface integrity of the tube left behind.

The age of the woman is the most important predeterminant for pregnancy rates following tubal reversal. The younger the woman, the better the pregnancy rates. Women <40 years have cumulative intrauterine pregnancy rates as high as 70% and 90%, respectively, following non-microsurgical and microsurgical reversal of tubal sterilization.[41] Another study noted that significantly higher cumulative pregnancy rates obtained and lesser cost per delivery incurred following tubal reanastomosis compared to IVF in women younger than 37 years.[42] The rate of ectopic pregnancy following tubal reanastomosis is 2–10%, compared to 2% for IVF.

Sterilization reversal success rate is inversely related to the extent of tubal damage that occurred during the sterilization procedure and directly related to the length of healthy tube retained. Understandably the reversal success rates are more when the tubes were either clipped or ringed, compared to sterilization by Pomeroy's method (as large lengths of tube may be removed) or by electrocautery where the cautery energy may cause irreversible functional damage to the tube. Some methods of sterilization like fimbriectomy are irreversible and IVF is the fertility option to be opted.

Isthmus to isthmus reanastomosis and longer final tubal lengths (>4 cm) are generally thought to yield higher success rates. Traditionally tubal reanastomosis is done via laparotomy as it is an easier approach to implement microsurgical tubal reanastomosis effectively. Laparoscopic microsurgical tubal reanastomosis requires good laparoscopic suturing skill and experience but have comparable outcomes to laparotomy sterilization reversal.[13] Recently, robotic laparoscopic tubal reconstruction is also being applied.

Destructive Tubal Surgery Followed by IVF—For Severe and Bipolar Tubal Disease and Hydrosalpinx

Tubal reconstruction is not beneficial for women with severe and/or bipolar (both proximal and distal) tubal disease. The presence of unresolving hydrosalpinx is pathognomonic of severe tubal disease and is associated with poor ART outcomes. In such cases salpingectomy, tubal occlusion or clipping followed by IVF is the preferred treatment to conceive. All sonologically detectable hydrosalpinges should be removed or occluded prior to applying ART.

In vitro fertilization was developed primarily to allow pregnancy in women with tubal infertility, but paradoxically it was noted that IVF outcomes were poorer in women with extensive tubal disease as in hydrosalpinges. Poor implantation rates and higher miscarriage rates were noted.[43-45] RCTs have reported that IVF and ET following salpingectomy restore the rates of pregnancy and live birth to levels similar to those of women without hydrosalpinx who were treated with IVF.[46,47]

It is believed that the hydrosalpinges adversely affect the various embryo–endometrial interactions involved in implantation. At the molecular level, hydrosalpinges have been associated with reduced αvβ3 integrin and leukemia inhibitory factor (LIF) expressions as well as decreased *HOXA10* (homeobox gene) expression in the endometrium that hamper implantation.[48]

The hydrosalpingeal fluid is considered the main culprit for deleterious IVF outcomes though why it is so, is still unclear. It contains various cytokines and growth factors which may be toxic to gametes or embryos.[49] Bathing of the endometrial cavity in hydrosalpinx fluid may hinder embryo endometrium cross talk and cause potential embryo toxicity.[50,51] The mechanical effects exerted by hydrorrhea through the uterine cavity may cause changes in endometrial peristalsis that may washout or hinder implantation of the transferred embryo.[45] Furthermore, the hydrosalpinges provide unfavorable environment for early follicular recruitment.

The best method to detect hydrosalpinx is by routine 2D TVS (sensitivity: 84.6%; specificity: 99.7%). HyCoSy is ideal to assess the uterine cavity and tubes in women with two more unexplained implantation failures as sonography distending and visualizing the tubal and uterine lumen will reveal pathologies like intrauterine polyps or adhesions and hydrosalpinges that were not detected on routine evaluation.[8]

The less invasive laparoscopic salpingectomy is the preferred approach. The tube is delinked by coagulating and dividing the proximal tube close to the cornua. The mesosalpinx is then serially coagulated and cut, staying close to the tube to avoid compromising the ovarian blood supply.[13,37]

A Scandinavian RCT published in 1999 that included 141 women showed that salpingectomy prior to IVF in all transvaginal ultrasound detectable hydrosalpinges improved IVF outcomes in terms of increased pregnancy and delivery rates. This was especially proven in women with bilateral hydrosalpinges. The histopathological examination of the

tubes showed that >90% of the tubes showed pathology that could not be corrected by restorative tubal surgery.[52] Thus hydrosalpinges that are detectable on ultrasound almost always represent dysfunctional and uncorrectable tubal pathology.

Strandell et al. in 2001 provided reassuring evidence that the salpingectomy prior to IVF does not compromise ovarian function.[53] Salpingectomy for hydrosalpinges also does not adversely influence the response to ovarian stimulation or alter IVF parameters.[53]

The 2010 Cochrane on surgical treatment of tubal disease for IVF reviewed five RCTs including 646 women. Outcomes following laparoscopic salpingectomy, laparoscopic tubal occlusion, and USG-guided aspiration were compared. They found that the ongoing pregnancy rates and clinical pregnancy rates were increased with laparoscopic salpingectomy prior to IVF, while laparoscopic tubal occlusion was associated with significant increase in clinical pregnancy. IVF outcomes following salpingectomy and tubal occlusion were similar. Ultrasound-guided aspiration of hydrosalpinx (covered with intravenous amoxicillin + clavulanic acid followed by oral azithromycin for 3 days) was found to be effective in one RCT although no significant improvement in pregnancy rates were noted.[54] The adverse effects following the different surgical techniques were not significantly different.[32]

They concluded that both laparoscopic salpingectomy and tubal occlusion (electrocautery delinking or proximal tubal clipping) prior to IVF improved pregnancy rates. Hence, the less invasive laparoscopic occlusion may be considered as an alternative to salpingectomy.[32]

Dreyer et al. (2016) noted that the ongoing pregnancy rates were significantly lower in ART cycles following hysteroscopic occlusion compared to laparoscopic salpingectomy.[55]

From the above discussion, it is clear that hydrosalpinges left unattended prior to IVF are associated with poorer pregnancy rates. So, all hydrosalpinges detected prior to IVF should ideally be occluded or removed. Concurrent transvaginal aspiration of hydrosalpinges noted during oocyte pick up reduces their presence at the time of ET but whether it improves clinical outcomes is still under debate.[32]

MANAGEMENT OF TUBAL ECTOPIC PREGNANCY

Management of ectopic pregnancy is being addressed here as ectopic pregnancy is often a consequence of tubal pathology which worsens the tubal integrity. When managing ectopic pregnancy, the aim is to restore the chance of natural fertility where feasible weighing is against the risks of life-threatening repeated occurrence of ectopic pregnancy. In women presenting with ectopic pregnancy who require surgical management, we need to provide the patient appropriate treatment, by educating her regarding the plausible intraoperative findings and factoring in her priorities and concerns before deciding the surgical treatment.

The UK guidelines state that in the event of an ectopic pregnancy requiring surgical management:

- A laparoscopic surgical approach is preferable to an open approach (unless the patient is decompensated, when laparotomy is the best strategy).
- In the presence of a healthy contralateral tube, salpingectomy is preferred to salpingotomy.
- In women with a history of fertility-reducing factors (previous ectopic pregnancy, contralateral tubal damage, previous abdominal surgery, previous PID), salpingotomy should be considered, after informing about the risk of persisting trophoblast and need for serial beta human chorionic gonadotropin (β-hCG) monitoring.

This rationale is based on reliable published evidence showing increased intrauterine pregnancy rates without resorting to assisted reproduction strategies, when salpingotomy was resorted to in women presenting with ectopic pregnancy, in whom the contralateral tube was likely to be diseased due to the presence of preexisting comorbidity or on appearance.[56-58]

KEY POINTS

- Pelvic inflammatory disease causing salpingitis and tubal infertility should be diagnosed early and treated following the CDC guidelines.
- HSG is the recommended first-line test to assess tubal patency, but where available sonohysterosalpingography using saline or contrast to visualize the uterine cavity and tubes is preferred.
- Laparoscopy and chromopertubation is the current gold standard to assess tubal patency and should be offered as a first-line test for women with a history of pelvic comorbidities like endometriosis and PID.
- IVF and ET is the best option to achieve intrauterine pregnancy in severe tubal disease.
- IVF is also the best option for tubal infertility when associated with other factors like abnormal semen parameters, anovulation, and rapidly declining ovarian reserve.
- Tubal cannulation is recommended for proximal tubal obstruction in young women with isolated tubal factors as it restores patency in most of the cases.
- Tubal reconstructive surgery—laparoscopic neosalpingostomy or fimbrioplasty improves fertility in young women with isolated tubal factor infertility due to mild distal tubal disease.
- Microsurgical tubal sterilization reversal is recommended in women younger than 40 years as the subsequent cumulative pregnancy rates are comparable if not higher than IVF pregnancy rates. It is also more cost-effective.

- Laparoscopic salpingectomy or proximal tubal occlusion is recommended prior to IVF in all cases of sonologically detected hydrosalpinges and severe tubal disease to improve IVF pregnancy rates.

CHAPTER 35

Infections and Infertility

Chandrika Kulkarni

INTRODUCTION

Infertility is a consequence of a number of factors. The causes could be hormonal, infectious, gonadal, or unexplained.[1] About one-third of women with fertility problems are, in fact, afflicted with tubal and peritoneal changes affecting the tubo-ovarian relationship. The specific and nonspecific bacterial infections of the genital tract majorly contribute to these alterations. The World Health Organization (WHO) estimated that nearly 1 million people become infected every day with any of the four curable sexually transmitted infections (STIs): Chlamydia, gonorrhea, syphilis, and trichomoniasis.[2] The complications of curable STIs include pelvic inflammatory disease (PID), ectopic pregnancy, infertility, chronic pelvic pain, seronegative arthropathy, and neurological and cardiovascular diseases.[3] Several STIs including *Chlamydia trachomatis* and *Neisseria gonorrhoeae* have been found to be important causal factors of infertility. However, there are no definitive evidence linking other organisms such as *Mycoplasma* and *Trichomonas vaginalis* (TV) to tubal damage and subsequent infertility.[4] Pelvic tuberculosis is an important cause of salpingitis and has been dealt with in detail in a different chapter.

Nontuberculous salpingitis can be divided into chlamydial, gonococcal, and nongonococcal–nonchlamydial disease based on the results of endocervical or peritoneal fluid cultures.[5]

CHLAMYDIA

Prevalence

Chlamydia remains the most commonly diagnosed bacterial STI in high-income countries despite widespread testing recommendations, sensitive and specific noninvasive testing techniques, and cheap effective therapy.[2] It is more common in sexually active young adults (15–24 years) and also in patients with secondary infertility.[6,7] Incidence varies widely, ranging between 2.2 and 10.7%.[8,9] Earlier studies had shown a higher prevalence of chlamydia to the tune of 20–28%.[6,8] Studies in developing countries such as India have shown a similar prevalence (19.9–23%).[10,11]

Microbiology

Chlamydiae are obligate intracellular bacteria. They are spherical or ovoid in shape. They have a peptidoglycan-free cell wall similar to that of gram-negative bacteria. Their intracellular nature differentiates them from other bacteria. Unlike viruses, chlamydia possesses both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Chlamydia exists in two forms—the infective form, called the elementary body, is the extracellular form, and the intracellular form or the reticulate body is required for intracellular survival and multiplication.[12,13]

There are three types of chlamydial species which infect humans namely, *C. trachomatis, Chlamydia psittaci,* and *Chlamydia pneumoniae. C. trachomatis* is the species causing the STI.[14]

Pathophysiology

The main targets of chlamydia infection are the columnar epithelial cells.[15] The cells which are infected with chlamydia secrete chemokines which attract leukocytes and cytokines leading to inflammatory response.[16] The inflammatory response is also thought to be mediated through heat shock protein.[17] This inflammation leads to direct damage of the tissues and eventual fibrosis and scarring—the hallmark of chlamydia-induced oviduct disease.[18] *C. trachomatis* infection can lead to irrevocable damage in the fallopian tubes, including proximal and distal tubal occlusions. Multiple sequelae can result from *C. trachomatis* infection among women, the most serious of which include PID, ectopic pregnancy, and infertility.[7]

Infection of the endosalpinx can also produce peritonitis by contiguous spread, including perihepatitis (Fitz-Hugh–Curtis syndrome). Chlamydia also causes urethritis, cervicitis, epididymitis, proctitis, and reactive arthritis. PID is seen in 20% of the infected women and around 4% will

have chronic pelvic pain. Infertility as a squeal is seen in 3% of women.[19]

Risk factors for chlamydial infection:
- Young age <25 years
- New sexual partner within the past year
- Use of nonbarrier contraception
- Poor socioeconomic status
- Other STIs.

Clinical Features

The incubation period for the onset of symptoms is longer in chlamydia when compared to other bacteria because of the longer half-life (24–48 hours). A large number of women (around 80%) are asymptomatic,[20] and some women may present with vaginal discharge, dysuria, intermenstrual bleeding, or postcoital bleeding. Untreated infection may lead to mucopurulent cervicitis, acute urethral syndrome, and PID.[21]

On examination, cervix may appear reddened and friable with contact bleeding. Patients with Fitz-Hugh–Curtis syndrome may present with right upper quadrant pain. Women with chlamydial infection may have gonorrhea and vice versa.[5]

Symptoms are more common in men with chlamydial infection when compared to women. The chief symptoms in men are dysuria and urethral discharge. They may also develop epididymo-orchitis with pain and swelling of testis or the epididymis.[20]

Diagnosis

Urogenital chlamydial infection can be diagnosed by testing the first-catch urine sample, swabs from endocervix or vagina, and swabs from urethra.[22] Culture confirms the presence of viable organisms. However, antigens, antibodies, and nucleic acid can be present even in the absence of viable organisms. Chlamydial antigens can be detected using commercially available enzyme immunoassays (EIAs).[20,23] The EIAs usually use monoclonal or polyclonal antibodies to detect the lipopolysaccharide (LPS). Nucleic acid amplification tests (NAATs) are more sensitive (90–95%) and specific (97–99%) than other tests such as culture, microscopy, and immunoassay and are therefore recommended.[19,22] The specimen of choice for detecting chlamydia in women is a vulvovaginal NAAT test, either self-collected or taken by the clinician. In men, a "first-catch urine sample" or urethral swab is the specimen of choice.

Management

Annual screening of all sexually active women aged <25 years is recommended, as is screening of older women at increased risk for infection (e.g., women aged ≥25 years who have a new sex partner, more than one sex partner, a sex partner with concurrent partners, or a sex partner who has an STI).[7,24] Contact tracing and treatment forms an important part of the treatment strategy. Infected patients should also be screened for other STIs such as human immunodeficiency virus (HIV), hepatitis B surface antigen (HBsAg), hepatitis C virus (HCV), and gonorrhea. Pregnant women with chlamydia should be treated to prevent transmission of infection to the neonate; however, doxycycline used in the regimen is contraindicated.[25]

To minimize disease transmission to sex partners, persons treated for chlamydia should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen and resolution of symptoms if present.[7]

Recommended antibiotic treatment according to Centres for Disease Control (CDC)[7] has been given in **Box 1**.

BOX 1: Recommended regimen for chlamydial infection among adolescents and adults.

- *Doxycycline* 100 mg orally 2 times/day for 7 days

Alternative regimens:

- *Azithromycin* 1 g orally in a single dose

or

- *Levofloxacin* 500 mg orally once daily for 7 days

GONORRHEA

Prevalence

Gonorrhea is still one of the important causes for infertility in developing Asian and African countries.[26] However, it is the second most common cause of bacterial STI in the United Kingdom and United States of America.[7] Gonococcal infection is most common in sexually active young people in the age group of 15–24 years. A study in Mumbai sexually transmitted disease (STD) clinic found a prevalence of 9.2%. It was found that the prevalence of gonococcal infection was more common than in those with HIV.[27]

Microbiology

Gonococcal infection is caused by *N. gonorrhoeae* which is found in the neutrophils of the infected host. In 1879, Albert Neisser isolated this gram-negative bacterium. *N. gonorrhoeae* is typically intracellular, aerobic, coffee bean shaped and appears in pairs (diplococci). *N. gonorrhoeae* and *N. meningitidis* are the only two pathogenic species of the total 11 species found in humans.[27,28] It can be cultured in Thayer–Martin media which is a chocolate-enriched agar in the presence of carbon dioxide.[27]

Pathophysiology

Traditionally, it was thought that *N. gonorrhoeae* gets attached to spermatozoan and ascends up the female genital tract. But this does not explain the transmission of

the disease from female to male. Anderson et al.[29] suggest that rather than "surf" on wiggling sperm, the bacteria use pili which are hair-like structures to anchor to sperm surface proteins and move through semen.

Neisseria gonorrhoeae infects the mucous membranes of the urethra, endocervix, rectum, pharynx, and conjunctiva by direct inoculation of infected secretions. The most common site of *N. gonorrhoeae* infection is the urogenital tract. *N. gonorrhoeae* infects the nonciliated tubal cells, but the toxin produced also destroys the adjacent ciliated cells which play a major part in transport of fertilized eggs toward the uterus. The gonococcal LPS targets the ciliated cells by upregulating the tumor necrosis factor alpha.[30]

About 10–20% of infected women suffer from ascending infections resulting in PID. These PIDs can further lead to other complications such as salpingitis, endometritis, and tubo-ovarian abscess, which promote ectopic pregnancy, sterility, and chronic pelvic pain.[31]

Clinical Features

More than 50% of the women may be asymptomatic. Rest of those infected may present with nonspecific vaginal discharge, lower abdominal discomfort, and/or dysuria. The symptoms usually appear during or just after menses. On the other hand, most men are symptomatic with dysuria (>50%) and urethral discharge (>80%), both of which usually start within 2–5 days of exposure.[32] Subsequently, if the infection is left untreated, it may lead to urethral scarring. *N. gonorrhoeae* can also cause epididymo-orchitis and prostatitis.[28]

Diagnosis

There are two ways of detecting gonococcal infection. One is the culture method and the other is the nonculture techniques, which include Gram staining and NAAT. Culture is the method of choice which requires endocervical swabs in women and urethral swabs in men. Culture is more favored because it can also provide information about antimicrobial susceptibility. But, the NAAT as well as Gram staining have a very high sensitivity (96 and 95%) and specificity (both nearing 99%). Gram staining can only be used in symptomatic men, and it is not sufficiently sensitive to rule out infection in asymptomatic men. Culture is superior to nonculture techniques in case of treatment failure.[20,32]

Management

According to CDC 2015,[20] ceftriaxone 250 mg with azithromycin 1 g was considered as the treatment of choice. However, the first clinical failure with the above treatment was reported in 2016.[33] Therefore, a new treatment regime was formulated **(Boxes 2 and 3)**.[7]

In addition to antibiotic treatment, management also includes counseling, screening for other STIs, contact tracing/treatment, and advice on safe sex. Due to the emerging problem of antibiotic resistance, test of cure is recommended in all cases. In those with persistent symptoms, culture should be done 72 hours posttreatment, and in those who are asymptomatic, NAAT should be performed after 2 weeks.

BOX 2: Uncomplicated gonococcal infection of the cervix, urethra, or rectum.

- *Recommended regimen for uncomplicated gonococcal infection of the cervix, urethra, or rectum among adults and adolescents*
- *Ceftriaxone* 500 mg* intramuscular (IM) in a single dose for persons weighing <150 kg
- If chlamydial infection has not been excluded, treat for chlamydia with doxycycline 100 mg orally 2 times/day for 7 days

*For persons weighing ≥150 kg, 1 g ceftriaxone should be administered.

BOX 3: Alternative regimens if ceftriaxone is not available.

- *Gentamicin* 240 mg intramuscular (IM) in a single dose *plus*
- *Azithromycin* 2 g orally in a single dose

or

- *Cefixime** 800 mg orally in a single dose

*If chlamydial infection has not been excluded, providers should treat for chlamydia with doxycycline 100 mg orally 2 times/day for 7 days.

NONGONOCOCCAL–NONCHLAMYDIAL INFECTIONS

Mycoplasma

Prevalence

In an analysis of 34 studies published from 1993 to 2011 involving men with nongonococcal urethritis, 13% of 7,123 tested positive for *M. genitalium*.[34]

Microbiology

Mycoplasmas are small membrane-bound (i.e., they lack a cell wall) free-living prokaryotes. They are the smallest organisms, capable of independent replication. Mycoplasma differs from viruses in that they can reproduce outside of living cells. They are unique among prokaryotes because they lack a cell wall. This absence of cell wall is responsible for their lack of a reaction to Gram stain and their lack of susceptibility to many commonly prescribed antimicrobial agents, including β-lactams.

Three types of mycoplasmas have been isolated from female genital mucosal surfaces:

1. *M. genitalium*
2. *M. hominis*
3. Ureaplasma urealyticum.

Pathophysiology

The exact role of mycoplasma in patients with infertility problems is not completely understood. Colonization with genital mycoplasmas happens mainly through sexual contact. Women are more commonly infected than men. The recently discovered *M. genitalium* may also have the ability to cause reproductive tract infections.[35] Whether this organism, alone or in combination with other microbes, contributes to fallopian tube occlusion is unclear.[5]

Clinical Features

Genital mycoplasmas may be associated with nonspecific urethritis, cervicitis, and vaginitis. They may also be responsible for some cases of acute salpingitis, fever after abortions, chorioamnionitis, and puerperal infections.[10] While evidence shows that *M. genitalium* is often present in or associated with PID cases,[34] more data is necessary to determine the role of this microorganism in the pathogenesis of PID and subsequent tubal factor infertility.[4] However, controlled studies have not demonstrated any significant difference in isolation of the organism in fertile and infertile couples.[36] Since its discovery, it has demonstrated that *M. genitalium* is strongly associated with male urethritis.[34]

Diagnosis and Management

Mycoplasma genitalium is diagnosed by NAAT testing of urine, urethral, vaginal, and cervical swabs and through endometrial biopsies.[5] There is little point in testing for mycoplasmas and ureaplasmas in culture due to the high level of colonization in the general population. In addition, these microorganisms are rarely isolated from pure cultures and may take a very long time to grow.[7,20]

Mycoplasma genitalium lacks a cell wall, and thus antibiotics targeting cell-wall biosynthesis (e.g., β-lactams including penicillins and cephalosporins) are ineffective against this organism. Because of the high rates of macrolide resistance with treatment failures[37] and efficient selection of additional resistance, a 1 g dose of azithromycin should not be used.

Two-stage therapy approaches, ideally using resistance-guided therapy, are recommended for treatment. Resistance-guided therapy has demonstrated cure rates of >90% and should be used whenever possible;[38,39] however, it requires access to macrolide-resistance testing. As part of this approach, doxycycline is provided as initial empiric therapy, which reduces the organism load and facilitates organism clearance, followed by macrolide-sensitive *M. genitalium* infections treated with high-dose azithromycin; macrolide-resistant infections are treated with moxifloxacin **(Box 4)**.[7,40,41]

BOX 4: Recommended regimens if *Mycoplasma genitalium* resistance testing is available.

- *If macrolide sensitive: Doxycycline* 100 mg orally 2 times/day for 7 days, followed by *azithromycin* 1 g orally initial dose, followed by 500 mg orally daily for 3 additional days (2.5 g total)
- *If macrolide resistant: Doxycycline* 100 mg orally 2 times/day for 7 days, followed by *moxifloxacin* 400 mg orally once daily for 7 days
- *Recommended regimen if M. genitalium resistance testing is not available*
- *If M. genitalium is detected by an FDA-cleared NAAT: Doxycycline* 100 mg orally 2 times/day for 7 days, followed by *moxifloxacin* 400 mg orally once daily for 7 days

(FDA: Food and Drug Administration; NAAT: nucleic acid amplification test)
Source: CDC (2021).[7]

Trichomonas

Prevalence

Trichomonas vaginalis is the most common nonviral STI.[42] More than 50% of the curable STIs can be attributed to TV.[43]

Microbiology

Trichomonas vaginalis is a flagellated protozoan. It is typically pyriform in shape and is an anaerobic obligate parasite.[44] TV is sometimes amoeboid in shape. TV possesses five flagella, out of which four arise from the anterior aspect of the organism. The fifth flagella are incorporated into the undulating membrane, giving it a characteristic motility.[45] TV generally reproduces by longitudinal binary fission.

Pathophysiology

The genital tract squamous epithelium is the main site of infection of TV. Humans are the only known hosts of TV. It is primarily transmitted via sexual intercourse.[42] The cell surface of the organism plays an important role in adhesion, host–parasite interaction, nutrition, and these functions may be mediated via the proteins and glycoproteins on the surface. There is alteration in the normal vaginal pH from 4.5 to >5.0.[35]

Clinical Features

Trichomoniasis in women may be classified as acute, chronic, or asymptomatic, depending on the severity. In acute infection, women have a copious vaginal discharge, which is typically copious, malodorous, frothy, yellow–green in color with or without vulval irritation.[7] The cervix and the vagina may appear speckled with small punctate hemorrhagic spots, referred to as a "strawberry appearance." However, this characteristic feature is seen only in 2% of the patients. In chronic infection, the symptoms are mild with pruritus and dyspareunia and the discharge is minimal.

Around 25–50% are asymptomatic carriers of TV. The long-term sequelae may include pyosalpinx, endometritis, and infertility. Trichomoniasis is also associated with increased HIV transmission.[46]

Male partners of women with trichomoniasis are likely to have infection. Trichomoniasis in men is largely asymptomatic, and these men are the carriers of TV. Occasionally it may produce symptoms in men with complaints of scanty, clear to mucopurulent discharge, dysuria, and mild pruritus or burning sensation immediately after sexual intercourse.[46] TV can also lead to epididymitis, prostatitis, and decreased sperm cell motility.

Diagnosis

Traditionally, direct observation of the organism on wet mount microscopy has been the method used. This must be performed within 10–20 minutes of collection of the sample, or the organisms will lose viability. But the test method has very poor sensitivity (51–65%);[46,47] therefore, NAAT which is highly sensitive has replaced the wet mount. Also, culture using specialized culture media is another method used and will be diagnostic in 95% of cases, but it may take as long as 2–7 days.[46,48]

Management

Metronidazole gives a cure rate of approximately 95%. During treatment and for at least 48 hours afterward, alcohol should not be taken because of the antabuse effect with metronidazole. Sexual partners should be treated, and abstinence is advised until treatment is completed. All patients should be screened for other STIs **(Box 5)**.[20]

Bacterial Vaginosis

Bacterial vaginosis (BV) is being included as an STI, despite it not being considered a traditional STI because an accumulating body of epidemiological and microbiological evidence suggests that sexual transmission is integral to its pathogenesis. It is the most prevalent urogenital disorder of women in reproductive age with reproductive and obstetric sequelae and is also highly resistant to treatment.[49,50] BV is a vaginal dysbiosis resulting from replacement of normal hydrogen peroxide and lactic acid-producing *Lactobacillus* species in the vagina with high concentrations of anaerobic bacteria, including *Gardnerella vaginalis*, *Prevotella* species, *Mobiluncus* species, *Atopobium vaginae*, and other BV-associated bacteria. BV is a highly prevalent condition and the most common cause of vaginal discharge worldwide.[7]

Although BV-associated bacteria can be identified on male genitalia, treatment of male sex partners has not been beneficial in preventing the recurrence of BV.[51]

Diagnostic Considerations

Bacterial vaginosis can be diagnosed by using clinical criteria (i.e., Amsel's diagnostic criteria)[52] or by determining the Nugent score from a vaginal Gram stain.[53]

A Nugent score of 0–3 is consistent with a *Lactobacillus*-predominant vaginal microbiota, 4–6 with intermediate microbiota (emergence of *G. vaginalis*), and 7–10 with BV.

Clinical diagnosis of BV by Amsel's criteria requires at least three of the following four symptoms or signs:

1. Homogeneous, thin discharge (milk-like consistency) that smoothly coats the vaginal walls.
2. Clue cells (e.g., vaginal epithelial cells studded with adherent bacteria) on microscopic examination.
3. pH of vaginal fluid >4.5.
4. A fishy odor of vaginal discharge before or after addition of 10% potassium hydroxide (KOH) (i.e., the whiff test).

Current treatments are associated with frequent recurrence. Recurrence after treatment might relate to evidence that suggests sexual transmission is integral to the pathogenesis of BV, which has substantial implications for the development of effective management approaches **(Boxes 6 and 7)**.[2]

BOX 5: Recommended regimen for trichomoniasis among women.

- *Metronidazole* 500 mg orally 2 times/day for 7 days
- *Recommended regimen for trichomoniasis among men*
- *Metronidazole* 2 g orally in a single dose
- *Alternative regimen for women and men*
- *Tinidazole* 2 g orally in a single dose

Source: CDC (2021).

BOX 6: Alternative regimens—clindamycin, secnidazole, and tinidazole.

Alternative regimens:

- *Clindamycin* 300 mg orally 2 times/day for 7 days
  or
- *Clindamycin ovules* 100 mg intravaginally once at bedtime for 3 days*
  or
- *Secnidazole* 2 g oral granules in a single dose†
  or
- *Tinidazole* 2 g orally once daily for 2 days
  or
- *Tinidazole* 1 g orally once daily for 5 days

*Clindamycin ovules use an oleaginous base that might weaken latex or rubber products (e.g., condoms and diaphragms). Use of such products within 72 hours after treatment with clindamycin ovules is not recommended.

†Oral granules should be sprinkled onto unsweetened applesauce, yogurt, or pudding before ingestion. A glass of water can be taken after administration to aid in swallowing.

BOX 7: Recommended regimens for bacterial vaginosis

- *Metronidazole* 500 mg orally 2 times/day for 7 days
  or
- *Metronidazole gel 0.75%* one full applicator (5 g) intravaginally, once daily for 5 days
  or
- *Clindamycin cream 2%* one full applicator (5 g) intravaginally at bedtime for 7 days

Pelvic Inflammatory Disease

Pelvic inflammatory disease comprises a spectrum of inflammatory disorders of the upper female genital tract, including any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis.[54,55]

Microbiology

Pelvic inflammatory disease is a polymicrobial infection of the upper genital tract (UGT). It is mainly caused by *N. gonorrhoeae* and *C. trachomatis* in many cases. However, of late, it has been found that the number of cases of PID attributable to the above organisms is decreasing; hardly around 50% of the cases test positive for these. PID can also be caused by a host of other organisms, including *G. vaginalis*, *Haemophilus influenzae*, enteric gram-negative rods, and *Streptococcus agalactiae*.[56]

Pathophysiology

Tubal damage is a very common sequela of PID, with the incidence of tubal occlusion being proportional to the number of episodes of PID. Tubal damage can ultimately lead to infertility and increased risk of ectopic pregnancy. Delay in treatment can also lead to chronic pelvic pain.

The likelihood of developing tubal-factor infertility after PID is related to the following:

- The number of episodes of PID
- Severity of the episodes
- Length of time before treatment
- The age of the woman.

Clinical Features and Diagnosis

No single historical, physical, or laboratory finding is both sensitive and specific for the diagnosis of acute PID. Women with lower abdominal or pelvic pain should be diagnosed with PID if at least one of the three minimum criteria are present. One or more of the additional criteria will enhance the specificity of the minimum clinical criteria and support a diagnosis of PID.[7,20]

Minimum criteria (any one) for the diagnosis of PID:

- Cervical motion tenderness
  or
- Uterine tenderness
  or
- Adnexal tenderness

BOX 8: Recommended intramuscular (IM) or oral regimens for pelvic inflammatory disease.

- *Ceftriaxone* 500 mg* IM in a single dose *plus*
- *Doxycycline* 100 mg orally 2 times/day for 14 days with *metronidazole* 500 mg orally 2 times/day for 14 days
  or
- *Cefoxitin* 2 g IM in a single dose and *probenecid* 1 g orally administered concurrently in a single dose *plus*
- *Doxycycline* 100 mg orally 2 times/day for 14 days with *metronidazole* 500 mg orally 2 times/day for 14 days
- *Other parenteral third-generation cephalosporin* (e.g., ceftizoxime or cefotaxime) *plus*
- *Doxycycline* 100 mg orally 2 times/day for 14 days with *metronidazole* 500 mg orally 2 times/day for 14 days

*For persons weighing >150 kg, 1 g of ceftriaxone should be administered.

Additional criteria:

- Oral temperature >101°F (>38.3°C)
- Abnormal cervical mucopurulent discharge or cervical friability
- Presence of abundant numbers of white blood count (WBC) on saline microscopy of vaginal fluid
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein
- Laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis.*

Specific criteria:

- Endometrial biopsy with histopathologic evidence of endometritis
- Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, or Doppler studies suggesting pelvic infection (e.g., tubal hyperemia); or
- Laparoscopic findings consistent with PID.

Management

Treatment needs to be started no sooner than the presumptive diagnosis is made because prevention of long-term sequelae is related to the efficacious and urgent start of treatment.

Women with mild to moderately severe PID should be treated with oral regimen. In case of very severe infection or intolerance or no response, it is recommended to switch over to parenteral regimen **(Boxes 8 and 9)**.[7]

Hospitalization may be required in cases of:

- Pregnancy
- Tubo-ovarian abscess
- Inability to tolerate an outpatient oral regimen
- Absent response to oral therapy.

BOX 9: Recommended parenteral regimens for pelvic inflammatory disease.

- *Ceftriaxone* 1 g by every 24 hours *plus*
- *Doxycycline* 100 mg orally or intravenous (IV) every 12 hours *plus*
- *Metronidazole* 500 mg orally or IV every 12 hours *or*
- *Cefotetan* 2 g IV every 12 hours *plus*
- *Doxycycline* 100 mg orally or IV every 12 hours *or*
- *Cefoxitin* 2 g IV every 6 hours *plus*
- *Doxycycline* 100 mg orally or IV every 12 hours

Women should be instructed to avoid sexual intercourse until therapy is completed and symptoms have resolved. Sex partners should be appropriately treated.[7]

SEXUALLY TRANSMITTED VIRAL INFECTIONS

Around 4.2 million people of childbearing age in the United States of America are infected with HIV, HCV, hepatitis B virus (HBV), or a combination.[57]

Majority (around 75%) of the men and women infected with viral infections are in their reproductive age and many of these couples look for reducing the risk of transmission to their partners and child.[58] A few of them may require treatment for their fertility problems.

- Preconception counseling explaining the risks of transmission
- Treatment of infection when possible
- Usage of appropriate measures to prevent transmission.

Sperm-wash Methods

Sperm-wash procedures involving density-gradient centrifugation followed by a sperm swim-up step have been used to separate motile sperm from free HIV virus and HIV-infected somatic cells.[59-61] Quantitative assessment of HIV in semen before and after the sperm-wash procedure indicates that >99% of HIV is removed.[60] Virologic testing of the sperm fraction for the presence of residual detectable HIV before its use for insemination can provide an added measure of safety as up to 5–10% of samples may contain residual virus after this procedure.[61] Similar sperm preparation techniques have been used to separate HCV from sperm[62] and may be useful for other viral infections where the majority of virus is found in free form or associated with semen somatic cells (i.e., white blood cells, epithelial cells).

Management of Cryopreserved Tissue

Contamination with HIV, HBV, and HCV has been documented in assisted reproductive technology (ART) clinics[63] and blood banks.[64] Although there is no documentation of cross-contamination of cryopreserved stored human tissue, it is highly recommended that samples from viral carriers be processed in a separate laboratory or designated space within the main laboratory. HIV, HCV, HBV, and possibly other viruses can survive in liquid nitrogen, making it possible to cross-contaminate samples in liquid nitrogen storage tanks, although this risk is very low.

To protect cryopreserved specimens from the potential cross-contamination risk, it is advised that HIV, HBV, and HCV-infected specimens be stored in separate tanks.

The risks of cross contamination of samples in liquid nitrogen storage could be reduced by following the below-given measures:[58]

- Use of a closed-system vitrification device to avoid direct contact with liquid nitrogen
- Storage of samples in liquid nitrogen vapor instead of in the liquid phase of nitrogen itself
- Use of sperm-wash techniques to decrease the viral load before freezing semen samples.

Human Immunodeficiency Virus

Human immunodeficiency virus is a retrovirus because it uses enzyme reverse transcriptase to transcribe RNA to DNA. It binds to CD4+ T-lymphocytes and leads to their destruction. HIV leads to the development of acquired immunodeficiency syndrome (AIDS) once the CD4+ cell count drops below 200.[65]

Sexual transmission is the predominant mode of spread of HIV. The global prevalence of HIV is 0.7% (WHO–HIV 2020). It is highly prevalent in high-risk groups, including users of unscreened blood products, intravenous drug users, sex workers, and men who have sex with men (MSM). HIV is transmitted both sexually and vertically through blood, semen, vaginal secretions, and breast milk. The rate of HIV heterosexual transmission is relatively low (approximately 1/1,000 acts of unprotected intercourse). Risk factors for HIV transmission include genital-tract infections and ulceration, sexual practices that induce trauma or bleeding, and lack of male circumcision.[58]

Worldwide, approximately 73% of adults and children have access to highly active antiretroviral therapy (HAART), which is combined HAART where three or more antiretroviral drugs are used to control HIV infection [Joint United Nations Programme on HIV/AIDS (UNAIDS) factsheet 2021].[66]

HIV and Infertility

Semen parameters in HIV-positive men are impaired compared to WHO normal range. There is a decrease in sperm count, motility, and morphology.[67]

It has been found that these parameters are abnormal even though the patient is on HAART. HIV-positive women are prone to have reduced fertility with a decreased ovarian reserve when compared to HIV-negative individuals.

Patients on HAART have impaired oocyte quality because of the effect of the drugs on oocyte mitochondria.[68]

The American Society for Reproductive Medicine (ASRM) has stated that fertility services cannot be withheld ethically from individuals with chronic viral infections, including HIV, if a center has the resources to provide care.[58]

HIV-infected Individuals and Risk Reduction Strategies

In case of an uninfected partner of an HIV-positive individual, the rate of transmission is approximately 1 in 500–1,000 episodes of unprotected intercourse.[69]

The risk of transmission increases drastically if the viral load is high or if the HIV-negative partner has a concomitant genital infection, inflammation, or abrasions.[70]

Serodiscordant Couples with Near-normal Gamete Parameters

Earlier to 2008, there were controversies regarding the treatment of serodiscordant couples with European countries going in for sperm wash and intrauterine insemination (IUI).

In 2008, the Swiss Commission for HIV care[71,72] stated that an HIV-positive person (male or female) receiving HAART and with an undetectable viral load (<50 copies/mL) for 6 months and without genital infection does not transmit HIV by sex. Therefore, they can be allowed to conceive naturally. According to Cochrane review,[73] the risk of transmission of HIV to the uninfected partner in such cases is negligible. But despite this strong evidence, the United States of America still follows a conservative approach with sperm washing and intracytoplasmic sperm injection (ICSI) being the primary treatment modality in HIV-positive male with negative partner irrespective of the viral load.[57] Ongoing research now supports the CDC statement that people with HIV who take antiretroviral therapy as prescribed and achieve and maintain an undetectable viral load have effectively no risk of transmitting HIV through sex.[74]

Sperm washing may still be offered to couples (with male being HIV positive) if:

- Couple unwilling to conceive naturally despite counseling about negligible risk
- Inability to achieve low viral loads despite HAART
- Difficult to access HAART therapy as in underdeveloped countries.

In case of an HIV-infected woman with negative partner, ideally, HAART is advocated to reduce the risk of transmission to both the partner and the future child. However, if HAART is not fully effective, autoinsemination with the partner's sperm is a simple method to avoid the risk of transmission to the man.

Serodiscordant Couples with Abnormal Gamete Parameters

Men and women with conception problems can no longer be denied access to fertility treatment, citing HIV status. The modalities of treatment are the same as that of the noninfected patients. However, in view of the complexities involved in handling of the infected gametes, it is advisable according to the European Society of Human Reproduction and Embryology (ESHRE) 2015 and ASRM practice committee 2013 to assign a dedicated laboratory space and separate cryostorage facility for the purpose.[75,76]

Seroconcordant Couples for HIV

There is obviously no risk of infecting an uninfected partner in seroconcordant couple for HIV; however, there is a possibility of superinfection. There are increasing reports that one HIV-infected partner can transmit their unique strain of HIV to another infected partner.[77]

Therefore, it is worthwhile for both partners to have low viral loads before attempting conception. Also, in case of abnormal gamete parameters, fertility treatment must follow the accepted protocol.

Sperm-wash Techniques

Fiore et al.[78] in their unique experiment using semen samples preloaded with known concentration of HIV virus found that density gradient centrifugation is sufficient to clear the virus of samples containing 1 × 103–5 × 104 copies viral RNA/mL, density gradient followed by swim up is required for samples containing 1 × 105–5 × 105 copies viral RNA/mL. In semen samples containing 1–3 × 106 copies of viral RNA/mL, viral RNA was persistent in some even after the two standard washing procedures.

This study concludes that the effectiveness of the sperm-washing techniques is dependent on the viral load.[79]

Hepatitis B Virus

Hepatitis B virus is a DNA virus that attacks the liver and can cause both acute and chronic diseases. The virus is transmitted through contact with the blood or other body fluids of an infected person. It is a highly infectious virus which is 100 times more infective than HIV or HCV. It is also transmitted by sexual intercourse and is twice as infective as HIV by this modality. HBV vaccine was developed in 1982. The vaccine is 95% effective in preventing infection and the development of chronic disease and liver cancer due to hepatitis B. The vaccine also protects uninfected partner against sexual transmission.

Hepatitis B virus is one of the most common infectious diseases in the world; it has been estimated that 350 million people worldwide are HBV carrier. HBV can be transmitted

parenterally, sexually, vertically, and via other routes of mucosal exposure. Approximately 25% of regular sexual contacts of HBV-infected persons will become seropositive for HBV, and HBV has been transmitted through artificial insemination.[58]

Hepatitis B virus is a disease that is transmitted through fluids; many studies also showed that HBV DNA can be detected in urine, saliva, and other tissues beyond the liver and blood. HBV is not only able to pass through the blood–testis barrier and enter the sperm cell but also integrate into their sperm chromosome.[80] When human sperm-mediated HBV genes were delivered into zona-free hamster oocytes via the in vitro fertilization (IVF) method, HBV genes were able to replicate and express in early embryonic cells.[81] Actually, the sperm-washing procedures could eliminate the presence of viruses, but the risk of HBV DNA integrated into sperm chromosome could not be eliminated.[82] These results suggest that sperm cells of HBV patients might act as vectors for transmitting the HBV genes during IVF and ICSI procedures.

All couples being evaluated for IVF should be screened for HBV via HBsAg. In couples who are discordant for HBV infection, the partner who is seronegative for HbsAg and has no evidence of immunity on additional serologic testing (i.e., is negative for HbsAb and core antibody) should be vaccinated against HBV. Fertility treatments may be initiated once the vaccinated partner's anti-HbsAb titer is positive. Modified sperm wash to reduce viral load is not required after the female partner is immunized against HBV.[58]

Hepatitis B virus-discordant couples can be allowed to conceive naturally once the negative individual is fully vaccinated. The effectiveness of HBV vaccination is measured by the presence of HBV surface antibody. 5% of the individuals are nonresponders, i.e., they do not produce HBV surface antibody. Such couples may be subjected to sperm wash and IUI.

All HBsAg-positive HBV-infected females should be offered referral to a hepatologist to determine if she is immune tolerant or has immune-active disease. Immune-tolerant individuals are a carrier of the virus with normal alanine transaminase and aspartate transaminase levels and do not have active hepatitis. Immune-active disease (previously termed chronic active hepatitis) occurs in those individuals who have elevated liver function tests associated with chronic hepatitis. For the immune-tolerant patient with HBV, the current recommendations would be to treat individuals with HBV DNA viral level >200,000 IU/mL with appropriate antiviral therapy.[58]

Vertical transmission accounts for over 40% of cases of chronic infection. In case of HBV-positive women, additionally, the newborn has to be given immunoprophylaxis (HBV vaccination and one dose of HBV immunoglobulins) immediately at birth (within 24 hours) and two more doses of vaccine at 1 and 6 months to minimize vertical transmission. In women with high viral load (>100,000 IU/mL) risk of transmission is much higher; therefore, antiviral therapy is advocated during pregnancy.[83]

Hepatitis B virus infection is associated with a reduced sperm motility and a higher proportion of apoptotic and necrotic sperm, resulting in lower fertility index.[84] HBV-positive men had decreased sperm motility and viability but normal morphology compared to the controls.[80]

Zhou et al.[85] reported ICSI could aggravate HBV transmission into the oocyte, and HBV-infected men had lower rates of 2 pro-nuclei (2PN) fertilization (70.9 vs. 74.0%), high-grade embryos acquisition (57.6 vs. 60.4%), implantation (18.3 vs. 24.2%), and clinical pregnancy (31.2 vs. 39.3%) in ICSI cycles. However, Lutgens et al.[82] thought sperm washing could effectively reduce the risk of vertical transmission and prevent introduction of HBV into the oocyte in the case of ICSI. As previous studies found that hepatotropism was a prominent feature of HBV infection, the HBV DNA level in semen was lower compared with that in serum.[86] In addition, these patients had been in a convalescent stage for >6 months, which exceed the spermatogenic cycle.

According to two similar studies, they found that the rates of HBV-positive embryos were only 16.6 and 21.3% in male HBsAg positive/female HBsAg-negative couples, respectively.[87,88] It can assume that HBV DNA integrate into human sperm chromosomes, causing adverse effects on human sperm function, but that those infected embryos could not be fully functional, and the HBV-positive males still have the opportunity to get uninfected sperm and embryos to fertilize and implant. These may explain why no adverse effect on outcomes of ICSI/IVF cycles was observed in the HBV-infected group. There is little information about HBV-positive males of IUI cycles. In our research, the significant difference in total motile sperm count before sperm preparation (50.0 ± 31.6 vs. 69.2 ± 47.1, $p < 0.01$) disappeared after preparation (23.5 ± 14.4 vs. 27.8 ± 17.4, $p > 0.05$). And the two groups showed similar clinical pregnancy rate and abortion rate. It showed that the use of semen processing was effective enough to improve the properties of the sperm, leading to a high chance of fertility. Therefore, IUI might be beneficial for improving HBV-infected males fertility outcomes. However, these findings are insufficient to make a definite conclusion on the subject.[80]

The presence of HBsAg and HBV–DNA has been detected in the ovary and the ovum of patients with chronic HBV infection.[89] There was no statistically significant association between HBV carrier status and clinical pregnancy, live birth, or miscarriage.[90]

Hepatitis C Virus

Hepatitis C virus is an RNA virus which affects the liver. It spreads primarily by parenteral route involving mainly blood. Occasionally, it may be transmitted sexually in MSM. Heterosexual transmission is not seen normally.[91] There is currently no vaccine available for HCV.

Natural conception is recommended for discordant couples; however, antiviral therapy is advocated for infected individuals before planning conception. In case of fertility problems, ART is indicated as per treatment protocol. Vertical transmission is seen in around 5–6% of HCV-positive women and is around 10–12% in women with concurrent HIV.[92] Cesarean delivery is not indicated, and breastfeeding is not contraindicated.

There is a small but measurable risk of HCV transmission via semen. All patients with hepatitis C should be counseled about the risks of transmission to their partner, which is rare through sexual transmission, and to their children through vertical transmission (occurring in 4–6%). They should be referred to a hepatitis specialist for discussion of potential treatment and cure. Current treatment of hepatitis C with direct-acting antiviral (DAA) therapy is 98% effective in achieving a sustained virologic response (SVR, i.e., a cure) within 8–12 weeks of treatment. An SVR is defined as a negative HCV RNA 12 weeks after treatment. With the ease, accessibility of insurance coverage, and short duration of therapy, it is recommended to treat all patients before IVF.[93]

CONCLUSION

The bacterial infections are associated with decreased fertility in view of alteration of the tubal factor and the semen parameters. Timely identification and treatment prevent occurrence of infertility. However, the viral infections and their treatment affect fertility. It is no longer ethically appropriate to deny treatment for any infertile couple based on their viral status. Necessary precautions need to be taken and required additional procedures offered in infected patients.
